DAA regimens can present renal side effects, especially sofosbuvir combinations. Close monitoring of renal function is required in at-risk patients comprising patients with CKD, ESRD and hemodialysis, hypertension and diabetes, HIV coinfection, and transplant patients. Current recommendations require the universal monitoring of renal function in patients treated with DAAs. However, patients with none of the above described comorbidities are probably at very low risk of renal toxicity and will no longer require such close monitoring in future.

## ACKNOWLEDGMENTS

We thank Céline Rigaud for her help and Sarah Demai for her English proofreading.

### Abstract

Toll-like receptors (TLRs) are pattern recognition receptors that participate in host defense by recognizing pathogen-associated molecular patterns alongside inflammatory processes by recognizing damage associated

molecular patterns. Given constant exposure to pathogens from gut, strict control of TLR-associated signaling pathways is essential in the liver, which otherwise may lead to inappropriate production of pro-inflammatory cytokines and interferons and may generate a predisposition to several autoimmune and chronic inflammatory diseases. The liver is considered to be a site of tolerance induction rather than immunity induction, with specificity in hepatic cell functions and distribution of TLR. Recent data emphasize significant contribution of TLR signaling in chronic liver diseases *via* complex immune responses mediating hepatocyte (*i.e.*, hepatocellular injury and regeneration) or hepatic stellate cell (*i.e.*, fibrosis and cirrhosis) inflammatory or immune pathologies. Herein, we review the available data on TLR signaling, hepatic expression of TLRs and associated ligands, as well as the contribution of TLRs to the pathophysiology of hepatic diseases.

**Core tip:** Toll-like receptors (TLRs) are known to be pattern recognition receptors that recognize pathogen- and damage-associated molecular pattern molecules and thus participate in the activation of innate immune system. TLR signaling plays a significant role in liver diseases, whereas inflammatory or immune pathologies targeting distinct liver cells are based on complex immune responses. Herein, we review the current data on TLR signaling, hepatic expression of TLRs and associated ligands, as well as the contribution of TLRs to the pathophysiology of hepatic diseases.

## INTRODUCTION

Liver, main filter organ acting as a first line of defense, is continuously exposed to massive gut-derived antigenic load *via* the portal vein, whereas inflammatory signs occur under normal conditions owing to highly specific immune properties leading to immune tolerance<sup>[1-7]</sup>.

Pathogen-associated molecular patterns (PAMP) are specific signature molecules essential to entire categories of microorganisms<sup>[8-11]</sup>. Innate immune system recognizes PAMPs *via* pattern recognition receptors (PRRs)<sup>[7-9,12,13]</sup> and consequent downstream signaling cascades for proper host recognition and prevention of immune system hyperactivation<sup>[7-9,14]</sup>.

Toll-like receptors (TLRs) are a family of PRRs that induce innate immune system by recognizing PAMPs and damage-associated molecular pattern molecules (DAMPs)<sup>[15-18]</sup>. Although the recognition of PAMPs enables a prompt and effective protection against invading pathogens<sup>[5,11,12]</sup>, TLRs also contribute to the activation of adaptive immune responses, epithelial regeneration and carcinogenesis and regulation of sterile inflammation<sup>[5,19,20]</sup>.

Consistent with their extensive hepatocellular expression<sup>[7,18,21,22]</sup>, TLRs have recently been recognized as principal elements of the hepatic immune system that also play a crucial role in liver physiology and pathophysiology<sup>[11,15,23]</sup>. Despite being constantly exposed to gut-derived PAMPs, healthy liver is free of inflammation risk due to presence of "liver tolerance" in which modulation of TLR signals also plays a role<sup>[5,15,23-25]</sup>. A tight regulation of TLR activation occurs at many levels involving the receptor itself, the signaling cascade and a distinct compartmentalization of TLRs<sup>[24,26,27]</sup>. Acute and chronic liver diseases are highly associated with triggering TLR signaling by gut-derived microbiota in the breakdown of the tolerance and sterile insult-associated products of damaged cells<sup>[28]</sup>.

Ligand mediated stimulation of TLRs activates downstream adaptor molecules, including myeloid differentiation primary response protein 88 (MyD88), myeloid toll/interleukin (IL)-1 receptor (TIR)-domain-containing adaptor-inducing interferon- $\beta$  (TRIF) and TRIF-related adaptor molecule (TRAM). This triggers signaling cascades that converge on nuclear factor- $\kappa$ B (NF- $\kappa$ B), interferon (IFN) response factors (IRFs) and mitogen-activated protein (MAP) kinases<sup>[23,29-32]</sup>. As a result, transcription of certain proinflammatory agents including IL-6, IL-12, IL-23, and tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) is induced<sup>[23,29-32]</sup>.

TLR-mediated inflammatory-signaling pathways are shown to be associated with entire spectrum of liver diseases, from hepatitis, liver fibrosis and cirrhosis to alcoholic and nonalcoholic liver disease, ischemia/reperfusion injury, liver regeneration and hepatocellular carcinoma<sup>[4,5,7,8,15,18,23,33]</sup>.

Herein, we review the available literature on TLR signaling, hepatic expression of TLRs and associated ligands, as well as the contribution of TLRs to the patho-

physiology of hepatic diseases.

## TLR FAMILY, DISTRIBUTION, LIGANDS

TLRs are a group of evolutionarily conserved type I transmembrane proteins responsible for innate immune and inflammatory responses<sup>[34-38]</sup>. They comprise an extracellular domain with receptor specific leucine-rich repeat motifs and a highly conserved cytosolic domain alike to the IL-1 receptor called TIR<sup>[13,29,36,37]</sup>.

Of 13 TLRs exist in mammals, only TLRs 1-10 exist in humans<sup>[9,26,39-41]</sup>. The presence of multiple widely expressed TLRs enables recognition of different pathogens and thus initiation of appropriate immunologic response by the innate immunity system<sup>[30,42,43]</sup>. PAMPs include microbial molecular structures such as Gram-negative related lipopolysaccharide (LPS); Gram-positive bacteria related lipoteichoic acid and peptidoglycan (PGN); lipoglycans, lipoarabinomannan, lipopeptides and lipomannans from mycobacteria; zymosan from yeast; and DNA from viruses and bacteria<sup>[34,44]</sup>.

DAMP include extracellular matrix and plasma membrane components, nuclear and cytosolic proteins and elements of damaged organelles<sup>[9,34,45,46]</sup>.

Each TLR is able to recognize a particular molecular pattern<sup>[29]</sup>. TLR1, TLR2, TLR4, TLR5 and TLR6 bind to molecules associated with bacterial membrane such as LPS, lipoprotein and PGN, whereas TLR3, TLR7, TLR8 and TLR9 detect viral and bacterial or endogenous nucleic acids, including ssRNA, dsRNA, and unmethylated cytosine phosphate guanine (CpG)-containing DNA<sup>[29]</sup>. TLR4 along with TLR2 can recognize antigens from bacteria, fungi, parasites, viruses and DAMPs<sup>[47,48]</sup>. TLR10 is the only family member among humans with no definite ligand, function or localization<sup>[9,13]</sup>.

Given their ability to detect wide range of non-microbial host-derived stimuli and their extensive expression in various cell types, TLRs are considered to participate in development, progression and resolution of several noninfectious inflammatory and immune diseases<sup>[37,49]</sup>.

## TLR SIGNALING PATHWAYS

Healthy liver contains low mRNA levels of TLRs and shows no activation of TLR-signaling pathways<sup>[5,50,51]</sup>. However, in the case of a breakdown in TLR tolerance against endogenous ligands under pathologic conditions, the TLR-related immune response induces TLR-ligand complex activated expression of proinflammatory/anti-inflammatory cytokines and interferons<sup>[7,9,27,52]</sup>.

The differential host cell response after TLR ligand stimulation is associated with the fact that TLRs selectively use four main adaptor molecules, including MyD88, TIR domain-containing adaptor protein (TIRAP, or MyD88 adaptor-like), TIR domain-containing adaptor protein inducing interferon- $\beta$  (TRIF) and TRAM<sup>[7,9,27,30,52]</sup>.

Signal transduction pathways following ligand-induced receptor dimerization involve one or more TIR-containing adaptor molecules, such as IL-1 receptor-associated

**Figure 1** Toll-like receptors signaling pathways. TLR: Toll-like receptors; LPS: Lipopolysaccharide; NF-κB: Nuclear factor; IFNs: Interferons; LBP: LPS-binding protein; TRIF: Toll/interleukin-1 receptor-domain-containing adaptor-inducing interferon-β; MyD88: Myeloid differentiation primary response protein 88; TRAM: TRIF-related adaptor molecule; TIRAP: TIR domain-containing adaptor protein; IRAK: IL-1 receptor-associated kinase; TRAF: Tumor necrosis factor receptor-associated factor; TBK1: TANK binding kinase-1; IKK: IκB kinase; AP: Activator protein; JNK: c-Jun N-terminal kinase.

kinase (IRAK)-1, IRAK-4, TNF receptor-associated factor (TRAF)-6 and TANK binding kinase (TBK)-1, MAP kinases and IκB kinase (IKK). This leads to activation of the nuclear transcriptional factor kappa-B (NF-κB), interferon (IFN) regulatory factor 3 (IRF-3) and activator protein (AP)-1<sup>[37,53]</sup>.

Upon binding with their ligand, all superfamily receptors except TLR3 use MyD88 to initiate signaling which may also act along with other adaptors, such as TIRAP, in the response induced by TLR4, TLR1/2, and TLR2/6. Activation of TLRs 5, 7, 8 and 9 also leads to NF-κB and AP-1 production, with no need for TIRAP to stimulate MyD88. TLRs 7 and 9 act through IRAK-1, 4 and TRAF-6, phosphorylate IRF-7 and lead to type 1 interferon mRNA expression. TLR3-mediated signaling uses only the TRIF adaptor molecule, which is also recruited by TLR4 in concert with another adaptor called TRAM<sup>[9,12,23,32,39,54]</sup> (Figure 1).

Hence, while intracellular signaling is similar, the final outcome of TLR activation differs depending on the nature of PAMPs, concomitantly activated TLRs and PRRs, the level of cytokines, and the cell stimulated<sup>[13,27,55-57]</sup>. Moreover, chronically activated signaling pathways is likely to induce transcription of oncogenic factors, which adds a further level of complexity to the intracellular

signaling for these receptors<sup>[13,27,58]</sup>.

## TLR EXPRESSION AND SIGNALING IN HEPATIC CELL POPULATIONS

Under constant exposure to gut-derived microbiota, strict regulation of TLR signaling pathways is crucial in the liver, which otherwise may lead to inappropriate production of proinflammatory cytokines and interferons creating a predisposition to several autoimmune and chronic inflammatory diseases<sup>[9]</sup>.

Liver cells are classified as parenchymal or non-parenchymal cells. Hepatocytes comprise 60%-80% of the parenchymal cells, whereas the remaining population of non-parenchymal cells include Kupffer cells (KCs), sinusoidal endothelial cells (SECs), hepatic stellate cells (HSCs), dendritic cells (DCs), biliary epithelial cells (BECs) and intrahepatic lymphocytes<sup>[1,9,33]</sup>.

Besides distinct function of liver cells with a highly specific distribution of TLR<sup>[1,33]</sup>, liver comprises many populations of cells with immune competence that may respond to TLR signals, indicating the complexity of immune responses underlying inflammatory or immune pathologies associated with the liver cells<sup>[10]</sup>.

mRNA levels of TLR1, TLR2, TLR4, TLR6, TLR7, TLR8,

**Table 1** Toll-like receptor expression and their signaling in the liver<sup>[5,9,11,15,23,33,49]</sup>

TLR subfamily	Members	Expression of cell population in the liver (protein level)	Location	Ligand (origin)	Signaling	Final product-effect
TLR2 subfamily	TLR1/2	NK cells, DCs (h)	Plasma membrane	Bacterial lipoproteins Triacylated lipopeptides	TIRAP-MyD88-NF-κB/AP-1/IRF5 pathway	Pro- and anti-inflammatory cytokines excluding type 1 IFNs; the apoptotic cascade <i>via</i> recruiting FADD leading to caspase-8 activation
	TLR2/6	Hepatocytes, Kupffer cells, NK cells, B cells, activated T cells, DCs (m), biliary epithelial cells		Diacylated lipopeptides LPS of Gram-positive bacteria Fungal zymosan Mycoplasma lipopeptides	TIRAP-MyD88-NF-κB/AP-1 pathway	
	TLR10	Unknown		ND		
TLR3 subfamily	TLR3	Hepatocytes, LSECs, Kupffer cells, NK cells, NKT cells, activated T cells, cDCs (m), biliary epithelial cells	Endosome	Double-stranded RNA (viruses)	PI3K/TRIF-IRF3 pathway TRAM-TRIF-NF-κB pathway PI3K/TRIF-RIP1-NF-κB pathway	Production of type 1 IFNs; the apoptotic cascade <i>via</i> recruiting FADD leading to caspase 8 activation; DC maturation
TLR4 subfamily	TLR4 <sup>1</sup>	Hepatocytes, LSECs, Kupffer cells, NK cells, B cells, activated T cells, DCs (m), biliary epithelial cells, HSCs	Plasma membrane	LPS of Gram-negative bacteria; fusion protein (respiratory syncytial virus), envelope protein (mouse mammary-tumor virus); HMGB1, hyaluronan, HSP60, free fatty acids (endogenous ligands); HSP72 (cells during stress and injury) surfactant protein A; fibrinogen; fibronectin extra domain A	TIRAP-MyD88-NF-κB/AP-1 pathway TRAM-TRIF-NF-κB/IRF3 pathway	Pro- and anti-inflammatory cytokines excluding type 1 IFNs; the apoptotic cascade <i>via</i> recruiting FADD leading to caspase 8 activation; DC maturation; activating caspase-1 through adaptor molecule apoptosis associated speck-like protein <sup>2</sup>
TLR5 subfamily	TLR5	Biliary epithelial cells	Plasma membrane	Flagellin protein (bacteria)	MyD88-NF-κB/IRF5 pathway	Pro- and anti-inflammatory cytokines excluding type 1 IFNs
TLR9 subfamily	TLR7/8	NK cells, B cells, DCs (h), DCs (m)	Endosome	Single-stranded RNA (viruses), double-stranded, shortinterfering RNA (siRNA)	MyD88 and endosomal acidification (maturation)-IRF7 pathway; MyD88-NF-κB pathway	High levels of type 1 IFN production in pDCs; proinflammatory cytokine production
	TLR9	LSECs, Kupffer cells, NK cells, B in mDCs and macrophages		Imidazoquinoline CpG-containing viral or bacterial DNA Endogenous host-DNA		

<sup>1</sup>TLR4 requires LPS-binding protein (LBP), CD14 and MD2 to recognize LPS; <sup>2</sup>Containing a caspase recruitment domain (ASC)<sup>[33]</sup>. RIP1: Receptor-interacting protein 1; FADD: Fas-associated death domain; TLR: Toll-like receptors; LPS: Lipopolysaccharide; DCs: Dendritic cells; HSCs: Hepatic stellate cells; LSECs: Liver sinusoidal endothelial cells; IFNs: Interferons; DC: Dendritic cell; MyD88: Myeloid differentiation primary response protein 88.

TLR9, TLR10 and signaling molecules such as MD-2 and MyD88 are lower in liver as compared with the levels observed in other organs<sup>[50,51,59]</sup>. This discrepancy indicates the high tolerance to TLR ligands from the intestinal microbiota in liver<sup>[11]</sup>, whereas no specific liver cell population is considered central in TLR-mediated pathologies, with the different effects of TLR ligation varying from cell to cell<sup>[10]</sup> (Table 1).

### Hepatocytes

Constituting 60% of liver cells, hepatocytes are the principal site for PRR production<sup>[5,33]</sup>. They express mRNA for all TLRs and are responsive to multiple PAMPs, while respond fairly weakly to TLR2 and TLR4 ligands<sup>[5,9,33]</sup>. While TLR4 expression in hepatocytes is not upregulated by proinflammatory mediators, hepatocytes show increased responsiveness to TLR2 ligands under inflammatory conditions leading to up-regulation of TLR2 expression by LPS, TNF-α, bacterial lipoprotein, and IL-1β in an NF-κB-dependent manner<sup>[5,11,33,60,61]</sup>.

### Kupffer cells

Accounting for approximately 20% of non-parenchymal cells, KCs play a significant role in host defense by orchestrating the inflammatory response *via* functional properties, including phagocytosis, antigen processing and presentation, and secretion of proinflammatory mediators such as cytokines, prostanoids, nitric oxide, and reactive oxygen intermediates<sup>[5,9,11,33,62]</sup>.

KCs express TLRs 2, 3, 4 and 9 and have a higher threshold for activation when compared with other immune cells given their milieu<sup>[5,9,33,63]</sup>.

KCs are less responsive to "LPS tolerance" in the physiological environment, whereas upon activation, they produce several pro-inflammatory (IL-6, IL-12, IL-18 and TNFα) and anti-inflammatory (IL-10) mediators<sup>[33,64-66]</sup>. Additionally, KCs produce IFN-β, upregulate the expression of MHC-II/costimulatory molecules and promote T cell proliferation and IFN-γ production; when stimulated with TLR3/TLR4 ligands; TLR1/TLR8 ligands and TLR1/2/4/6 ligands, respectively<sup>[22,33]</sup>.

### Hepatic stellate cells

Constituting < 1% of non-parenchymal cells, HSCs undergo an activation process after liver injury and become the main liver cell type that produce extracellular matrix, contributing onset of liver fibrosis<sup>[67-70]</sup>.

HSCs express TLRs 4 and 9, whereas expression of TLR2 is induced by TLR4 stimulation in HSCs<sup>[68-70]</sup>. Activated HSCs express TLR4 and CD14 and respond to LPS upon the activation of IKK/NF- $\kappa$ B and c-Jun N-terminal kinase (JNK) as well as the secretion of proinflammatory cytokines such as transforming growth factor (TGF)- $\beta$ , IL-6, IL-8 and several chemokines such as MCP-1, MIP-2, intercellular cell adhesion molecule 1, vascular cell adhesion molecule 1, and E-selectin<sup>[9,33,70]</sup>. TLR4 enhances TGF- $\beta$  signaling, and stellate cell activation was shown to promote hepatic fibrosis<sup>[71]</sup>. In chimeric C3H/HeJ mice with TLR4 mutation in HSC or KCs, amelioration of hepatic fibrosis by LPS indicated a cardinal role for KCs and HSC in hepatic inflammation and fibrosis<sup>[9,72]</sup>. LPS was shown to downregulate the TGF- $\beta$  pseudoreceptor BAMBI in quiescent HSCs to induce TGF- $\beta$  signaling and stellate cell activation<sup>[71]</sup>. Additionally, TLR9 signaling activated *via* DNA from apoptotic hepatocytes was shown to modulate liver fibrosis *via* its effects on HSC differentiation through increased collagen production and inhibited HSC migration<sup>[73]</sup>. Hence, LPS and other TLR ligands are suggested to facilitate fibrogenic responses in the liver *via* their direct effects on HSCs<sup>[9,11,33]</sup>.

### Biliary epithelial cells

Accounting for approximately 5% of non-parenchymal cell population in the liver, BECs are commonly exposed to several gut-derived microbes<sup>[74,75]</sup>. BECs mainly express TLRs 2, 3, 4 and 5, which are upregulated by IFN- $\gamma$  stimulation<sup>[74,75]</sup>. TLR2 and TLR4 activation results in increased IRAK-M expression and provide negative feedback in human intrahepatic BECs<sup>[76]</sup>.

Under normal conditions, increased IRAK-M expression is critical in preventing undesired induction of the TLR signaling cascade, while in case of inflammatory conditions, upregulation of BEC-associated TLRs leads to IFN- $\gamma$  and TNF- $\alpha$  exposure, participating in biliary pathogenic responses<sup>[9,75]</sup>.

### Sinusoidal endothelial cells

Making up 50% of the non-parenchymal cells, SECs function in hepatic perfusion and nutrient supply<sup>[66,77-79]</sup>. They express TLR3, 4 and 9 and show increased NF- $\kappa$ B activation and CD54 expression alongside a limited ability to trigger leukocyte adhesion after LPS stimulation<sup>[66,77-79]</sup>. Although these effects indicate a scavenging role and thus the likelihood of SECs acting as antigen presenting cells, the exact role of the TLR signaling in inflammatory process in SEC remains inconclusive<sup>[9,11,33,66,77-79]</sup>.

Isolated SECs from WT mice were shown to respond to TLR1, 2, 6 and 9 ligands *via* producing TNF- $\alpha$ ; to TLR3 ligands by producing TNF- $\alpha$ , IL-6 and IFN- $\beta$ ; and to TLR4 ligands *via* production of TNF- $\alpha$  and IL-6<sup>[22,33]</sup>. Upon TLR8

ligand binding, SECs leads to TNF- $\alpha$  production alongside upregulation of major histocompatibility complex (MHC)-II and co-stimulatory molecules. Stimulation of SECs by TLR1, 2 or 6 ligands is suggested to be associated with activation of allogeneic T cells, as evaluated by the mixed lymphocyte reaction<sup>[22,33]</sup>. The SEC immune response is also modulated by LPS tolerance, which appears to be based on prostanoid expression rather than regulation at the level of TLR4 surface expression<sup>[78]</sup>. Although SECs have been suggested to be involved in the hepatic uptake of LPS in some studies, several studies have not confirmed such a role<sup>[33,80,81]</sup>.

### Hepatic dendritic cells

Comprising < 1% of non-parenchymal cells, hepatic DCs are recruited into the liver sinusoids during inflammation and then they may migrate to periportal and pericentral areas<sup>[5,33,82,83]</sup>. Plasmacytoid DCs (pDCs), myeloid DCs, lymphoid DCs, mixed lymphoid + myeloid DCs and natural killer DCs are amongst the DC subsets, whereas lymphoid and myeloid DCs are considered conventional DCs<sup>[33,82,83]</sup>.

Each DC subset show distinct TLR expression pattern in humans with TLR1, 7 and 9 expression *via* pDCs, while expression of all TLRs excluding TLR9 by other DC subsets<sup>[20,33,84]</sup>. Cytokines TNF- $\alpha$ , IL-6 and IL-12 TLR7 are produced by hepatic pDCs upon TLR7 and TLR9 activation, whereas TNF- $\alpha$  and IL-6 in response to TLR2, TLR3 and TLR4 activation<sup>[50,85]</sup>.

## TLRs IN THE PATHOPHYSIOLOGY OF LIVER DISEASES

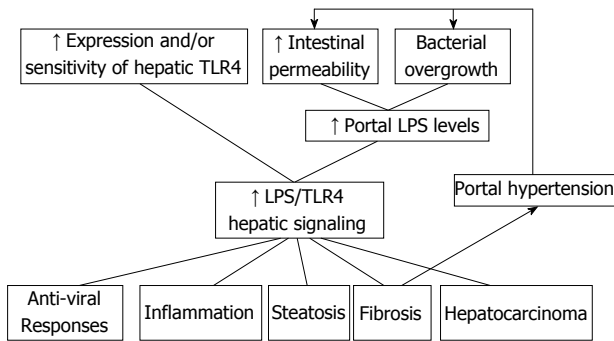

Increasing evidence suggests that TLRs have significant contribution to the pathogenesis and progression of several liver diseases, *i.e.*, non-alcoholic fatty liver disease (NAFLD), alcoholic liver disease (ALD), viral hepatitis, autoimmune liver disease and hepatic inflammation-fibrosis-carcinoma (IFC) sequence including hepatic fibrosis and/or cirrhosis and hepatocarcinoma<sup>[9,11,13,15,23,33]</sup>.

LPS/TLR4 and TLR2 signaling have been suggested to be principal actors in the human hepatic IFC sequence associated with viral chronic hepatitis<sup>[86]</sup>, while the participation of TLR3 in the pathophysiology of several liver diseases has also been suggested in the recent studies<sup>[11,15,23,87]</sup> (Figure 2).

### NAFLD and steatohepatitis

NAFLD and steatohepatitis is characterized by a pathologic spectrum that ranges from fatty liver (hepatic steatosis) to cirrhosis with intervening non-alcoholic steatohepatitis (NASH) and usually occurs in association with obesity and insulin resistance<sup>[13,72,88-90]</sup>.

Increased serum PAMP levels were observed in both experimental models and in NAFLD patients<sup>[9,18,91-96]</sup>. A shift in microbial populations to adopt an "obese" phenotype in NAFLD is referred to as "metabolic endotoxaemia", in which a high-fat diet is associated with

**Figure 2 Enhanced lipopolysaccharide/toll-like receptors 4 signaling in chronic liver diseases.** Induction of anti-viral responses, inflammation, steatosis, fibrosis, and hepatocarcinoma via LPS/TLR4 signaling alongside hepatic fibrosis mediated portal hypertension which further increases bacterial overgrowth and intestinal permeability, creating a positive feedback process. TLR4: Toll-like receptors 4; LPS: Lipopolysaccharide.

elevated levels of LPS translocation<sup>[27,90,97]</sup>.

While TLR2, TLR4 and TLR9 participate in the development of NASH and NAFLD, LPS-TLR4 is considered to be the main pathway for the progression of NAFLD<sup>[98-100]</sup>. The role of bacterial overgrowth has also been associated with development of NASH, emphasizing the interaction between bacterial overgrowth, gut permeability and liver injury<sup>[90,101,102]</sup>.

While the role of adipose tissue macrophages in the development of NAFLD is not yet clear, KCs are known to play a pivotal role in the development of NAFLD alongside accompanying hepatic inflammation and related complications<sup>[18,98]</sup>.

When inflammation occurs in NAFLD, NF- $\kappa$ B and transcriptional factor AP1 are activated, stimulating the production of TNF- $\alpha$  and IL-10, in particular, by KCs<sup>[23,103]</sup>. Studies in animal models indicated the likelihood of TLRs 2, 4 and 9 to participate in NAFLD onset or progression<sup>[9,18,91,104]</sup>. LPS/TLR4 and TLR9 signaling in KCs have been associated with both onset and progression of NAFLD by inducing reactive oxygen species (ROS)-dependent activation of X-box binding protein-1 and IL-1b, respectively, whereas induction of hepatic steatosis occurs independent of TLR2 signaling in KCs<sup>[18,104-106]</sup> (Figure 2).

While free fatty acids and denatured host DNA are considered to be potential candidates to activate TLR2, TLR4 and TLR9 signals, no clear-cut evidence exists to confirm their capacity to activate TLRs in NAFLD<sup>[18]</sup>. TLR4 signaling has been considered to play a major role in the pathogenesis of NAFLD that operates *via* KCs stimulation and increased ROS and TNF- $\alpha$  production<sup>[13]</sup>.

## ALD

ALD is described along a disease spectrum ranging from steatosis and steatohepatitis to fibrosis and cirrhosis and potential development of hepatocellular carcinoma (HCC)<sup>[90,107]</sup>.

Despite a strong association between alcohol and hepatotoxicity, the exact pathogenesis has not yet been

elucidated<sup>[90]</sup>. Involvement of the gut microbiota *via* a "leaky" gut has been indicated in the development of ALD<sup>[18]</sup>, whereas the role of alcohol has also been suggested in increasing gut permeability by disrupting tight junctions<sup>[108,109]</sup>. Increased plasma LPS levels and hepatic endotoxin levels, which leads to increased TLR4 signaling on KCs, HSC, LSECs and hepatocytes and thus the release of pro-inflammatory cytokines have been associated with inflammation and liver damage<sup>[9,107,108,110]</sup>.

Recent studies indicate significant contribution of TLR4 signaling and thus the crucial role of both KCs and HSCs in development of gut-derived endotoxin related effects in ALD<sup>[18]</sup>. Chronic alcohol consumption is also associated with the increased expression of TLR1, TLR2, TLR4 and TLR6-TLR9, which further potentiates the secretion of the pro-inflammatory TNF- $\alpha$  in response to LPS<sup>[111]</sup>.

KCs produce pro-inflammatory cytokines (TNF- $\alpha$ , IL-1, IL-6 and IL-8, chemokines) and profibrogenic factors (TGF- $\beta$ ) under post-LPS mediated TLR4-dependent stimulation, and consequent liver inflammation and stellate cell activation induce liver fibrosis<sup>[9,15,112,113]</sup>. The TLR4-dependent downstream signaling cascade in ALD was shown to proceed *via* the MyD88-independent pathway, possibly *via* adapter molecule TRIF<sup>[114]</sup>. Nonetheless, increased expression of not only TLR4 but also other TLRs such as TLR1, 2, 6, 7, 8 and 9 was shown in an experimental chronic alcohol model<sup>[115]</sup>.

Although activation of KCs *via* TLR4 signaling is a key event in the pathogenesis of alcohol-induced liver injury<sup>[18]</sup>, recent data emphasize the activation of TLR4 signaling in HSCs as well, indicating the their contribution to alcohol-induced hepatocyte injury, steatosis, inflammation, and fibrogenesis<sup>[18,116]</sup>. In HSCs, activated TLR4 signaling downregulates TGF- $\beta$  pseudoreceptor BMP and activin membrane-bound inhibitor (BAMBI), resulting in enhancement of TGF- $\beta$  signaling, whereas BAMBI downregulation is dependent on MyD88 but not TRIF<sup>[18,110]</sup>. The TLR4-TRIF-IRF3-dependent pathway associated with bone marrow-derived cells including KCs is considered to be more important than the TLR4-MyD88-dependent pathway in the development of alcoholic steatohepatitis<sup>[18,110,114]</sup>.

Acting through upregulation of TLR4 and MD-2 and induction of a Th1-type immune response, bacterial DNA recognition by TLR9 was also shown to be associated with LPS induced liver injury<sup>[117]</sup>, indicating the likelihood of TLR9 signaling to contribute to pathogenesis of ALD<sup>[18]</sup>.

## Hepatic fibrosis and cirrhosis

The development of hepatic fibrosis and consequent cirrhosis upon continued liver insults may occur in any type of chronic hepatic injury, including viral hepatitis, alcohol, autoimmune and metabolic disease<sup>[9,67]</sup>.

Prolonged or repeated liver injury leads to a maladaptive interplay of hepatocytes, HSCs and KCs in association with TLR expression, eventually resulting in abnormal extracellular matrix protein deposition in the

liver<sup>[35,67,118]</sup>.

LPS-TLR4 activation is considered essential for hepatic fibrogenesis, whereas TLR4 is expressed on KCs and HSCs, the key mediators of hepatic fibrogenesis<sup>[27,75,80,81]</sup>.

KCs express the highest levels of TLR4 and act as the principal target of LPS leading to release of several pro-inflammatory and pro-fibrogenic mediators<sup>[5,27,71,114,119]</sup>. However, HSCs are crucial in the pathogenesis of fibrosis and cirrhosis given their myofibroblastic phenotype and ability to produce collagen, the principal component of fibrotic tissue<sup>[9,120]</sup>.

Activation of HSC occurs either *via* pro-inflammatory cytokines and growth factors secreted by LPS-TLR4-stimulated KCs, or directly *via* LPS-TLR4-dependent HSC stimulation<sup>[9,71]</sup>. LPS/TLR4 signaling in HSCs is essential for development of liver fibrosis and acts *via* stimulating production of chemokines that recruit KCs alongside enabling unrestricted activation of HSCs by KCs-derived profibrogenic cytokine TGF- $\beta$ <sup>[11,13,103,121]</sup> (Figure 2).

TLR4 activation in HSCs is considered to be the main step for collagen production and the main mediator of fibrosis and cirrhosis<sup>[9,11,67,70,71]</sup>.

KCs induce fibrogenesis by means of proinflammatory and profibrogenic cytokine secretion, whereas HSCs are the leading source of extracellular matrix production in the fibrotic liver<sup>[11,67]</sup>.

TLR9 signaling-associated metabolic pathways are also considered important in the genesis of hepatic fibrosis *in vivo*, leading to activation of pathways such as IL-1 production and thus HSCs by upregulating profibrogenic genes, such as procollagen type I and tissue inhibitor metalloproteinase-1<sup>[16,69,103,104]</sup>.

Moreover, a deficiency of TLR3-mediated NK cell-dependent apoptosis of HSCs has been linked to the progression of alcohol-induced liver fibrosis<sup>[122,123]</sup>. Upregulation of TLR2 was shown to promote liver inflammation and fibrogenesis in NASH<sup>[106]</sup> and HSCs activation and inflammation response during carbon tetrachloride-induced liver fibrosis mediated *via* MAPK and NF- $\kappa$ B signaling pathways<sup>[124]</sup>, whereas TLR5 was also shown to be directly involved in the progression of fibrosis *via* activation of the NF- $\kappa$ B and MAPK signaling pathways<sup>[52]</sup>.

### Hepatitis B

Hepatitis B virus (HBV) is a DNA virus responsible for acute hepatitis, which is self-limiting in 80%-90% of adults and chronic in 10%-20% of cases<sup>[5,125]</sup>. Hepatitis B is associated with an increased risk of developing cirrhosis, hepatic decompensation and HCC, but prognosis shows interpersonal variation depending on the viral susceptibility and induction of antiviral immune response<sup>[126,127]</sup>.

Indicating the role of TLRs in HBV infection, the activation of TLR3, TLR7 and TLR9 as well as TLR4 and TLR5, has been associated with blockage of viral replication *via* IFN-dependent inhibition of HBV<sup>[76,128,129]</sup>. Moreover, HBV leads to TLR downregulation alongside restriction of receptor activity, increasing the likelihood of persistent infection<sup>[27]</sup>.

*In vitro* HBV studies on TLR expression in HepG2 cells revealed elevated expression of TLRs 2, 3, 4, 5, 6, 7 and 9 mRNA upon ligand binding along with an induced IFN response and abolished HBV DNA replication and RNA transcription, whereas no or very limited expression of TLRs 1, 8 and 10<sup>[9,130]</sup>. Furthermore, transfection of HBV-positive cell lines with TLR adaptor molecules was shown to be associated with elevated TLR activity and a consequent reduction in HBV DNA and mRNA levels<sup>[131]</sup>, whereas HBV replication was completely abolished after injection of TLR3, TLR4, TLR5, TLR7 and TLR9 ligands into HBV transgenic mice<sup>[129]</sup>.

TLR1, TLR2, TLR4 and TLR6 were shown to be down-regulated in HBV-infected peripheral blood monocytes along with a decreased cytokine response to TLR2 and TLR4 ligands<sup>[132]</sup>. Downregulation of TLR2 on hepatocytes and hepatic KCs was demonstrated in HBeAg-positive CHB-infected patients, whereas upregulation of TLR2 and cytokine expression was observed in HBeAg-negative CHB patients<sup>[133]</sup>. Hence, HBeAg-induced downregulation of TLR2 *via* precore protein has been accused for the accelerated progression of disease in HBeAg-positive patients<sup>[9,133]</sup>.

Although HBV is able to downregulate TLRs and thus avoid anti-viral pathways, prolonged infection and loss of HBeAg is considered likely to upregulate TLR signaling pathways such as TLR2 that are not primarily involved in anti-HBV responses while trigger hepatic inflammation and disease progression<sup>[11]</sup>.

*In vitro* analysis of HBV-Met cells revealed that TLR-treated KCs and SECs to have a modulatory effect on HBV replication<sup>[134]</sup>. TLR3- and TLR4-stimulated KCs and TLR3-activated SECs were shown to affect HBV replication *via* MyD88-independent pathway<sup>[66]</sup>. HBV-suppressing effect was mediated by IFN- $\beta$  in case of TLR3 ligand activation, whereas by cytokines of an undefined nature in case of TLR4-activated KCs<sup>[66]</sup>.

HBV is a stealth virus and thus does not induce an IFN response during the early phase of infection, whereas its recognition by liver resident cells is considered likely to activate innate immune responses without IFN induction<sup>[107,135]</sup>. Notably, HBV was shown to be recognized by hepatic NPCs, mainly by KCs, leading to NF- $\kappa$ B-dependent induction of the release of the inflammatory cytokines IL-6, IL-8, TNF- $\alpha$  and IL-1 $\beta$  as well as reduced expression of transcription factors essential for HBV gene expression and replication including hepatocyte nuclear factor (HNF) 1 $\alpha$  and HNF4 $\alpha$ <sup>[136]</sup>.

### Hepatitis C

Hepatitis C virus (HCV) is a hepatotropic virus responsible for development of chronic hepatitis and related complications such as liver cirrhosis, liver failure or HCC<sup>[137,138]</sup>.

Similarly to HBV, current evidence indicates that HCV selectively impairs activation of TLR signaling controlling HCV replication, while it concomitantly stimulates TLR pathways that generate a chronic inflammatory state

leading to persistent liver injury<sup>[11,27,139,140]</sup>.

HCV-induced inhibition of TLR signaling contributes to its chronicity related to virus dissemination, inflammation and eventual progression to fibrosis and cirrhosis<sup>[9,11]</sup>.

Regulation of HCV replication by non-parenchymal liver cells occurs through the production of IFN- $\beta$  upon their stimulation by TLR3 and TLR4<sup>[141]</sup>. The inhibitory effect of HCV proteins on TLR7 and TLR9, is also likely to prevent virus clearance<sup>[27]</sup>. Furthermore, activation of TLR2 along with TLR1 and TLR6 and possibly TLR4 by HCV core protein and NS3 promotes hepatic inflammation and injury<sup>[142-145]</sup>.

In the presence of HCV, significantly decreased TLR7 expression along with TLR7-independent activation of IRF-7 pathway was demonstrated both *in vitro* and *in vivo*<sup>[146]</sup>.

The NS3/4A serine protease of HCV, HCV NS3 protein and HCV NS5A act *via* three signaling pathways including the TLR3-TRIF-TBK1-IRF-3, TLRMyD88, and RIG-I/MDA5-IPS-1 pathways to enable HCV to evade innate immune signaling<sup>[33]</sup>. Moreover, LPS, the HCV core protein and IFN- $\gamma$  have been suggested to amplify inflammatory monocyte/macrophage activation *via* formation of MyD88-IRAK complexes, increased NF- $\kappa$ B activation and increased production of TNF- $\alpha$ , leading to the loss of TLR tolerance<sup>[147]</sup>.

Based on these findings, both host- and virus derived factors have been considered likely to act on macrophages to induce persistent inflammation during chronic HCV infection<sup>[53,107]</sup>.

### Hepatocarcinoma

Diseases associated with uncontrolled innate immunity related to TLR ligand exposure in the liver (fibrosis, hepatitis B and C infection, ALD and NASH) are also among the etiologies for HCC. Therefore, it appears likely that TLRs play a role in the development of inflammation-associated liver cancer and are involved in the progression of HCC<sup>[18,107]</sup>. Hence, chronic hepatic inflammation and fibrosis, as regulated by TLR activation, promotes HCC formation in approximately 10% of cases of cirrhosis<sup>[9,54]</sup>.

TLRs, TLR4 in particular, are considered to play a significant role in associating hepatic chronic inflammation and hepatocarcinoma<sup>[13]</sup>. A significant regression in liver tumors in TLR4 and MyD88 deficient mice indicates a prominent contribution of TLR signaling to hepatocarcinogenesis<sup>[23,148]</sup>.

HCC has been indicated to be promoted *via* gut microbiota and TLR4 in association with increased production of proinflammatory cytokines (TNF- $\alpha$ , IL-6), hepatomitogen epiregulin expression and prevention of apoptosis, whereas a reduction in the development of HCC was shown *via* gut sterilization, germ-free status or TLR4 inactivation<sup>[18,149,150]</sup>.

Activation of KCs *via* TLRs is considered to be involved in the process of tumorigenesis<sup>[18]</sup> by inducing proinflammatory cytokines and hepatomitogens responsible for enhanced development of HCC<sup>[150,151]</sup>, whereas TLR4

expression on non-marrow-derived resident liver cells is considered to be required for the promotion of HCC<sup>[149]</sup>.

TLR4 contributes significantly to hepatic inflammation and fibrosis, whereas upregulation of inflammatory factors such as COX-2 and NF- $\kappa$ B by TLR4 as well as the TLR adaptor protein Myd-88 is also important in hepatocarcinogenesis<sup>[148,152-155]</sup>. TLR3 expression is suggested to contribute to hepatocarcinoma *via* proapoptotic activity, while activation of TLR9 *via* CpG DNA of HBV has been associated with malignant transformation in liver cells<sup>[27,156,157]</sup>.

Although, TLR2 binding with ligands such as HMGB1 and HSPA1A is associated with tumor enhancement, the effect of TLR2 activation is considered likely to differ according to the phase of HCC carcinogenesis, with anti-oncogenic potential slowing down the onset and development of HCC in earlier phases, whereas pro-oncogenic potential during later stages that promotes the progression of inflammation and fibrosis<sup>[158]</sup>.

Activation of the NF- $\kappa$ B and JNK pathways and higher expression levels of IKK $\alpha$  and IKK $\beta$  are considered critical in the production of the cytokines related to TLR-induced liver damage and HCC progression<sup>[107]</sup>.

Recently, spontaneous HCC development was demonstrated in hepatocyte-specific TAK1 deleted (TAK1DHEP) mice along with a resistance for HCC development that occurs *via* deletion of MyD88, TLR4 or TLR9 signaling<sup>[159]</sup>.

Alcohol and HCV are suggested to interact in causing progression of liver disease and malignancy, whereas TLR4, TLR4 downstream gene Nanog and activated LPS-TLR4 are also considered to contribute to this synergy *via* triggering proliferative and anti-apoptotic signals to non-marrow-derived resident liver cells and thus HCC progression<sup>[9,149,150,160]</sup>.

### Ischemic/reperfusion injury and liver allograft rejection

Ischemia-reperfusion (I/R) injury in partial hepatectomy and liver transplantation is associated with the release of various endogenous ligands for hepatic tissue TLRs and thus the activation of complex signaling pathways that induce neutrophilic and T-lymphocytic tissue inflammation and injury<sup>[53,161,162]</sup>.

Among the most studied TLRs in hepatic I/R, TLR4 was shown to participate in certain acute sterile injury models, including liver I/R, by mobilizing the immune system upon detection of endogenous ligands, whereas limited data are available on TLR2 and TLR9<sup>[163,164]</sup>.

MyD88-independent activation of TLR4 by DAMPs is considered central to the inflammatory process observed in I/R lesions<sup>[165-167]</sup>, whereas HSP, heparan sulfate, fibronectin, fibrinogen, hyaluronan and HMGB1 are known to act as endogenous ligands for TLR4 activation in hepatic I/R injury<sup>[5,163]</sup>.

Release of HMGB1 activates the cell surface TLR4 on KCs and leads to a subsequent release of cytotoxic mediators (TNF- $\alpha$ , IL-6 and chemokine IP-10), alongside an inappropriate activation of the pro-apoptotic protein kinase JNK and stress-responsive NF- $\kappa$ B, all of which are mediators of cell injury<sup>[5,163,168,169]</sup>. Cellular expression

of TLR4 is further upregulated *via* newly synthesized mediators such as TNF- $\alpha$ , leading to formation of a vicious cycle of proinflammatory cytokine production<sup>[61,163,170]</sup>.

Downstream TLR4 signaling pathways in I/R injury seems to be independent of MyD88 signaling, whereas TRIF-dependent activation of the interferon response and IRF1 expression is considered critical for mediating I/R injury in hepatocytes in terms of releasing the danger signal HMGB1<sup>[164,171,172]</sup>. Hence, TLR4, IRF1 and HMGB1 are considered three important and interacting mediators of I/R injury<sup>[164]</sup>.

Albeit not consistent, available data suggest that besides lack of TLR4, downregulation of TLR2 expression in the donor organ also suppress I/R injury<sup>[27,165,173]</sup>. Accordingly, given the amelioration of liver injury in I/R *via* non-selective inhibition of TLR2 and TLR4 activation by certain molecules such as bicyclol or N-acetylcysteine, role of TLRs in I/R lesion has been emphasized<sup>[27,174,175]</sup>.

TLR9, which shows affinity toward both pathogen-derived and endogenous host DNA, is considered to play a crucial role in non-pathogen-induced hepatic I/R injury by causing neutrophil activation, liver necrosis, and inflammatory cytokine release<sup>[163,176,177]</sup>.

Although TLR signaling dependent early activation of the innate immune system is consistently reported in the setting of I/R injury, additional studies are required to fully explore the roles of other TLRs and TLR signaling pathways in I/R injury<sup>[163,164]</sup>.

### **Liver regeneration after partial hepatectomy**

Recognizing the mechanism of liver regeneration is important not only for managing acute liver failure and post-transplant hepatic dysfunction but also for disturbed liver regeneration in NASH or NAFLD and advanced liver fibrosis<sup>[178]</sup>. The deposition of excessive amounts of extracellular matrix, the presence of persistent inflammation, the transformation of SECs and HSCs, portal blood flow reduction and increased JNK activity are considered among the factors associated with the regenerative ability of fibrotic livers<sup>[178,179]</sup>.

TLR/MyD88-mediated pathways are associated with onset of liver regeneration after partial hepatectomy (PH) *via* activation of NF- $\kappa$ B, release of TNF- $\alpha$  and IL-6 and the expression of the immediate early genes for cell replication in hepatocytes, whereas distinct TLR ligands responsible for the priming process have not yet been clarified<sup>[33,178]</sup>. No contribution of TLR2, TLR4 or TLR9 to MyD88-mediated pathways and no influence of TLR2 or TLR4 on proinflammatory cytokine production or gene replication have been reported for liver regeneration after PH<sup>[33,180,181]</sup>.

In fact, given the inhibition of regenerative process *via* excessive TLR signaling produced by LPS injection after PH, the magnitude of TLR signaling is considered critical for intact liver regeneration<sup>[178,182]</sup>.

TLR3 signaling, which utilizes a distinct adaptor protein, TRIF, is considered to attenuate the initiation of liver regeneration *via* TLR3-dependent NF- $\kappa$ B activation in hepatocytes and TLR3-induced IFN- $\gamma$  through

STAT1 and consequent induction of the IRF-1 and p21 pathways<sup>[178,183,184]</sup>.

In addition, although a non-TLR MyD88-dependent pathway with IL-1 and IL-18 has been suggested to play a role in allograft rejection initially, findings on the existence of normal liver regeneration after PH in caspase 1-deficient mice indicate unremarkable participation of IL-1 $\beta$  and IL-18 in liver regeneration<sup>[178]</sup>.

### **Hepatic autoimmune disorders**

Although antibody formation against self-antigens is key to the development of autoimmune hepatic diseases, including autoimmune hepatitis, primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC)<sup>[185]</sup>, recently the influence of gut microbiota on the propagation of these diseases has been indicated<sup>[90]</sup>.

Given that the liver is considered a classical immunoprivileged site, TLR signals may act as an important promoter for overcoming this immunoprivilege and inducing hepatic autoimmune disease<sup>[11,13,186]</sup>.

Previous studies have suggested regulator role of gut-derived products on T cell function within the liver<sup>[90]</sup>, based on the connection between TLR4 signaling and the trapping of CD8+ T cells in the murine liver<sup>[187]</sup>, as well as contribution of TLR9 to the homing and stimulation of hepatic NKT cells *via* a KC and IL-12 dependent process<sup>[188]</sup>. The role of LPS/TLR4 signaling has been indicated in the pathogenesis of PBC and PSC<sup>[13]</sup>. Monocytes from PBC patients have been suggested to show increased sensitivity to activation of selective TLRs (TLR2, TLR4, TLR3, TLR5 and TLR9), while the subsequent release of proinflammatory cytokines has been associated with development of self-tolerance and autoimmune progression<sup>[189]</sup> (Figure 2).

LPS was shown to accumulate in significant amounts in the biliary epithelia of PBC patients, whereas positivity for IgM antibodies against lipid A, an immunogenic and toxic component of LPS, is confirmed in 64% of PBC sera<sup>[190,191]</sup>. TLR4 expression is significantly elevated in BECs, periportal hepatocytes and blood monocytes of PBC patients<sup>[192,193]</sup>, whereas LPS/TLR4 signaling has been associated with an increased release of proinflammatory cytokines such as IL-1b, IL-6, IL-8 and TNF- $\alpha$ <sup>[189]</sup>. TLR4 ligand-stimulated NK cells have been suggested to be associated with BEC damage in the presence of TLR3 ligand-activated monocytes among PBC patients<sup>[194]</sup>. Despite similar levels of TLRs in BECs isolated from livers from patients and controls, stimulation *via* TLR3 agonist poly I:C and co-culture with liver-infiltrating mononuclear cells resulted in elevated chemokine levels in livers from patients<sup>[195]</sup>. Moreover, when compared to patients with autoimmune hepatitis and Hepatitis C, patients with PBC showed higher levels of TLR3 and IFN- $\alpha/\beta$  in portal tracts and liver parenchyma<sup>[196]</sup>. Furthermore, TLR9 ligand (CpG) stimulation of peripheral blood monocytes from PBC patients was demonstrated to activate IgM-producing B cells and to increase TLR9 expression on these cells<sup>[197,198]</sup>. These findings emphasize the role of innate immunity not only in the pathogenesis and pro-

gression of PBC but also in the regulation of adaptive immune responses<sup>[9]</sup>.

The role of TLRs in PSC has not been extensively studied<sup>[11]</sup>. Abnormal LPS accumulation was demonstrated in BECs in PSC<sup>[190]</sup>. Stimulating isolated BECs with anti-BEC antibodies from patients with PSC leads to increased expression of TLR4 along with higher levels of inflammatory cytokines in the presence of LPS<sup>[199]</sup>.

Accordingly, increased LPS accumulation and TLR4 expression in BECs has been suggested to induce breakdown of self-tolerance and onset of bile duct damage in PBC and PSC thorough their stimulatory effects on selective pro-inflammatory cytokines with a critical role<sup>[13]</sup>. Given the signs of inflammatory bowel disease to exist in most patients with PSC and the likelihood of gut factors to induce response onset per se with no preceding immune cell dysfunction, future investigations are needed addressing the role of gut microbiota in conjunction with PSC and PBC to provide a better understanding of the mechanisms and treatment of these complex diseases<sup>[90]</sup>.

## CONCLUSION

TLRs have been recognized as key regulators of innate and adaptive immune responses in the liver, although growing evidence suggests the critical role of TLR dysregulation in the pathogenesis and progression of many liver diseases<sup>[9,107]</sup>. TLRs, mainly TLR4 and TLR2, play a fundamental role in the inflammation and fibrosis of the liver and promote the progression of chronic liver diseases<sup>[27,35,86]</sup>. Indeed, LPS/TLR4 signaling is enhanced and essential in liver diseases such as ALD, NAFLD, PSC, CBP and fibrosis, and inhibition of TLR4 has been associated with amelioration of liver injury, emphasizing the contribution of LPS/TLR4 signaling to the pathogenesis of liver diseases<sup>[13]</sup>.

The local innate immune system represented by liver cells participates in tolerance induction or inflammation alongside its interaction with the adaptive immune system, whereas suppression of the TLR system in the liver by pathogens enhance chronicity of infection<sup>[107]</sup>. Therefore, targeting TLR signaling at different levels of cascade appears to offer therapeutic potential in the management of chronic liver disease<sup>[11]</sup>.

LPS/TLR4 signaling pathway has been recognized as an important pharmacological target in chronic liver diseases. Suppression of TLR4 signaling *via* modulation of LPS production, TLR and co-receptor expression and downstream signaling molecules has been shown to ameliorate liver injury, indicating the contribution of LPS/TLR4 signaling to the pathogenesis of chronic liver diseases. Given the likelihood of systemic suppression of TLR4 to disable responding pattern of TLR4 to invading pathogens, modulation of intestinal microbiota *via* probiotics and symbiotics become a preferred therapeutic strategy for liver diseases, associated with favorable tolerability and safety<sup>[13,23]</sup>. Besides, certain synthetic ligands of TLRs have been considered to act as target molecules for drug

development given their effects on regulation of innate and adaptive immune responses, including TLR activators (for infections and certain cancers), TLR inhibitors (for inflammatory diseases and sepsis) as well as TLR neutralizing antibodies<sup>[34,37]</sup>. Further investigation of the role of TLR pathways in liver diseases addressing the downstream mediators and regulation of TLR signaling, the specific cell populations involved, the role of TLR polymorphisms and the mechanisms underlying liver tumorigenesis is needed to transfer knowledge on TLR pathophysiology into clinical practice in treating human liver diseases<sup>[5,23]</sup>.

## Abstract

### AIM

To study the differences in immune response and cytokine profile between acute liver failure and self-limited acute hepatitis.

### METHODS

Forty-six patients with self-limited acute hepatitis (AH), sixteen patients with acute liver failure (ALF), and twenty-two healthy subjects were involved in this study. The inflammatory and anti-inflammatory products in plasma samples were quantified using commercial enzyme-linked immunoassays and quantitative real-time PCR. The cellular immune responses were measured by proliferation assay using flow cytometry. The groups were divided into viral- and non-viral-induced self-limited AH and ALF. Thus, we worked with five groups: Hepatitis A virus (HAV)-induced self-limited acute hepatitis (HAV-AH), HAV-induced ALF (HAV-ALF), non-viral-induced self-limited acute hepatitis (non-viral AH), non-viral-induced acute liver failure (non-viral ALF), and healthy subjects (HC). Comparisons among HAV and non-viral-induced AH and ALF were performed.

### RESULTS

The levels of mitochondrial DNA (mtDNA) and the cytokines investigated [interleukin (IL)-6, IL-8, IL-10, interferon gamma, and tumor necrosis factor] were significantly increased in ALF patients, independently of etiology ( $P < 0.05$ ). High plasma mtDNA and IL-10 were the best markers associated with ALF [mtDNA: OR = 320.5 (95%CI: 14.42-7123.33),  $P < 0.0001$ ; and IL-10: OR = 18.8 (95%CI: 1.38-257.94),  $P = 0.028$ ] and death [mtDNA: OR = 12.1 (95%CI: 2.57-57.07),  $P = 0.002$ ; and IL-10: OR = 8.01 (95%CI: 1.26-50.97),  $P = 0.027$ ]. In the cellular proliferation assay, NK<sup>bright</sup>, NKT and regulatory T cells (TReg) predominated in virus-specific stimulation in HAV-induced ALF patients with an anergic behavior in the cellular response to mitotic stimulation. Therefore, in non-viral-induced ALF, anergic behavior of activated T cells was not observed after mitotic stimulation, as expected and as described by the literature.

### CONCLUSION

mtDNA and IL-10 may be predictors of ALF and death. TReg cells are involved in immunological disturbance in

HAV-induced ALF.

**Key words:** Acute liver failure; Cytokines; Mitochondrial DNA; Cellular immune response; Hepatitis A virus

**Core tip:** Acute liver diseases induced by viral infections are considered major causes of liver failure and death in Brazil. To better understand this pathogenesis, we investigated in a pioneering way the cellular immune response, inflammatory mediators and mitochondrial products in patients with hepatitis A virus (HAV)-induced acute liver failure (ALF) in comparison to patients with non-virus-induced ALF in a cross-sectional study. The results showed that non-invasive samples could be helpful to assay early prognostic markers that would indicate the necessity for liver transplantation. The contribution of *in vitro* immune response involved in ALF can be helpful to show the necessity of mass vaccination against HAV.

## INTRODUCTION

Acute liver failure (ALF) is a rare (0.5%-1% of the acute hepatitis cases) and devastating clinical syndrome resulting from an acute insult that occurs when a high percentage of liver cells are rapidly lost. Liver transplantation is the only effective therapy<sup>[1-4]</sup>. Non-invasive methods have been proposed to evaluate the liver damage<sup>[5-7]</sup> and predict the worst outcome (death)<sup>[8-10]</sup>, with little success. Nevertheless, there are few studies on the systemically released inflammatory products that indicate liver failure or regeneration before liver transplantation, such as cytokine profile or mitochondrial DNA<sup>[11-15]</sup>. Additional early prognostic markers are urgently requested to evaluate the necessity of liver transplantation therapy.

The causes of ALF involve a variety of toxic, viral, metabolic, and vascular liver injuries. The etiology of ALF varies with geography<sup>[16]</sup>, and the hepatitis A virus (HAV) is the major cause of acute hepatitis in Brazil<sup>[17,18]</sup> due to absence of an effective hepatitis A vaccination program. Recent studies have shown high counts of natural killer (NK) cells (NK<sup>bright</sup> and NK<sup>dim</sup>) during self-limited hepatitis A<sup>[19]</sup>. Functionally, NK cells are important components of liver immunology, mediating pro-inflammatory functions, such as IFN $\gamma$  secretion by NK<sup>bright</sup> (CD3<sup>-</sup>CD56<sup>+</sup>CD16<sup>-</sup>) cells, as well as the lysis of target cells by a subset of NK<sup>dim</sup> (CD3<sup>-</sup>CD56<sup>low</sup>CD16<sup>+</sup>) cells<sup>[7,19-22]</sup>.

Perrella *et al.*<sup>[23]</sup> (2008) showed that regulatory T cells (TReg) (CD4<sup>+</sup>CD25<sup>+</sup>) are important factors in acute hepatitis A resolution. Trujillo-Ochoa *et al.*<sup>[14]</sup> showed that serum IL-17 is elevated in children with acute hepatitis A infection; however, the involvement of TReg and helper T cells in ALF caused by hepatitis A is unknown.

The goal of our study was to evaluate plasma levels of inflammatory and anti-inflammatory cytokines and mtDNA in a pilot study with a case series of liver injury patients and their association with ALF and occurrence of death. We quantified the mechanism of viral (HAV) and non-viral liver dysfunction by phenotypically characterizing cytotoxic, helper, and TReg and analyzed the cytokine secretion in a peripheral blood mononuclear cell (PBMC) clonal proliferation assay.

## MATERIALS AND METHODS

### Patients and samples

Eighty-four subjects agreed to participate in this study in Rio de Janeiro, Brazil, from 2009 to 2012: 46 (54.76%) were consecutive outpatients with self-limited acute hepatitis (AH) that were referred to the Viral Hepatitis Clinic of Oswaldo Cruz Institute - Fiocruz; 16 (19.05%) inpatients were admitted to the Bonsucesso Federal Hospital, a referral hospital for patients with ALF requiring transplantation; and 22 (26.19%) were healthy donors.

All samples were assayed for HAV, hepatitis B virus (HBV), hepatitis C virus (HCV), and hepatitis E virus (HEV) serological markers using commercially available enzyme-linked immunoassays (ELISAs): Anti-HAV IgM (Abbott, United States), Vikia HBsAg (Biomerieux, France), Murex anti-HCV version 4.0 (Diasorin, South Africa), and bioELISA HEV IgM version 3.0 (Biokit, Spain). Blood samples were also assayed using rapid tests for syphilis (DPP<sup>®</sup>, Bio-manguinhos, Brazil), HIV-1/2 (DPP<sup>®</sup>, Bio-manguinhos, Brazil), dengue (SD BIOLINE, Standard Diagnostics, South Korea), and leptospirosis (SD BIOLINE, Standard Diagnostics, South Korea). Other current infections and autoimmune diseases were analyzed with a chemiluminescent ELISA for Epstein-Barr, cytomegalovirus and antinuclear antibodies (ANA). The respective reference levels of  $\geq 20$  U/mL,  $\geq 30$  UA/mL, and  $\geq 1.5$  UI/mL were considered positive. Herpes virus type 1 (HSV-1) and herpes virus type 2 (HSV-2) were investigated using a TaqMan-based multiplex assay as previously described<sup>[24]</sup>. Metabolic disorders were also investigated whether the routine exams (biochemical, hematological, etc.) presented alterations or whether the patient had a family history of metabolic disorders.

AH cases were defined by aminotransferase levels of at least  $10 \times$  the upper normal limit and the onset of jaundice in a previously healthy individual<sup>[25]</sup>. The cases were further categorized according to international normalized ratio (INR) and hepatic encephalopathy grade (HE). Cases with INR  $< 1.5$  and no HE were classified as self-limited AH and those with INR  $\geq 1.5$  and an HE score above II as ALF<sup>[4]</sup>.

The timing of sample collection was based on the

onset of jaundice and liver enzyme levels for self-limited AH patients. In ALF patients, the timing of sample collection was based on ALF diagnosis and hospital admission. In healthy subjects, the sample collection was based on the lack of infection found in their routine exams.

The study population was divided into five groups according to etiology and clinical condition: Group 1: Virus-induced self-limited hepatitis, of which all cases were caused by HAV-AH; group 2: Non-viral-induced self-limited hepatitis, which included drug and indeterminate causes (non-viral AH); group 3: Virus-induced ALF, of which all cases were caused by HAV-ALF; group 4: Non-viral-induced ALF, which included drug and indeterminate causes (non-viral ALF); and group 5: Healthy subjects, as the control group (HC).

To assess the PBMCs, blood samples were collected in the anticoagulant citrate-dextrose solution-A (Greiner Bio-one, Kremsmünster, Austria) and stored at  $-70^{\circ}\text{C}$  (plasma) or in liquid nitrogen (peripheral blood mononuclear cells, PBMCs) until assay. Plasma and PBMC samples used were thawed only once for the different assays.

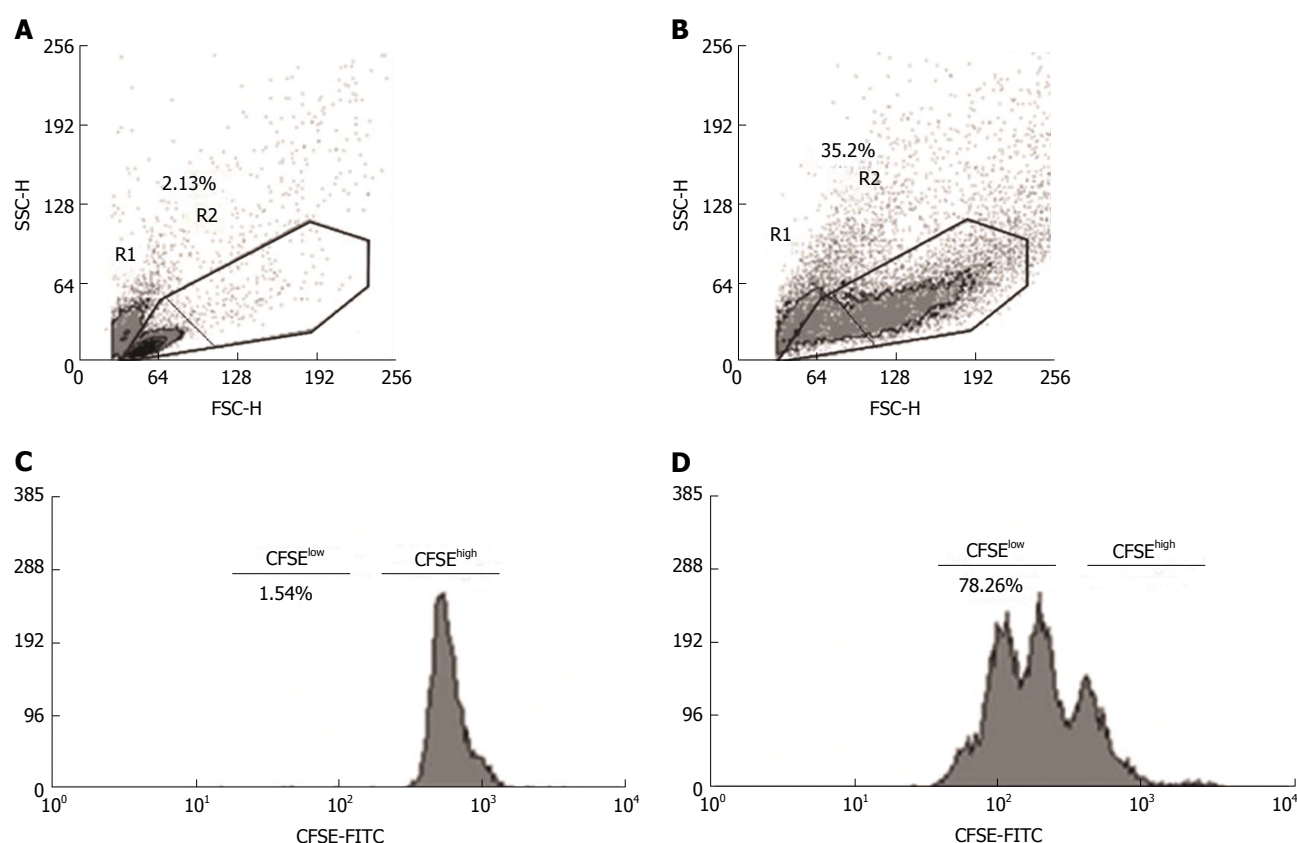

The study protocol was approved by the National Commission on Ethics in Research (CONEP), and by the institutional review board of the Oswaldo Cruz Foundation, FIOCRUZ (222/03). Signed informed consent was obtained from all participants. The study was performed in compliance with the relevant laws and institutional guidelines and in accord with the ethical standards of the Declaration of Helsinki.

### Quantitative detection of cytokines and mitochondrial-derived DNA in ALF, AH and healthy control subjects

To assess the liver inflammatory/anti-inflammatory status, plasma levels of the cytokines IL-6, IL-8, IL-10, IFN $\gamma$  and tumor necrosis factor alpha (TNF $\alpha$ ) were quantified using commercially available Standard ELISA Development kits (Peprotech, United States). To assess hepatocellular damage, the total DNA was purified from the plasma samples using the QIAamp DNA Blood Mini Kit (Qiagen, United States) according to the manufacturer's instructions<sup>[26]</sup>. The mitochondrial DNA (mtDNA) was quantified by real-time PCR as previously reported<sup>[26]</sup> using 3 pairs of primers specific for human cytochrome B (sense 5'atgacccaatacgcacaaat-3' and antisense 5'cgaagtttcacatgcggag3'), human cytochrome C oxidase subunit III (sense 5'atgacccaatacgcacatgc3' and antisense 5'atcacatggctaggccggag3'), and human NADH dehydrogenase (sense 5'ataccatggccaacctct3' and antisense 5'gggcctttgcgtagtgtat3'). The total mtDNA value corresponds to the sum of the individual values from each test. Colorimetric commercial kits were used to assess the levels of liver enzymes and total bilirubin.

### Quantitative evaluation of the clonal proliferation response and cell phenotypes of proliferated PBMCs from ALF and AH patients

Twenty-nine PBMC samples from 62 patients were evaluated for the proliferative cellular immune response: 16

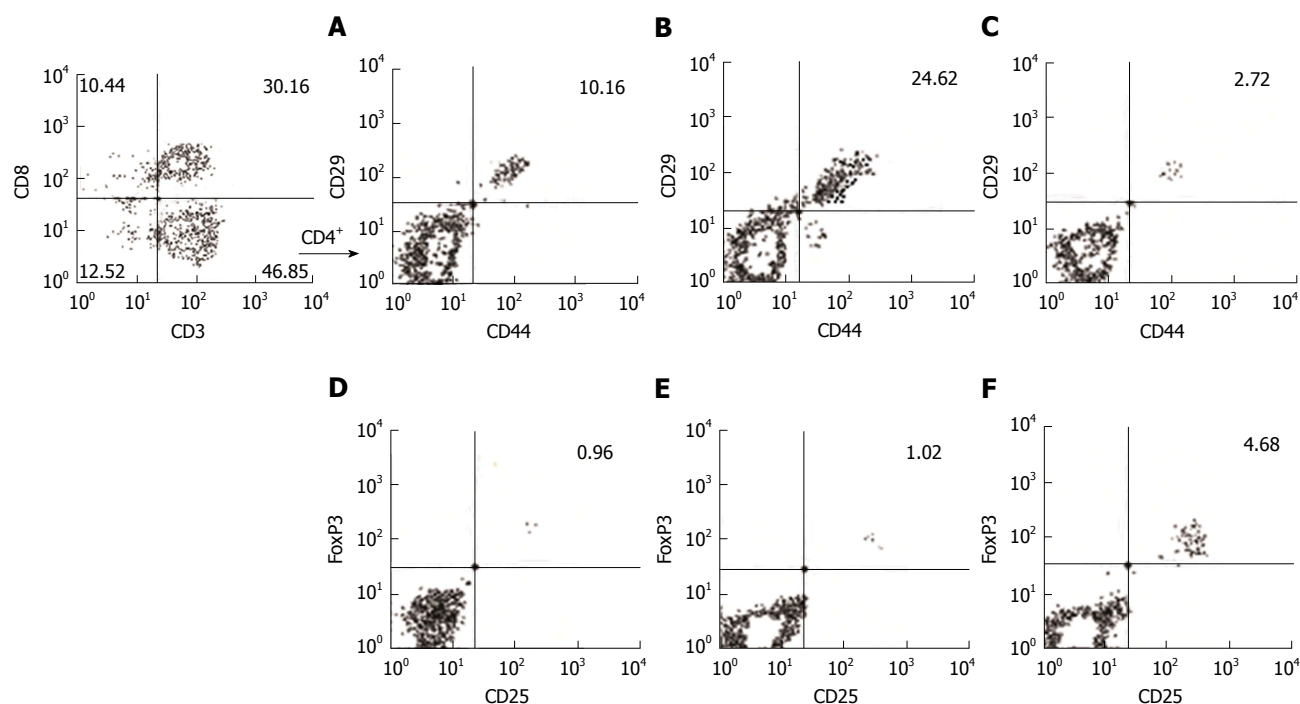

**Figure 1** Flow cytometry analysis of proliferating mononuclear cells in antigenic stimulation. Mononuclear cell populations were gated using forward (FSC) and side (SSC) scatter, and the dot plot identifies the total cells (R1 + R2), resting cells (R1) and blasts (R2). Peripheral blood mononuclear cells, either unstimulated (A and C) or stimulated with antigens (PHA, LPS or HAV Ag) (B and D), were labeled with CFSE. The histograms show the proportion of total (CFSE<sup>low</sup> + CFSE<sup>high</sup>), resting (CFSE<sup>high</sup>) and proliferating cells (CFSE<sup>low</sup>) observed using the Cyan flow cytometer and analyzed using the off-line software Summit version 6.0. CFSE: Carboxyfluorescein succinimidyl ester; PHA: Phytohemagglutinin; LPS: Lipopolysaccharide.

samples from patients with self-limited AH (8 patients diagnosed with HAV-induced hepatitis and 8 with non-viral hepatitis) and 13 samples from patients with ALF (8 patients diagnosed with HAV-induced hepatitis and 5 with non-viral hepatitis). Ten of twenty-two healthy subject samples were included in the cellular response assay.

The PBMCs from each patient were separated on a Ficoll density gradient by centrifugation (30 min at 400 g at 18 °C). The concentration of viable cells was determined by trypan blue exclusion. Samples with less than 80% of viable cells at this stage were excluded. In the proliferation assay, the PBMCs were suspended in RPMI 1640 (Sigma Aldrich, United States) medium at a concentration of  $5 \times 10^6$  cells/mL and mixed with an equal volume of 10 mmol/L carboxyfluorescein succinimidyl ester working solution (CFSE-FITC) (Molecular Probes, Invitrogen, United States) that was diluted 1/1000 for all analyses. Cells that were not labeled with CFSE were used as a negative control for the flow cytometry analysis. The mitogen inducers phytohemagglutinin (PHA) and lipopolysaccharide (LPS) (Sigma Aldrich, United States) were used at final concentrations of 10 µg/mL and 1 ng/mL, respectively, for non-viral proliferation. The HAF-203 strain of HAV was propagated in FRhK-4 cells<sup>[27]</sup> and was used for viral-antigen-specific (HAV Ag) proliferation (viral titer of  $10^6$  HAV-RNA/mL).

Duplicate proliferation cultures were performed with  $5 \times 10^5$  cells/well in 96-well flat bottom culture plates. The plates were incubated at 37 °C in a 5% CO<sub>2</sub> incubator for 72 h with PHA, 24 h with LPS and 96 h with HAV Ag. After incubation, the cells were harvested for the flow cytometry assay.

To assess the cell phenotypes and proliferative response, 20000 live cells were collected from each sample using a Cyan flow cytometer (BD Biosciences, United States) and analyzed using the off-line software Summit version 6.0 (Dako Cytomation, United States) (Figures 1 and 2). PBMCs were labeled and quantified with αCD8-PerCP (clone DK25), αCD25-PE (clone ACT1), αCD56-PE (clone CM55B), αCD16-FITC (clone DJ130c) (all from Dako Cytomation, United States), αCD3-APC (clone OKT3), αCD29-FITC (clone MEM101a), αCD44-PECy7 (clone IM7), αFoxP3-FITC (clone PCH101) and isotypes (eBiosciences, San Diego, CA, United States). The intracellular staining for FoxP3 expression was performed with a Cytofix/Cytoperm<sup>®</sup> kit (BD Biosciences, United States). Total mononuclear cells were electronically gated in R1 *plus* R2 using forward (FSC) and side (SSC) properties; cellular debris and granular cells were excluded (Figure 1A and B). The proliferating cells (R1 + R2) were defined based on their FSC and SSC properties<sup>[28]</sup>. The proliferation index (PI)

**Figure 2** Hepatitis A virus Ag-activated CD4<sup>+</sup> T cells in acute liver disease caused by hepatitis A virus. The data from three subjects selected from our study groups were used to represent the gating strategy to select CD29<sup>+</sup>CD44<sup>+</sup> and CD25<sup>+</sup>FoxP3<sup>+</sup> on CD4<sup>+</sup> cells (CD3<sup>+</sup>CD8<sup>-</sup>). Representative contour plots of the frequency of migratory T helper cells (%) in HAV Ag-activated mononuclear cells from healthy subjects (A), patients with acute hepatitis A (B), patients with acute liver failure with HAV infection (C) and in HAV Ag-activated regulatory T cells from healthy subjects (D), patients with acute hepatitis (E), and patients with acute liver failure (F). HAV: Hepatitis A virus.

was determined by the software program; this index is a measure of the frequency of cells that have gone through more than three divisions (positive proliferation, CFSE<sup>low</sup>) (Figure 1C and D)<sup>[28-30]</sup>. The final PI was determined by calculating the ratio of the average PI for mitogen- or antigen-stimulated cells divided by the average PI of unstimulated cells (Figure 1). The highly expressed surface markers on the T, NK and NKT cell subsets that were activated by antigenic stimulation (R1 + R2) were considered in the off-line software analysis (e.g., Figure 1A and B, and Figure 2). The cell culture supernatants were assayed to quantify IL-6, IL-8, IL-10, IFN $\gamma$  and TNF $\alpha$  using commercially available Standard ELISA Development kits (Peprotech, United States). Human cytokine IL-17/17A was quantified with the commercially available Mini ELISA Development kit (Peprotech, United States).

### Statistical analysis

The data are expressed as the mean  $\pm$  standard deviation (SD) at a 95%CI. The distribution of the data in the groups was initially evaluated by the Kolmogorov-Smirnov test. The correlations were evaluated using the Spearman rank correlation test (R project for Statistical Computing (<http://www.r-project.org/>)). The differences between self-limited AH, ALF, and healthy subjects were evaluated by intergroup comparisons using the Kruskal-Wallis test. If a significant difference was found, a pair of variables in the three groups was assessed with the Mann-Whitney *U*-test. For the plasma samples, receiver

operating characteristic (ROC) curve analysis was used to compare the predictive strength of markers with chance. The area under the curve was used as a measure of the ability of the test to distinguish between the two groups. The software GraphPad Prism 5 for Windows, version 5.01 (San Diego, CA, United States), was used to perform statistical ROC curve analysis. Multivariate logistic regression was applied to select the independent predictors in plasma samples associated with ALF based on cut-off points (90% specificity and with the highest likelihood ratio value) obtained from ROC curve analysis. In the initial logistic model, all variables were tested for predictive strength. The variables showing statistically significant differences were kept in the final model. The logistic regression analyses were performed using SPSS software version 17.0 for Windows (SPSS Inc., Chicago, IL, United States). The significance for all statistical analyses was defined as  $P < 0.05$ .

## RESULTS

### Characterization of the AH and ALF patients

Non-viral ALF cases were caused by  $\alpha$ -methylidopa (1 patient), rifampicin (1), and cryptogenic disease (3). The self-limited AH were caused by NSAIDs (2) and cryptogenic disease (6). HAV infection was the viral etiology found in self-limited AH (38) and ALF (11). The mean  $\pm$  SD of viral load for the HAV was  $1.4 \times 10^6 \pm 8.6 \times 10^5$  HAV-RNA/mL in plasma samples from ALF patients and  $3.6 \times 10^3 \pm 1.8 \times 10^3$  HAV-RNA/mL in

samples from AH self-limited patients (AH).

The time of blood collection in self-limited AH was 1-4 wk in the HAV-AH group and 2-6 wk in the non-viral AH group. In the ALF patient group it was 1-3 wk for HAV-ALF and non-viral ALF. Three patients with acute HAV infection, INR < 1.5 and no coma grade (HE < I) had their samples collected before the evolution to liver failure. They progressed to death before transplant, according to medical records, so they were included in the ALF group. Table 1 shows more information about the study population, including age, gender, coma grade, coagulopathy, liver enzymes, total bilirubin, and outcome.

### **Elevated plasma cytokines and mtDNA are seen in AH and ALF patients compared to healthy controls**

The intensity of the inflammatory status was not associated with etiology ( $P > 0.05$ ). Table 2 compares the systemic inflammatory parameters between clinical conditions. The cytokines IL-6, IL-8, IL-10 and IFN $\gamma$  were significantly raised in the AH and ALF patients compared to the healthy subjects. TNF $\alpha$  was also elevated in the ALF patients compared to the healthy subjects (Table 2). Similarly, total mtDNA was significantly higher in both the AH and ALF groups than in the healthy controls. ALF patients showed a significant elevation in IL-6, IL-10, IFN $\gamma$  and TNF $\alpha$  as well as high levels of mtDNA compared to the AH patients (Table 2).

### **Elevated plasma cytokines and mtDNA are positively correlated with the degree of liver damage, as represented by the presence of HE or coagulopathy**

When we evaluated the correlations between INR and

HE and the plasma cytokine and mtDNA levels, the HE grade showed significant positive correlations with IL-6 ( $P < 0.0001$ ), IL-10 ( $P < 0.0001$ ), TNF $\alpha$  ( $P = 0.0001$ ), and IL-8 ( $P = 0.0034$ ) (Supplementary Figure 1A, C, E and G). The elevated INR values showed significant positive correlations with IL-6 ( $P < 0.0001$ ), IL-10 ( $P = 0.0002$ ), TNF $\alpha$  ( $P = 0.0004$ ) and IFN $\gamma$  ( $P = 0.0057$ ) (Supplementary Figure 1B, D, F and H). A positive correlation was observed between mtDNA and HE ( $P = 0.0002$ ; Supplementary Figure 1I) as well as INR ( $P = 0.0043$ ; Supplementary Figure 1J).

### **Elevated cytokines and mtDNA are correlated with outcome in ALF**

To determine whether the plasma concentrations of the inflammatory or anti-inflammatory cytokines could be used as indicators of liver dysfunction, we used ROC curve analysis, which showed that IL-6 ( $P < 0.0001$ ), IL-10 ( $P < 0.0001$ ), TNF $\alpha$  ( $P < 0.0001$ ), and IFN $\gamma$  ( $P < 0.00104$ ) had the highest diagnostic accuracy for ALF. When we evaluated hepatocyte damage, the ROC curve showed that mtDNA ( $P = 0.0046$ ) had the highest diagnostic accuracy for ALF.

Among the cytokines, elevated IL-10 was the best indicator of ALF ( $P = 0.028$ ). Although the IL-6, IL-8, IFN $\gamma$  and TNF $\alpha$  levels had a positive correlation with hepatic encephalopathy, the association with ALF was not significant (Table 3). Elevated mtDNA ( $P < 0.0001$ ) was associated with ALF diagnosis.

Subsequently, the indicators that were associated with death were investigated in all 62 acute liver disease patients: 52 survived (AH and ALF patients) and 10 died (ALF patients). Figure 3 shows that the mtDNA ( $P$

< 0.01) and all investigated cytokines were significantly elevated in the non-surviving patients ( $P < 0.01$ ). The ROC curve analysis showed that elevated INR, IL-6, IL-8, IL-10, TNF $\alpha$ , IFN $\gamma$  and mtDNA in the plasma samples were able to discriminate survivors from non-survivors with a sensitivity and specificity above 70%. The high plasma levels of mtDNA, IL-8, IL-10 and INR were considered predictive factors for poor outcome (death) in patients with acute liver disease (Table 3). Despite the high levels of IL-6, and TNF $\alpha$ , these factors did not predict death (Figure 3 and Table 3).

### Changes in the frequency of mononuclear cell phenotypes and cytokine secretion after the clonal proliferation assay are associated with virus (HAV)-induced AH and ALF syndrome

The panel of phenotypic analyses for PBMC clonal proliferation was composed of activated and migratory T helper cells (CD4<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup>), activated and migratory cytotoxic T cells (CD8<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup>), activated NK cells [CD3<sup>+</sup>CD56<sup>low</sup>CD16<sup>+</sup> (NK<sup>dim</sup>), CD3<sup>+</sup>CD56<sup>+</sup>CD16<sup>-</sup> (NK<sup>bright</sup>)], and NKT cells (CD3<sup>+</sup>CD16<sup>+</sup>CD56<sup>+</sup>). Mitogens (PHA and LPS) and virus particles (HAV Ag) were used for non-specific and specific PBMC proliferation, respectively.

The mitogen stimulation showed a reduced frequency (anergic behavior) in all investigated phenotypes from HAV-induced hepatitis (ALF and AH patients) (Table 4). The same patients, when stimulated with HAV Ag, exhibited positive proliferation of the regulatory (CD4<sup>+</sup>CD25<sup>+</sup>FoxP3<sup>+</sup>), NKT (CD3<sup>+</sup>CD16<sup>+</sup>CD56<sup>+</sup>), and NK<sup>bright</sup> (CD3<sup>+</sup>CD56<sup>+</sup>CD16<sup>-</sup>) phenotypes, and only the helper phenotype (CD4<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup>) frequency was reduced in HAV-induced ALF patients (Figure 2). In general, the PBMCs from HAV-induced AH showed a tendency toward negative proliferation after mitogen stimulation in all analyzed phenotypes. A significant decrease was detected in the T helper and NKT cells (AH vs HC) (Table 4). The PBMCs showed a significant positive proliferation of the T helper, cytotoxic (CD8<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup>), and NKT cells with HAV-specific stimulation.

The secreted cytokines, IL-6, TNF $\alpha$ , IL-8 and IL-17, were reduced in the supernatant of HAV-induced hepatitis PBMCs from ALF patients compared to AH patients during mitogen stimulation. Additionally, IL-10 and IFN $\gamma$  were reduced in ALF patients vs the HC subjects. In patients with AH A, we observed a significant reduction in IL-6 secretion and a general tendency toward a reduced

The differences between the hepatitis A-induced acute liver failure (ALF) patients, the self-limited acute hepatitis A (AH) patients, and the healthy control (HC) subjects were evaluated by intergroup comparisons using the Mann-Whitney *U*-test. The significance cutoff for all statistical analyses was defined as *P* < 0.05. IL: Interleukin; IFNγ: Interferon gamma; TNFα: Tumor necrosis factor alpha; ns: Not significant; PI: Proliferation index.

**Figure 3** Differences in inflammatory cytokines (interleukin 6, 8 and 10, interferon gamma, and tumor necrosis factor α) and hepatocyte damage (mitochondrial DNA) parameters between the surviving and non-surviving patients. <sup>b</sup>*P* < 0.01; <sup>d</sup>*P* < 0.001. IL-6: Interleukin 6; IFNγ: Interferon gamma; TNFα: Tumor necrosis factor alpha; mtDNA: Mitochondrial DNA.

secretion of all cytokines, but there were no significant differences (Table 4).

The analysis of the secreted cytokines after HAV Ag stimulation of PBMCs from HAV-induced hepatitis patients showed reduced levels of TNFα and IL-17 when comparing the ALF and AH patients. Reduced levels of secreted TNFα were also observed in the ALF patients compared to the HC subjects. Additionally, we observed elevated levels of secreted IL-10 and IFNγ. The ALF patients presented elevated levels of secreted IL-8 compared to the HC subjects. The levels of secreted IL-10, IFNγ, IL-8 and IL-17 were elevated in cultures

from the AH patients (Table 5).

#### Changes in the frequency of mononuclear cell phenotypes and cytokine secretion after the clonal proliferation assay in non-viral-induced AH and ALF

We observed a tendency toward positive proliferation for the migratory T helper (CD4<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup>) and cytotoxic T (CD8<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup>) cells for IL-6 and IL-17 release in the ALF patients compared to the AH patients. Significant elevations of NK<sup>dim</sup> (CD3<sup>+</sup>CD56<sup>low</sup>CD16<sup>+</sup>) and NK<sup>bright</sup> (CD3<sup>+</sup>CD56<sup>+</sup>CD16<sup>-</sup>) cell frequencies were associated with high levels of TNFα in the non-viral

The differences between the hepatitis A-induced acute liver failure (ALF) patients, the self-limited acute hepatitis A (AH) patients and the healthy control (HC) subjects were evaluated by intergroup comparisons using the Mann-Whitney *U*-test. The significance cutoff for all statistical analyses was defined as *P* < 0.05. IL: Interleukin; IFNγ: Interferon gamma; TNFα: Tumor necrosis factor alpha; ns: Not significant; PI: Proliferation index.

ALF patients compared to the AH patients and the HC subjects. The IL-8 levels were also significantly elevated in the ALF patients compared to the HC subjects (Table 5). In general, the comparison between the PBMCs from non-viral AH patients and the HC subjects showed a tendency toward a negative proliferation of all phenotypes investigated and the secreted cytokines IL-6, IL-10, IFNγ and IL-17 (Table 6).

#### **Evidence of effects on the TReg and migratory T helper cells obtained from viral and non-viral AH and ALF patients**

To understand the influence of the TReg in AH and ALF, we evaluated the balance between the frequency of TReg with the innate and adaptive immune cells studied. Tables 5 and 6 reveal the change in the frequencies of TReg (CD4<sup>+</sup>CD25<sup>+</sup>FoxP3<sup>+</sup>) and migratory T helper frequencies (CD4<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup>) in viral ALF after HAV stimulation and in non-viral ALF after mitogen stimulation. Figure 4A shows an elevated TReg-to-T-helper ratio in the HAV-induced ALF patients after HAV stimulation compared to the AH patients and the HC subjects. No changes in the ratios between the TReg and the other phenotypes were observed. After mitogen stimulation, the imbalance between the TReg-to-T helper ratio was significantly reduced in the non-viral ALF patients compared to the AH patients (Figure 4B). For the other investigated phenotypes, the alterations in this

ratio were not significant.

## **DISCUSSION**

Acute viral hepatitis was represented by hepatitis A cases in our study. There are a large number of outbreaks of hepatitis A in Brazil; HAV infection is the major etiology of AH and ALF<sup>[17,31,32]</sup>. Here, we introduced plasma mtDNA level as a new predictor for HAV-induced ALF syndrome. In our opinion, the gross elevation of mtDNA in the ALF patients resulted from massive liver necrosis, as expected. mtDNA, inflammatory and anti-inflammatory cytokines and effector cells are involved in drug-induced liver failure in murine models and in patients<sup>[5,8,33]</sup>.

Increased levels of cytokines and chemokines have been observed in all ALF and non-surviving patients, as described by other authors investigating both drug- and viral-induced ALF<sup>[5,34-36]</sup>. In our study, the high levels of IL-8 and IL-10 were predictive markers of death in acute liver disease.

Additionally, the imbalance between IL-10 and IL-12 levels has been noted in HBV-induced ALF<sup>[37]</sup>, indicating an ineffective attempt to activate the anti-inflammatory pathway<sup>[38-40]</sup>. The elevated plasma levels of IL-8 that were detected in all cases of ALF are also described in patients with drug-induced ALF and are correlated with granulocyte migration into the liver parenchyma<sup>[5,41]</sup>. The elevated levels of circulating IL-6 and TNFα, also described by others<sup>[42,43]</sup>, have been related to attempts

at liver regeneration<sup>[44,45]</sup> and liver injury<sup>[46]</sup>, respectively. Therapeutic approaches targeting the clearance of inflammatory/toxic products (plasmapheresis, hemodiafiltration, and bioartificial livers) from the liver or anti-cytokine therapy are currently being considered<sup>[42,47-49]</sup> despite contradictory clinical results<sup>[50,51]</sup>.

Even though the profile of monocytes was not explored here, several studies showed the important role of these cells in association with their activation, migration to the liver, and differentiation into hepatic macrophages induced by growth-factor β and IL-10 in humans<sup>[52,53]</sup> and experimental animal models<sup>[54]</sup>. Production of the inflammatory cytokines TNF, IL1-β, IL-6, IL-8 and MCP-1 by hepatic macrophages has been associated with cytokine storm in liver injury<sup>[52,53]</sup>. These findings could explain the biological relevance of high levels of circulating IL-6, IL-8 and IL-10 in ALF patients with the worst outcomes, which were produced by activated monocytes/macrophages, by antigen presentation, and by T cell proliferation.

When we evaluated the linear correlation between coagulopathy/encephalopathy and the plasma variables studied, we observed that the INR and HE scores increased in ALF cases. mtDNA, IL-6, IL-10, IFNγ, TNFα and IL-8 were also significantly elevated and were positively correlated with the elevated INR and/or HE scores observed in severe liver disease. Thus, this study also showed that elevated mtDNA and

IL-10 are positively associated with the risk of ALF and mortality. Other authors described IL-10 as an important immunosuppressive cytokine that is released by TReg and is strongly expressed in HBV-induced acute-on-chronic liver failure<sup>[38,55,56]</sup>.

Indeed, the most puzzling fact revealed here was the anergic behavior of the PBMCs from HAV-induced AH and ALF after *in vitro* mitotic stimulation. This fact may be explained by PBMC clonal exhaustion<sup>[57-59]</sup> or may suggest that the TReg influence HAV Ag-primed PBMCs *in vivo* during AH and ALF syndrome<sup>[23]</sup>. In addition, when the TReg cells have been previously primed by a specific antigen (e.g., viral antigen), they may develop a non-specific suppressor activity, as described by others<sup>[60]</sup>.

Here, the impairment of the PBMC response was associated with liver dysfunction in patients with AH A. The high TReg cell frequencies in HAV-induced ALF and the increase in IL-10 after HAV Ag stimulation were consistent with the reduced frequency found for the Th17 migratory phenotype (CD4<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup> and IL-17 secretion) and the modulation of the T lymphocyte (CD3<sup>+</sup>) and cytotoxic T cell (CD8<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup>) phenotypes.

Our results suggest that the negative regulation of the TReg cells attempts to control liver inflammation and disease progression by reducing the Th17 migration to the liver tissue in patients with HAV-induced ALF. A similar profile of antigen-specific and unspecific stimulation was

**Figure 4** Imbalance between peripheral CD4<sup>+</sup> regulatory T cells and migratory T helper cells in viral and non-viral acute hepatitis cases. A: Comparison of the ratio of CD4<sup>+</sup> TReg-to-Thelper in HAV-induced acute liver disease (ALF and AH) and healthy controls (HC); B: Comparison of the ratio of CD4<sup>+</sup> TReg-to-Thelper cells in non-viral-induced acute liver disease (ALF and AH). <sup>a</sup>*P* < 0.05; <sup>b</sup>*P* < 0.01; <sup>d</sup>*P* < 0.001. HAV: Hepatitis A virus; AH: Acute hepatitis; ALF: Acute liver failure.

observed in patients with HEV-induced AH and ALF<sup>[59]</sup> and in chronic hepatitis B infection after anti-CD3/CD28 (unspecific) stimulation<sup>[56]</sup>. Our results did not confirm the TReg influence in non-viral ALF patients, which corroborates other results<sup>[61-63]</sup>. The expansion of T helper cells (Th17) and the suppression TReg cell production are involved in the mechanisms of liver damage in drug-induced liver disease<sup>[61,63]</sup>.

In HAV-AH, T helper cell proliferation was increased after HAV Ag stimulation and was reduced after mitogen stimulation. The scarce literature available describes defects in cell signaling in CD4<sup>+</sup> T cells that are secondary to ALF<sup>[59]</sup>. Other authors reported that an increase in TReg cells and a decrease in Th17 cells are associated with the survival of HBV-related acute-on-chronic liver failure patients<sup>[56]</sup>, although contradictory opinions have been reported<sup>[38,64]</sup>. In our study, a similar profile was exhibited by migratory cytotoxic T cells (CD8<sup>+</sup>CD29<sup>+</sup>CD44<sup>+</sup>) for both antigens (viral and mitogen) in HAV-induced AH and ALF. Impaired proliferation was also demonstrated with HEV Ag (pORF3), which was dependent on ERK activation (a member of mitogen-activated protein kinase) and involved in cell proliferation through the TCR/CD3 complex<sup>[65]</sup>.

A linear reduction of NK<sup>bright</sup>, NK<sup>dim</sup> and NKT cell reactivity occurred after mitogen stimulation in patients with HAV-induced AH and ALF, which was reversed

by HAV Ag-stimulation. The loss of NK<sup>dim</sup> reactivity in our ALF patients corroborated the suppressor function of the TReg cells, as described above, which appears to modulate the NK-mediated liver injury. A marked elevation in the frequency of NK<sup>bright</sup> and NKT cells in patients with HAV-induced ALF reinforces the importance of these cells in liver injury<sup>[19,66-69]</sup>.

The significant reduction in the secreted TNF $\alpha$  levels following the HAV Ag-stimulation of patients with HAV-induced AH and ALF shown here was also observed by other authors in HEV-induced AH and ALF<sup>[59]</sup>. However, TNF $\alpha$ , IL-17 and T helper cell reactivity are positively correlated with the progression to chronic liver disease and acute-on-chronic liver failure in hepatitis B infection<sup>[39,64]</sup>. In addition, Zhou *et al.*<sup>[70]</sup> (2012) observed a reduced frequency of the CD4<sup>+</sup>IL-2<sup>+</sup>IFN $\gamma$ <sup>+</sup>TNF<sup>+</sup> population after resolution of hepatitis A, suggesting an increased risk of hepatitis relapse. We observed that the frequency of T cells was not reduced in mitogen stimulated non-viral-induced AH and ALF. The NK<sup>bright</sup> and NK<sup>dim</sup> cells with TNF $\alpha$  and IL-8 secretion were significantly elevated in patients with ALF compared to patients with AH and the HC subjects, as expected. The literature describes that the NK cells have an important role in liver damage during non-viral-induced liver diseases and contribute to ALF progression<sup>[7,33]</sup>.

The relative weaknesses of our study included the variance in the plasma cytokine levels, the age of the patients, and the timing of sampling during the evolution of the disease. To minimize the effect of time on our analysis, the blood collection was performed considering the clinical manifestations in self-limited AH and the time of liver failure diagnosis and hospital admission for ALF patients. The sample size was small because the participants who were in the acute symptomatic phase (including pain and malaise) had to agree to the collection of additional samples for cellular immune response investigation; many patients did not return to the ambulatory clinic after resolution of their infection, hindering longitudinal assessment.

In conclusion, The increase of systemically released inflammatory and anti-inflammatory products is associated with AH and ALF. mtDNA and IL-10 may be useful clinical markers as part of a panel to indicate viral (HAV) and non-viral liver disease outcome. These markers, along with IL-8, may be useful to predict death. The anergic behavior of mononuclear cells in fulminant hepatitis A may, in part, be a consequence of the predominant TReg influence that is exclusively detected in HAV infection. Taken together, our results provide additional information to understand the complex immunological disturbances presented during ALF syndrome. Additional efforts are necessary to clarify the anergy mechanism in HAV infection.

## ACKNOWLEDGMENTS

The authors thank the blood donors and patients who

participated in this study, and Renata Tourinho for standardizing the molecular assay for detecting the HAV-RNA in biological samples.

## COMMENTS

### Background

The immune response can induce gross inflammation and consequently liver damage in acute liver diseases, independently of etiology. The role of immune cells in inducing acute liver failure (ALF) in hepatitis A infection is still unknown. High levels of systemic inflammatory products and *in vitro* immune response can be helpful markers to evaluate the necessity for liver transplantation, mainly in hepatitis A patients. Additionally, to minimize the effects of liver failure caused by hepatitis A, universal vaccination should be improved in developing countries such as Brazil.

### Research frontiers

Circulating cytokines have been associated with liver failure. Imbalance between peripheral regulatory T cells and helper T cells has been correlated with the worst outcome in hepatitis B-induced liver failure, a disease preventable by vaccination.

### Innovations and breakthroughs

This is the first study evaluating biological markers to show the necessity of liver transplantation, particularly in hepatitis A patients. The role of antigen-specific T cells during ALF caused by hepatitis A virus was investigated in a pioneering way in comparison to non-viral etiologies.

### Applications

Non-invasive samples as early prognostic markers are urgently needed to determine the necessity of liver transplantation. These findings can be helpful to highlight the development of facilities for laboratory diagnostics in acute liver diseases progression. This study supports the mass vaccination against hepatitis A in developing countries.

### Peer-review

The authors describe interesting findings in the circulating cytokines, mitochondrial damage and cell proliferation when comparing different clinical statuses in acute liver diseases (self-limited acute hepatitis and ALF) and healthy controls. The correlation of these factors with the severity of liver disease and outcome is also interesting. This study evaluated accurate markers to predict the necessity for liver transplantation, which is very important for guiding clinical work. Data from T cells in the hepatitis A cohort with liver failure, as the authors note, have not been reported.

## Retrospective Study

# Systemic-to-pulmonary artery pressure ratio as a predictor of patient outcome following liver transplantation

Annette Rebel, Dung Nguyen, Brooke Bauer, Paul A Sloan, Amy DiLorenzo, Zaki-Udin Hassan

Annette Rebel, Dung Nguyen, Brooke Bauer, Paul A Sloan, Amy DiLorenzo, Zaki-Udin Hassan, Department of Anesthesiology and Surgery, Medical Center N 202, University of Kentucky, Lexington, KY 40536, United States

**Author contributions:** Rebel A and Bauer B collected and analyzed the data, and drafted the manuscript; Nguyen D, Sloan PA, DiLorenzo A and Hassan ZU provided analytical oversight and supervised the study; all authors contributed and revised the manuscript for importance; all authors have read and approved the final version to be published.

**Institutional review board statement:** The need for informed consent of study participants was waived by the Institutional Review Board since the de-identified data review demonstrated minimal risk to patient population.

**Informed consent statement:** The need for informed consent of study participants was waived by the Institutional Review Board.

**Conflict-of-interest statement:** The authors have no conflict of interest to report.

**Data sharing statement:** Technical appendix, statistical code, and dataset are available from the corresponding author at arebe2@email.uky.edu.

**Open-Access:** This article is an open-access article which was selected by an in-house editor and fully peer-reviewed by external reviewers. ## Abstract

### AIM

To assess the value of the mean systemic-to-pulmonary artery pressure (MAP/mPAP) ratio for predicting outcomes following orthotopic liver transplant (OLT).

### METHODS

A retrospective data analysis was performed and data (mean arterial blood pressure, mean pulmonary artery pressure and Cardiac Index) were collected at several points during OLT. Outcomes evaluated were duration of postoperative endotracheal intubation [ET; minutes after intensive care unit (ICU) arrival], length of ICU stay, total hospitalization and frequency of immediate postoperative complications. A total of 91 patients were included in the data analysis. Based on the intraoperative course of the MAP/mPAP ratio, 2 hemodynamic responses were identified: Group 1 (MAP/mPAP ratio increase during anhepatic period with postreperfusion recovery,  $n = 66$ ); and Group 2 (MAP/mPAP ratio with no change during anhepatic period or decreased without recovery,  $n = 25$ ).

### RESULTS

The main finding was that the lack of increased MAP/mPAP ratio in the anhepatic period was associated with: (1) longer intubation times; and (2) prolonged ICU

stays and total hospitalization time, when compared to patients with an increase in MAP/mPAP ratio during the anhepatic period.

### CONCLUSION

The data from this retrospective study should raise awareness to the mean systemic to pulmonary artery pressure ratio as a potential indicator for poor outcome after OLT. Further prospective studies are needed for validation.

**Core tip:** The aim of this study was to assess the value of the mean systemic-to-pulmonary artery pressure (MAP/mPAP) ratio for predicting outcomes following orthotopic liver transplant. The intraoperative pattern of this ratio has not been previously described. Performing a retrospective analysis we identified 2 different MAP/mPAP patterns: Group 1 (MAP/mPAP ratio increase during anhepatic period with postreperfusion recovery,  $n = 66$ ); and Group 2 (MAP/mPAP ratio with no change during anhepatic period or decreased without recovery,  $n = 25$ ). The main finding was that the lack of increased MAP/mPAP ratio in the anhepatic period was associated with longer intubation times, and prolonged hospitalization time.

### INTRODUCTION

The mean systemic-to-pulmonary artery pressure ratio (MAP/mPAP) has been shown to be a valuable predictor of outcomes following cardiac surgery. Previous studies documented that the MAP/mPAP ratio was easy to obtain during cardiac surgery, and correlated with the development of pulmonary hypertension and diastolic dysfunction<sup>[1-4]</sup>. Outcomes following orthotopic liver transplant (OLT) are dependent on the ability of the patient's cardiovascular system to compensate for the physiological stress related to OLT. While detailed and expensive cardiac evaluation is routinely performed on patients before OLT, the extent of cirrhotic cardiomyopathy and biventricular dysfunction is often underestimated<sup>[5,6]</sup>. Intraoperatively, due to circumstances related to advanced multi-organ disease, limited cardiac reserve and procedural related stressors including blood loss, fluid shifts, acidosis, or hypothermia,

the patient may present more hemodynamic challenges than anticipated<sup>[7]</sup>.

The MAP/mPAP ratio as a predictor of patient outcome following OLT has not been investigated. We hypothesized that the pattern of the MAP/mPAP ratio during the different stages of OLT may predict the ability of the circulatory system to compensate for the surgery related stress. If the MAP/mPAP pattern indicates sufficient cardiac reserve, the patient should have a better outcome than patients with a MAP/mPAP ratio that is less favorable. In order to more reliably risk stratify these patients undergoing OLT, we performed a retrospective data analysis to explore the feasibility of obtaining useable data during OLT. With desirable outcomes defined as less morbidity/mortality, decreased need for mechanical ventilation and shorter length of stay, the aim of this study was to assess the value of the MAP/mPAP ratio for predicting desirable outcomes following OLT.

### MATERIALS AND METHODS

The Institutional Review Board (IRB) reviewed the study protocol and gave approval access to an institutional database to retrieve patient information. The IRB waived the need for informed consent since the de-identified data review demonstrated minimal risk to patient population.

The retrospective data analysis was performed on patients undergoing OLT for end-stage liver disease in the time period from October 2011 through October 2014 at a single University Hospital. All patients undergoing OLT during this time period regardless of underlying liver disease, model for end-stage liver disease (MELD) score and age were included. Exclusion criteria were patients undergoing OLT as a combined procedure with kidney transplant, redo-OLT or OLT as a treatment for acute liver failure. Patient records with incomplete intraoperative information were excluded from the data analysis.

The selected time period was based on the absence of changes in surgical approach or staff (transplant surgeon/anesthesiology). All patients underwent cardiac evaluation with transthoracic echocardiography prior to listing for liver transplant. None of the included patients were diagnosed with or had signs of pulmonary hypertension prior to OLT.

All OLT were performed using the end-to-end inferior vena cava (IVC) anastomosis technique requiring total IVC cross-clamp during the anhepatic period. Using this technique, the anhepatic period was less than 60 min for all OLTs in this study period. Intraoperative anesthesia care for all patients followed a standardized protocol for anesthesia induction, intravenous access, monitoring and vasoactive medications. All patients remained intubated at the conclusion of their surgical procedure and were transported to a dedicated intensive care unit (ICU) for anesthesia emergence and recovery.

Patient demographic data were collected including preoperative creatinine level, comorbidities, MELD score,

**Table 1 Patient demographics and surgical characteristics**

	Age (yr)	Gender (F:M ratio)	MELD (score)	OR duration (min)	Crystalloid (mL)	Colloid (mL)	PRBC (units)	FFP (units)
Group 1 ( <i>n</i> = 66)	55.6 ± 8.6	24:42 (36%)	18.7 ± 8.4	400.9 ± 43.5	5804 ± 2824	1440 ± 972	3.3 ± 3.7	2.8 ± 3.0
Group 2 ( <i>n</i> = 25)	58.9 ± 5.4	7:18 (28%)	16.3 ± 6.9	427.9 ± 63.3	6086 ± 3424	1607 ± 626	3.9 ± 3.1	4.0 ± 4.6
<i>P</i> -value	0.081	0.189	0.204	0.081	0.690	0.428	0.473	0.148

Data are shown as mean ± SD. *P* value was obtained using paired *t*-test for all parameters except gender. The 1-tail exact binomial calculation with probability value of 0.5. Group 1 (*n* = 66): Patients with MAP/mPAP ratio increase during anhepatic period; Group 2 (*n* = 25): Patients with MAP/mPAP ratio decrease or no change during anhepatic period. MELD: Model For End-Stage Liver Disease score; OR duration: Anesthesia time from induction to ICU transfer; Crystalloid: Amount of intraoperative normal saline; Colloid: Amount of intraoperative 5% Albumin; PRBC: Packed red blood concentrate; FFP: Fresh frozen plasma; MAP/mPAP: Mean systemic-to-pulmonary artery pressure.

age and gender. Basic intraoperative information such as procedure time, intraoperative intravenous fluids and blood component therapy were extracted from the surgical records. During the retrospective chart review, the following intraoperative hemodynamic data were gathered: Mean arterial blood pressure, mean pulmonary artery pressure and Cardiac Index (CI). These hemodynamic parameters were collected at several time points during the surgical procedure: Baseline (30 min after incision), pre-anhepatic (1 h before IVC cross-clamp), anhepatic (15 min before reperfusion), neo-hepatic (15 min after reperfusion), and 1 h neo-hepatic (1 h after reperfusion).

#### MAP/mPAP patterns

Based on pilot observations, the MAP/mPAP ratio was expected to increase during the anhepatic phase. During the data analysis, patients indicating an increase in MAP/mPAP ratio by  $\geq 1$  from baseline to anhepatic phase were categorized into Group 1. Patients showing a decrease in MAP/mPAP ratio of  $\geq -1$  or no change ( $< 1$  to  $> -1$ ) from baseline to anhepatic phase were categorized into Group 2. We chose the anhepatic period as comparison to the baseline value because this surgical stage is characterized by a single hemodynamic alteration (preload reduction) and for a prolonged duration. In our institution, the anhepatic period is approximately 45-55 min. Therefore, all patients received a similar type of cardiac stress. To account for fluctuations in this anhepatic period we chose a measurement point at 15 min before reperfusion (IVC cross-clamp release) to allow sufficient equilibration time for reduction in cardiac preload caused by the IVC flow interruption.

#### Vasopressor use

Further chart review was performed regarding the use of vasoactive agents in the anhepatic phase of the operation. The following medications are available intraoperatively: Norepinephrine (NE), Epinephrine (EPI), Vasopressin (V), Dopamine (DOP) and Phenylephrine (PHE). Intraoperative documentation allowed the investigators to identify the frequency and dosing of vasoactive medication at 30 to 15 min before reperfusion (anhepatic measurement of MAP/mPAP ratio). The patients were sorted into three categories: No vasoactive medication use, low dose vasoactive medication use (NE

$< 0.05$   $\mu\text{g/kg}$  per minute, EPI  $< 0.03$   $\mu\text{g/kg}$  per minute, V  $< 0.03$  units/min, or PHE  $< 0.1$   $\mu\text{g/kg}$  per minute) and high dose vasoactive medication use (NE  $\geq 0.05$   $\mu\text{g/kg}$  per minute, EPI  $\geq 0.03$   $\mu\text{g/kg}$  per minute, V  $\geq 0.03$  units/min or any vasopressor combination).

#### Outcomes

The patient outcomes evaluated were duration of post-operative endotracheal intubation (ET, minutes after ICU arrival), length of ICU stay (LOS ICU, days post OLT) and length of hospital stay (LOS Total, days post OLT to hospital discharge). Postoperative complications were recorded if they occurred in the first 14 postoperative days after OLT. The frequency of reintubation within 48 h post extubation, need for renal replacement therapy and the need for ICU readmission were recorded. Mortality  $< 1$  mo post OLT was also recorded.

Data is reported as mean ± SD. Statistical analysis was performed by the paired *t*-test or  $\chi^2$  test. A *P* value of  $< 0.05$  was used to identify statistical significance.

## RESULTS

A total of 100 patients were included in the study. Due to incomplete data recordings, 9 patients were excluded from data analysis. Thus, data from a total of 91 patients was included in this analysis. The demographic patient characteristics and characterization of intraoperative course are shown in Table 1. Age, gender and MELD scores were equally distributed in both groups. The most common causes for end-stage liver disease in our patient collective were Hepatitis C related liver cirrhosis (48 patients, Group 1: 35 patients; Group 2: 13 patients), NASH related cirrhosis (21 patients, Group 1: 16 patients; Group 2: 5 patients) and alcohol induced liver cirrhosis (25 patients, Group 1: 16 patients; Group 2: 9 patients). Primary sclerosing cholangitis related liver cirrhosis was the leading diagnosis in 5 patients (all in Group 1). Other rare OLT indications were autoimmune hepatitis or alpha-trypsin 2 deficiency (one patient each, all Group 1). Two patients had hepato-pulmonary syndrome prior to OLT (both in Group 1).

Pre-OLT Creatinine was not different between the two groups (Group 1:  $1.26 \pm 0.67$  mg/dL, Group 2:  $1.30 \pm 0.82$  mg/dL). There were no significant differences in surgical duration, fluid requirements or use of blood

**Table 2** Mean systemic-to-pulmonary artery pressure ratio and cardiac index, measured at several times during the liver transplant: Baseline (30 min after incision), preanhepatic (1 h before inferior vena cava cross-clamp), anhepatic (15 min before reperfusion), neohepatic (15 min after reperfusion), and 1 h neohepatic (1 h after reperfusion)

	Group 1 MAP/mPAP increase during anhepatic period ( <i>n</i> = 66)	Group 2 MAP/mPAP no change or decrease during anhepatic period ( <i>n</i> = 25)	<i>P</i> -value

% change is calculated as difference from value to baseline value; data are shown as mean ± SD, and median value for ET and LOS. *P* value was obtained using paired *t*-test. <sup>a</sup>*P* < 0.05. ET (duration of postoperative endotracheal intubation): Minutes from ICU arrival to extubation to supplemental oxygen; LOS ICU: Length of stay in intensive care unit; LOS total: Time from ICU arrival to hospital discharge; MAP/mPAP: Mean systemic-to-pulmonary artery pressure ratio; CI: Cardiac index.

**Figure 1** Mean systemic-to-pulmonary artery pressure ratio. MAP/mPAP = Mean systemic-to-pulmonary artery pressure ratio, measured at several times during the liver transplant: Baseline (30 min after incision), preanhepatic (1 h before IVC cross-clamp), anhepatic (15 min before reperfusion), neohepatic (15 min after reperfusion), and 1 h neohepatic (1 h after reperfusion). Group 1 (*n* = 66): Patients with MAP/mPAP ratio increase during anhepatic period; Group 2 (*n* = 25): Patients with MAP/mPAP ratio decrease or no change during anhepatic period. Data are shown as mean ± SD. *P* value was obtained using paired *t*-test. IVC: Inferior vena cava; MAP/mPAP: Mean systemic-to-pulmonary artery pressure.

component therapy between the patient collectives (Table 1).

The intraoperative MAP/mPAP values for each group at the different measurement points are shown in Figure 1. MAP/mPAP values at baseline and at the prean-

hepatic period were slightly higher in Group 2 than in Group 1 (Table 2). However, the difference was not statistically significant. Patients in Group 1 demonstrated a significant increase in MAP/mPAP during the anhepatic period. The MAP/mPAP ratio pattern in Group 2 showed less variability throughout the surgical procedure (Figure 1). The analysis of the absolute MAP/mPAP values indicated that MAP/mPAP recovered to baseline range after reperfusion in both groups. However, the percent change of MAP/mPAP ratio at baseline to the different measurement points indicated that MAP/mPAP recovered to baseline after reperfusion in Group 1. The percent change of MAP/mPAP ratio was significantly decreased in Group 2 after reperfusion, lasting up to 1 h post reperfusion (Table 2). In Group 1 the MAP/mPAP ratio increased by 2.9 ± 1.8 during the anhepatic period, while MAP/mPAP ratio in Group 2 only changed by 0.1 ± 1.1 at this observation point. CI measurements did not parallel the hemodynamic patterns shown by the MAP/mPAP ratio (Table 2). There were no significant changes in CI between both groups at any observation points during the surgical procedure.

The majority of patients required vasoactive medication during the anhepatic phase and the presence of these medications may have influenced the hemodynamic measurements at the anhepatic measurement point (Table 3). Approximately 80% of patients in both groups received some vasopressor assistance during the anhepatic phase. Phenylephrine, Vasopressin and Norepinephrine were the most commonly used vaso-pressors. While approximately half of patients required some low-dose vasoactive medication, the frequency

**Table 3** Vasopressor use

Vasopressor use frequency	Group 1 MAP/mPAP increase during anhepatic period ( <i>n</i> = 66)	Group 2 MAP/mPAP no change or decrease during anhepatic period ( <i>n</i> = 25)	<i>P</i> -value
No vasopressor use	14	5	0.624
Low dose vasopressor use	39	12	0.341
High dose vasopressor use	13	8	0.214

Following medications are intraoperatively available: Norepinephrine (NE), Epinephrine (EPI), Vasopressin (V), Dopamine or Phenylephrine (PHE). Based on intraoperative documentation at 15 min before reperfusion (anhepatic measurement of MAP/mPAP ratio). The patients were sorted into three different categories: No vasoactive medication use; low dose vasoactive medication use (NE < 0.05 mcg/kg per minute or EPI < 0.03 mcg/kg per minute or V < 0.03 units/min or PHE < 0.1 µg/kg per minute) and high dose vasoactive medication use (NE ≥ 0.05 µg/kg per minute, EPI ≥ 0.03 µg/kg per minute, V ≥ 0.03 units/min or any vasopressor combination). Data are shown as patient number receiving vasopressor therapy at the anhepatic measurement point (15 min before reperfusion). *P* value was obtained using  $\chi^2$  test. A *P*-value for < 0.05 was set for statistical significance. MAP/mPAP: Mean systemic-to-pulmonary artery pressure.

and severity of vasopressor support was not different between Group 1 and 2.

There were significant differences in duration of postoperative intubation, length of stay in the ICU and length of hospital stay between Group 1 and Group 2 (Table 2). Patients in Group 1 extubated on an average of 12 h earlier than the patients in Group 2 (16.1 ± 22.7 h vs 28.7 ± 32.2 h, respectively; *P* = 0.04). The duration of ICU stay was reduced by almost 8 d (Group 1: 3.9 ± 4.4 d, Group 2: 12.1 ± 19.2; *P* < 0.01). Total length of hospitalization was approximately 2 wk less in Group 1 than in Group 2 (12.0 ± 12.5 d vs 26.3 ± 33.2 d, respectively; *P* < 0.01).

In the immediate post OLT period (up to 30 d postoperatively) no mortality was reported in either group. In Group 1 four out of 66 patients (6%) required reintubation and five out of 66 patients (8%) received RRT; no other complications were reported in this group. In Group 2 three out of 25 patients (12%) required reintubation and seven out of 25 patients (28%) received RRT post OLT. One patient was readmitted to ICU and one patient developed seizures.

## DISCUSSION

The main finding of this study was that despite having similar preoperative pathophysiology, one quarter of patients undergoing OLT did not display the expected increase of MAP/mPAP ratio during the anhepatic phase. This lack of increased MAP/mPAP ratio in the anhepatic period by > 1 compared to baseline values was associated with: (1) longer duration of postoperative intubation; and (2) prolonged ICU stay and total hospitalization time when compared to patients with an increase in MAP/mPAP ratio during the anhepatic period. The changes in MAP/mPAP ratio were not mirrored by CI, thus the intraoperative pattern of MAP/mPAP may be predictive of patient clinical outcomes after liver transplantation. To our knowledge, this is the first study to describe the intraoperative pattern of MAP/mPAP ratio during liver transplant and its possible relationship with patient

outcomes following OLT.

Advanced liver disease has been known to affect other organ functions, most importantly the cardiovascular and renal systems<sup>[8,9]</sup>. The connection between liver cirrhosis and cardiac dysfunction has been previously recognized<sup>[8,10-12]</sup> as recent studies have documented that cirrhosis is associated with biventricular systolic dysfunction<sup>[5,6]</sup>. It is standard practice for patients to undergo an extensive preoperative cardiac evaluation to risk stratify them prior to listing for liver transplantation. The echocardiographic assessment and stress testing is usually centered on left ventricular function. While right ventricular systolic pressure and or Tricuspid annular plane systolic excursion is usually measured to evaluate the patient for right heart function and pulmonary hypertension; neither of these parameters correlates well with right systolic function<sup>[5]</sup>. Advanced echocardiography techniques (strain analysis/right ventricle relative area change) are rarely included in the standard pre OLT echocardiography assessment<sup>[5,13]</sup>.

Cardiologists commonly use the MAP/mPAP ratio to stratify the severity of pulmonary hypertension because it describes the close relationship between systemic and pulmonary circulations<sup>[14]</sup>. Preoperative value of MAP/mPAP < 4 would be of concern for cardiologists for possible pulmonary hypertension, and MAP/mPAP values < 4 have been correlated with lower survival rates after cardiac surgery<sup>[2,15]</sup>. We used the MAP/mPAP ratio in this study to assess its value to predict outcomes after liver transplantation, since this parameter has shown to be a useful predictor of hemodynamic complications after cardiac surgery<sup>[2]</sup>. Our data confirm the previous findings of the use of MAP/mPAP to identify patients at risk for adverse events after high-risk surgery. In this study, the intraoperative hemodynamic MAP/mPAP pattern of patients undergoing OLT indicated that an increase in MAP/mPAP during the anhepatic phase is associated with better outcomes. A novelty of this report is the analysis of the MAP/mPAP ratio intraoperative pattern and correlating it with postoperative outcomes.

While our reported data are truly observational, it is

not well established what significance the MAP/mPAP ratio represents, especially in patients with advanced liver disease. Cardiologists have set a normal value of  $> 4$ <sup>[14]</sup>. The observation that the majority of the included patients in our study had values  $< 4$  in absence of pulmonary hypertension may be due to advanced liver disease or the effect of anesthetic medications, since the baseline measurements were taken post induction of anesthesia. Previous studies indicated only minor effect of anesthesia on the MAP/mPAP ratio<sup>[2]</sup>. However, patients with advanced liver disease may have lower numbers due to systemic vasodilation and may have an exaggerated vascular response to anesthetics.

A recent study from Bushyhead *et al.*<sup>[16]</sup> investigated preoperative data of liver transplant recipients and found that the pulmonary artery systolic pressure correlates with posttransplant outcome and therefore emphasized the importance of right ventricular assessment and pulmonary vascular resistance for the morbidity and mortality associated with the procedure. However, the publication did not assess the value of the MAP/mPAP ratio for preoperative risk stratification. While our study did not obtain preoperative MAP/mPAP values prior to anesthesia induction and did not include patients with pre-existing pulmonary hypertension defined by elevated pulmonary artery pressures, the findings of our study support the need for more thorough assessment of right heart function and cardiac reserve prior to liver transplantation. With the scarcity of acceptable donor organs, the best surgical candidate with the least likelihood for postoperative complication needs to be identified. Including MAP/mPAP ratio into the preoperative assessment may provide useful information.

Minimizing the importance of a single measurement and focusing on the intraoperative patterns of the MAP/mPAP ratio, the trend of the parameter may be interpreted as an indication of contractility reserve. The hemodynamic hallmark of the anhepatic phase during liver transplantation is characterized by significant reduction in IVC flow and therefore blood return to the heart. The behavior of MAP/mPAP ratio during the anhepatic phase therefore may indicate the systemic and pulmonary circulatory response during reduced cardiac preload. An increase in MAP/mPAP ratio may suggest that circulatory systems are able to adjust to stress and hypovolemia by vasoconstriction and inotropic compensation. Therefore, the ability to increase the MAP/mPAP ratio in the anhepatic phase observed in Group 1 indicates better cardiovascular reserve than the lack of increase or decrease as observed in Group 2.

We chose to use the MAP/mPAP ratio difference between baseline and anhepatic phase because the anhepatic stage primarily represents a single hemodynamic alteration (preload reduction). Therefore, all patients received a similar type of cardiac stress and the MAP/mPAP ratio may be more representative for the cardiac ability to compensate for the preload reduction. Although hepatic reperfusion can cause significant cardiac

strain, the cardiac response to reperfusion depends on multiple factors and some of them may be due to the donor organ. The duration of reperfusion is usually short and therefore changes in MAP/mPAP may be not reflecting the cardiac response to the changes in preload, cardiac contractility or afterload. Our study used single MAP/mPAP ratio measurements at predetermined measurement point representing the hemodynamic situation during the surgical stage. Due to the fluctuating nature of all hemodynamic parameters during OLT, a continuous assessment of MAP/mPAP ratio throughout the entire surgical procedure may be more desirable in future studies to describe the cardiac reserve.

In our study, vasoactive medications were not controlled during the surgical procedure, and were titrated to effect by the anesthesia provider to ensure hemodynamic stability. Variable doses of vasoactive medications were given in both study groups. However, drug selection and dosing did not appear to influence the MAP/mPAP pattern since there were no statistical differences in distribution between both groups.

In previous studies on cardiac patients without pre-existing pulmonary hypertension, a low MAP/mPAP ratio was found to be an independent predictor of difficult separation of cardiopulmonary bypass and right heart failure<sup>[2,17]</sup>. Robitaille *et al.*<sup>[2]</sup> found that patients with lower MAP/mPAP ratios had more hemodynamic complications after cardiac surgery defined as cardiac arrest, vasopressor therapy  $> 24$  h postop, and/or use of intra-aortic balloon pump postop. These findings are in agreement with our interpretation of MAP/mPAP ratio as a predictor of the ability of the cardiovascular system to provide hemodynamic compensation. If a MAP/mPAP increase during the anhepatic phase is interpreted as a positive cardiovascular response to stressors, the lack of such compensation would explain why the patients without such a response would have less favorable outcomes.

Robitaille *et al.*<sup>[2]</sup> correlated the preoperative MAP/mPAP ratio with surgical outcome after cardiac surgery and reported that the preoperative MAP/mPAP ratio was significantly higher in survivors ( $3.9 \pm 1.4$ ) than in those who died ( $3.2 \pm 1.4$ ). Since the surgical procedure during liver transplantation has more complexity and varying hemodynamic challenges specific to each surgical phase, we chose (per expert consensus) observation points to describe the MAP/mPAP pattern throughout different surgical stages of the procedure. Our pattern analysis confirms the findings of the single preoperative measurement in the previous study<sup>[2]</sup>. However, our observation and current understanding of the ratio is that it is not a static parameter and, per our data, large ratio fluctuations can occur and should alert the clinician to initiate an adjustment in the treatment plan.

Our study has several limitations. First, all data was gathered as a retrospective study from only one institution without randomization or blinding. The normal hemodynamic response was defined by the authors

based on preliminary observations and understanding of hemodynamic response to the IVC flow alterations during the anhepatic phase. However, this categorization may be oversimplified to demonstrate the variety of possible dynamic responses in the anhepatic period. The study was also limited by data analysis. The data was not measured continuously, as we selected the ratio of mean systemic to pulmonary artery pressure at defined time points during the liver transplant. Our endpoint data (time to extubation in ICU, LOS ICU, *etc.*) could have also been affected by variability in ICU provider practice. Certain providers may not have been as aggressive as other providers in extubating patients. In addition, there are other factors that affect duration of endotracheal intubation, such as failure to extubate due to opioid induced apnea. All these variables are not factored into this study.

If future prospective trials confirm the value of intra-operative MAP/mPAP ratio patterns for postoperative outcome prediction, the question will arise if MAP/mPAP ratio manipulation may be able to alter the outcome after major surgery. Increasing MAP with vasopressor/inotropic medications or lowering mPAP with pulmonary vasodilators could be beneficial.

In conclusion, the data of this retrospective study raises awareness of the mean systemic to mean pulmonary artery pressure ratio during surgery as a potential indicator for poor patient outcome following OLT. To further delineate the significance of this parameter, a multi-center, randomized, blinded prospective study with more frequent measurement points is needed for validation.

## ACKNOWLEDGMENTS

The project was presented in part at the Annual Meeting of the International Anesthesia Research Society in May, 2016.

## COMMENTS

### Background

This study provides relevant information to identify patients at risk for complications after orthotopic liver transplantation.

### Research frontiers

With the scarcity of available livers for transplantation, it is crucial that patients are properly selected and every effort is made to have the best possible outcome after the procedure.

### Innovations and breakthroughs

The study is offering useful information for patient selection; the next step would be (after validation) to assess if intraoperative manipulation of this parameter would optimize patient outcomes.

### Applications

This study should be of interest to any care provider involved with the care of potential liver transplant recipients.

### Peer-review

Rebel *et al* described that the systemic to pulmonary artery pressure ratio can

be a predictor of survival after liver transplantation.

## Abstract

### AIM

To investigate the diagnostic ability of a non-invasive biological marker to predict liver fibrosis in hepatitis C genotype 4 patients with high accuracy.

## METHODS

A cohort of 332 patients infected with hepatitis C genotype 4 was included in this cross-sectional study. Fasting plasma glucose, insulin, C-peptide, and angiotensin-converting enzyme serum levels were measured. Insulin resistance was mathematically calculated using the homeostasis model of insulin resistance (HOMA-IR).

## RESULTS

Fibrosis stages were distributed based on Metavir score as follows: F0 = 43, F1 = 136, F2 = 64, F3 = 45 and F4 = 44. Statistical analysis relied upon reclassification of fibrosis stages into mild fibrosis (F0-F1) = 179, moderate fibrosis (F2) = 64, and advanced fibrosis (F3-F4) = 89. Univariate analysis indicated that age, log aspartate amino transaminase, log HOMA-IR and log platelet count were independent predictors of liver fibrosis stage ( $P < 0.0001$ ). A stepwise multivariate discriminant functional analysis was used to drive a discriminative model for liver fibrosis. Our index used cut-off values of  $\geq 0.86$  and  $\leq -0.31$  to diagnose advanced and mild fibrosis, respectively, with receiving operating characteristics of 0.91 and 0.88, respectively. The sensitivity, specificity, positive predictive value, negative predictive value and positive likelihood ratio were: 73%, 91%, 75%, 90% and 8.0 respectively for advanced fibrosis, and 67%, 88%, 84%, 70% and 4.9, respectively, for mild fibrosis.

## CONCLUSION

Our predictive model is easily available and reproducible, and predicted liver fibrosis with acceptable accuracy.

**Key words:** Liver fibrosis; Insulin resistance; Aspartate amino transaminase; Platelets; Age

**Core tip:** This observational study included a cohort of 332 recruited patients with hepatitis C virus (HCV) genotype 4 infections. The study assessed the status of demographic and biological variables at different stages of liver fibrosis. Liver biopsy with Metavir scoring was the reference standard used to classify patients into five stages of liver fibrosis (F0-F4). Patient regrouping to include three levels of fibrosis, mild (F0-F1), moderate (F2), and advanced (F3-F4), was performed to conform with practical guidelines for the management and follow-up of HCV patients. Age, aspartate transaminase enzyme (AST), insulin resistance (HOMA-IR), and platelet count were significant predictors of liver fibrosis as shown on univariate analysis. Log AST, log HOMA-IR, log platelet count and age were introduced into stepwise multivariate discriminative analysis, and a model for the prediction of liver fibrosis level was derived. Our predictive index exhibited an area under the curve (AUC) of 0.91 for the diagnosis of advanced stages of fibrosis and an AUC of 0.88 for the diagnosis of mild stages of fibrosis. The index exhibited a lower AUC of 0.64 in the diagnosis of moderate stages of fibrosis.

## INTRODUCTION

Hepatitis C virus (HCV) infection exhibits worldwide distribution with a global prevalence of 2.35%, and it affects 160-170 millions of chronically infected individuals<sup>[1]</sup>. Approximately three to four million peoples are infected annually<sup>[2]</sup>. Egypt has one of the highest prevalence rates worldwide, 14.9%, as estimated by the Egypt Demographic and Health Survey. HCV genotype 4 is the most common genotype in Egypt<sup>[3]</sup>. Liver fibrosis is the essential pathophysiological consequence of chronic liver injury regardless of injurious agent because it is the pathological outcome of chronic HCV infections<sup>[4]</sup>.

Hepatic stellate cells (HSCs) are the major fibrogenic cells in the liver. Apoptotic HSCs regulate the balance between the synthesis and degradation of the extracellular matrix<sup>[5]</sup>. HCV-induced bioactive transforming growth beta 1 is critical for the induction of  $\alpha$ -smooth muscle actin and type-1 collagen, which are markers for HSC activation and proliferation<sup>[6]</sup>.

The assessment of liver fibrosis level (stage) is a major issue for the management and follows-up of patients with chronic hepatitis C infection. Liver biopsy is the gold standard for the assessment of fibrosis and grade of necro-inflammation and histological staging is based on semi-quantitative scoring systems (e.g., Metavir and Ishak Scores)<sup>[7]</sup>.

However, liver biopsy exhibits certain drawbacks, including sampling error, invasiveness with potentiality adverse effects, complications, such as haemorrhage in 0.3% of cases, pain in 30% of cases and mortality in 0.01% of cases, and inter and intra observer variability in the reading of biopsy specimens<sup>[8]</sup>. Therefore, liver biopsy is not a perfect assessment of liver fibrosis and there is a growing need to identify surrogate non-invasive markers of liver injury with its clinical consequences and future events.

HCV chronic infections are associated with insulin resistance and type 2 diabetes mellitus, which are more frequently observed in HCV infections compared with healthy controls and liver diseases of other aetiology. HCV infection promotes insulin resistance primarily via increased TNF- $\alpha$  production and enhanced suppressor of cytokine, which block PI3K and Akt phosphorylation<sup>[9]</sup>. Insulin resistance and geographical origin (Egyptian) are the major predictors of liver fibrosis and response to therapy in HCV-genotype 4<sup>[10]</sup>.

Physiological hepatic angiogenesis occurs during liver regeneration and leads to the formation of new functional

sinusoids. However pathological angiogenesis occurs in fibrosis, and it is characterized by the appearance of capillaries vascular structures<sup>[11]</sup>. The resulting hypoxia in liver injury induces activation of the renin-angiotensin system (RAS), which plays a role in the pathogenesis of fibrosis in the heart, kidney, lung and liver<sup>[12]</sup>.

Multiple markers using non-invasive methods to determine liver fibrosis are available. No single non-invasive test or model can match the information obtained from actual perfect histology, and there is a need to develop further tests or models that alleviate or that reduce the need for invasive liver biopsy.

We used simple biological parameters that are related to the development and progression of liver fibrosis, to obtain a model of acceptable accuracy that predicted levels of liver fibrosis in HCV-genotype 4 patients.

## MATERIALS AND METHODS

This cross-sectional observational study included a cohort of 352 recruited patients with chronic hepatitis C infection. Patients were attending liver clinics at Minia University, Egypt, from June 2011 to July 2013. Data from twenty patients were excluded because eight patients were not genotype 4, five patients had a small core of liver biopsy that required correct assessment, four patients were diabetic, and three patients failed to follow-up. Only data of 332 patients were subjected to statistical analyses. Included patients had HCV-genotype 4 infection. HCV infection was defined as positive second generation anti-HCV antibodies and detection of HCV RNA in serum using quantitative reverse transcription polymerase chain reaction during the study period (Abbott M 2000, United States; -lower limit of detection 12 IU/mL). HCV genotyping was performed using line probe assay or reverse hybridisation and commercially available kits (Innolipa, Innogenetic, and Genetics, Belgium).

Exclusion criteria included co-infection with hepatitis B virus, human immunodeficiency virus or schistosomal infections, regular alcohol intake greater than 10 g/d, previous interferon therapy, other aetiologies of liver disease such as immune-mediated liver diseases, clinical evidence of liver decompensation and use of drugs that may alter insulin resistance, such as insulin sensitizers. Obesity determined as body mass index > 30 [body mass index (BMI) > 30] and frank diabetes mellitus diagnosed according to the American Diabetes Association diagnosis criteria<sup>[13]</sup> were exclusion criteria from the study because these conditions may confound the results. Associated lung disease was also excluded because it may confound angiotensin converting enzyme (ACE) levels.

### Informed consent

The Institutional Ethics Committee of participating units approved the study protocol, and all patients signed informed consent. The study was conducted in accordance with the ethical guidelines of the 1975

Helsinki Declaration.

### Liver histopathology

Sonographic-guided liver biopsy was performed on the second day of blood withdrawal for tests using disposable true cut needles (14 gauge) to obtain a sufficient liver tissue core. Liver biopsy specimens not less than 15 mm in length or the presence of at least 10 complete portal tracts were required for data inclusion.

Liver biopsy specimens were fixed and paraffin embedded, stained with the routinary haematoxylin and eosin (H and E) and mason trichrome stain to define fibrosis in combination with Prussian blue for iron staining. A single experienced pathologist who was blinded to clinical and laboratory data examined liver biopsy specimens.

Fibrosis staging and necroinflammatory grading were scored according to Metavir scores, which scores fibrosis as F0 (absent), F1 (portal fibrosis), F2 (portal fibrosis with few septa), F3 (septal fibrosis) and F4 (cirrhosis). Necroinflammatory activity was graded as A0 (absent), A1 (mild), A2 (moderate) and A3 (severe)<sup>[14]</sup>.

### Demographic and laboratory assessment

The following data were collected from all patients at baseline: Age, sex, weight (W) in kilograms, height (H) in meters, waist and hip circumferences in centimeters, and BMI calculated as W/H<sup>2</sup>, and Waist/Hip ratio. Venous blood was withdrawn after an 8-h overnight fast and was analysed for fasting plasma glucose.

Other sample of venous blood was withdrawn after a 12-h overnight fast and collected in three tubes, one of which contained EDTA-K3 for haemogram assessment. Serum from the other two tubes was distributed as follows: One sample was frozen in a -70 °C refrigerator for later assessments of insulin, C-peptide and ACE. Serum from the third tube was analysed on the same day for, cholesterol, triglycerides, and liver biochemical and renal profiles.

### Laboratory methods

Serum insulin and C-peptide were assayed using a sandwich ELISA technique and kits from Monobind Inc (Lake Forest, CA, United States); Serum ACE was assayed using kits from R and D systems (R and D Systems, Inc. United States and Canada) that employ a quantitative sandwich immunoassay technique; Liver function tests [serum total and conjugated bilirubin, alanine amino transferase (ALT), aspartate amino transferase (AST), alkaline phosphates, total proteins and albumin], kidney function tests (urea and creatinine), and total cholesterol and triglycerides were performed using a Synchron CX<sup>9</sup> auto-analyser using Beckman reagents (Beckman Instruments; Scientific Instruments Division, Fullerton, CA, United States); Complete blood count was performed on using Coulter Counter T 660 (Beckman Coulter, Inc., Harbor Blvd., Fullerton, CA, United States); Prothrombin time was assessed on an STA-Stago Compact CT autoanalyser (Diagnostic Stago,

Inc., Parsippany, NJ, United States) using reagents from Dade Behring (Dade Behring Holdings Inc., IL, United States); hepatitis B surface antigen and C-antibody were measured using Roche Cobase 411 (Roche Diagnostic GmbH); insulin resistance (IR) was determined using the homeostasis model assessment for insulin resistance (HOMA-IR) method and the following equation:  $\text{HOMA-IR} = \text{Fasting insulin (mU/mL)} \times \text{Fasting plasma glucose (mmol/L)} / 22.5$ . Insulin resistance as calculated using this method correlates closely with the gold standard hyperinsulinemic/euglycemic clamp method in diabetic and non-diabetic subjects<sup>[15,16]</sup>.

### Statistical analysis

Qualitative data are presented as numbers, (%). Normally distributed variables are presented as the means  $\pm$  SD and non-parametric data are presented as the medians and interquartile range. The distribution of qualitative variables was evaluated using the  $\chi^2$  test or Fisher's exact test, as indicated. The means were compared between groups using the non-parametric independent-samples Kruskal-Wallis test, and the level of significance following pairwise comparisons was adjusted for the number of comparisons made.

Fibrosis stages based on Metavir scores were distributed into 5 classes: F0, F1, F2, F3 and F4. Patients were further regrouped into 3 stages of mild (F0-F1), moderate (F2) and advanced fibrosis (F3-F4) for statistical analyses. Univariate analyses identified patient's age, AST and platelet count added to HOMA-IR as significantly different between the 3 levels of fibrosis in overall and pairwise comparisons. All variable were introduced in a stepwise discriminative functional analysis model for the three levels of fibrosis after normalising HOMA-IR, AST and platelet count into their  $\log^{10}$  values. Diagnostic accuracy is expressed as area under the curve of receiving operating characteristic (AUROC) (asymptomatic 95%CI), sensitivity, specificity, positive and negative predictive values, and positive and negative likelihood ratios. All tests were bilateral, and a *P* value of 0.05 was the limit of statistical significance. Statistical analyses were performed using the IBM SPSS statistical software package for MAC version 22.

## RESULTS

A total of 332 HCV-genotype 4 Egyptian patients were included to statistical analysis. Patients exhibited a mean age of  $42 \pm 10.7$  years and male to female ratio of 180/146 (65/44%). Gender showed no statistically significant difference between levels of liver fibrosis. Mean BMI and Waist/Hip ratio were  $26.7 \pm 4.4$  and  $0.89 \pm 0.08$ , respectively, which indicates that none of our patients was obese. None of the study patients consumed alcohol or had history of drug abuse. A total of 69.6% were non-smokers, 19% were moderate smokers and 11.4% were heavy smokers. The Metavir scoring system identified F0 = 43, F1 = 136, F2 = 64, F3 = 45 and F4 = 44 patients.

Table 1 presents quantitative variables such as the

mean, SD, median and quartile range in the five stages of liver fibrosis. Table 2 presents pairwise comparisons of significant variables between the three levels of fibrosis. Table 3 presents the overall significant variables using independent - samples Kruskal-Wallis tests which indicated that age, ACE, blood glucose, ALT, AST, platelet count, fasting serum insulin, serum creatinine, total and direct bilirubin, and serum albumin were significant predictors of liver fibrosis stage. Viral load showed no statistically significant difference among stages and levels of liver fibrosis.

Statistically significant variables that discriminated between the 3 levels of fibrosis on univariate analysis, namely AST, platelet count and age and HOMA-IR were introduced to a stepwise multivariate discriminant analysis. This analysis requires a normal distribution of the dependent variables and equality of variance. Therefore; HOMA-IR, AST and platelet count were transformed into  $\log^{10}$  values.

Table 4 indicates that all variables were statistically significant before being introduced in the model. These variables were introduced into a model that significantly predicted liver fibrosis. Stepwise analysis derived the following equation.

$\text{Outcome} = 0.514 (\text{age}) + 0.373 (\text{Log HOMA-IR}) + 0.49 (\text{Log AST}) + (-0.532) \text{Log platelet count}$ .

The interpretation of outcome is dependent on the functions of group centroids as: (1) mild fibrosis if outcome is  $\leq -0.31$  or more negative; (2) moderate fibrosis if outcome is  $> -0.31$  (more positive) and up to  $+0.86$ ; and (3) advance fibrosis if outcome is  $> 0.86$ .

Table 5 presents accuracy indices of the model in the discrimination of fibrosis stages. In mild fibrosis and at a cut-off value  $-0.31$  or more negative, AUC was 0.88 with sensitivity, specificity, positive predictive value, negative predictive value, positive likelihood ratios and negative likelihood ratios were 67.2%, 86.3%, 83.6%, 69.5%, 4.9 and 0.38, respectively, Figure 1. In advanced fibrosis and at a cut-off value  $> 0.86$ , AUC was 0.91 with sensitivity, specificity, positive predictive value, negative predictive value, positive likelihood ratios and negative likelihood ratios were 73%, 90.9%, 74.4%, 90.1%, 8.0 and 0.3, respectively (Figure 2). While, in moderate fibrosis and at a cut-off value  $> -0.31$  up to  $+0.86$ , AUC was 0.64 with sensitivity, specificity, positive predictive value, negative predictive value, positive likelihood ratios and negative likelihood ratios were 53.1%, 74.1%, 33%, 86.8%, 2.0 and 0.63, respectively, Figure 3.

The obtained model was validated by applying the model to the selected studied groups. Table 6 shows the results of this validation which indicated that two-thirds of the cases were correctly classified by the model (66.1%). This sensitivity increased to 67.2% and 73% in mild and advanced fibrosis, respectively, but dropped to 53.1% in moderate fibrosis.

## DISCUSSION

The prediction of liver fibrosis is a major issue for management and follow-up of patients with chronic

of liver fibrosis stages<sup>[17]</sup>, but this technique has its drawbacks. Liver biopsy is not the perfect tool for follow up assessments of fibrosis in patients with chronic hepatitis C with or without virological cure<sup>[18]</sup>.

The limitations of liver biopsy disclosed the need for the development of non-invasive tests to assess liver fibrosis. Currently available methods to predict liver fibrosis rely on two different but complementary approaches: (1) a biological approach based on measurements of serum levels of biological markers that

**Table 5** Accuracy indices of the discriminant score in the prediction of fibrosis

Stage of fibrosis	Cut-off value	AUC	95%CI	Sens	Specific	PPV	NPV	PLR	NLR
Mild fibrosis (F0-F1)	-0.31 or more negative	0.88	0.84-0.91	67.2%	86.3%	83.6%	69.5%	4.9	0.38
Moderate fibrosis (F2)	> -0.31 up to +0.86	0.64	0.61-0.74	53.1%	74.1%	33%	86.8%	2.0	0.63
Advanced fibrosis (F3-F4)	> 0.86	0.91	0.88-0.94	73%	90.9%	74.4%	90.1%	8.0	0.3

Sens: Sensitivity; Specific: Specificity; PPV: Positive predictive value; NPV: Negative predictive value; PLR: Positive likelihood ratio; NLR: Negative likelihood ratio; AUC: Area under the curve.

**Table 6** Validation results done on the studied selected groups

Stage of fibrosis	Predicted group membership			Total
	Mild fibrosis	Moderate fibrosis	Advanced fibrosis	
Count				
Mild fibrosis	119	50	8	177
Moderate fibrosis	16	34	14	64
Advanced fibrosis	5	19	65	89
Percent				
Mild fibrosis	67.2	28.2	4.5	100.0
Moderate fibrosis	25.0	53.1	21.9	100.0
Advanced fibrosis	5.6	21.3	73.0	100.0

**Figure 3** Receiving operating characteristic curve for discriminating moderate fibrosis. At cut off value > -0.31 up to +0.86: AUC 0.64, 95%CI: 0.61-0.74, sensitivity 53.1%, specificity 74.1%, PPV 33%, NPV 86.8%, PLR 2.0 and NLR 0.63. AUC: Area under the curve; PPV: Positive predictive value; NPV: Negative predictive value; PLR: Positive likelihood ratio; NLR: Negative likelihood ratio; ROC: Receiving operating characteristic.

are independent predictors of liver fibrosis<sup>[19]</sup>; and (2) a “physical” approach based on the measurement of liver stiffness using transient elastography or other recent radiological tools<sup>[20]</sup>.

Many biomarkers have been developed and validated, but none of these markers provide the perfect test. This result may be due to the relatively reduced accuracy of otherwise the sophisticated techniques and the high costs of these tests<sup>[21]</sup>. We developed a non-invasive biomarker using variables that are biologically relevant to the development and progression of liver fibrosis, because of limitations of the available methods of non-invasive markers for assessment of liver fibrosis<sup>[22]</sup>.

Our study demonstrated on univariate analysis that age significantly ( $P < 0.001$ ) correlated with the stage of liver fibrosis. Age is used with some of the current biomarkers as an independent determinant of liver fibrosis, such as Forn's Index<sup>[23]</sup> and Fib 4<sup>[24]</sup>.

The results of univariate and multivariate analyses demonstrated that AST was a highly significant ( $P < 0.0001$ ) independent predictor of liver fibrosis stage. AST is used in many available biomarker tests as an independent predictor for liver fibrosis, such as Fib-4<sup>[24]</sup>, APRI test<sup>[25]</sup>, Fibro index<sup>[26]</sup>, and Fibrometere<sup>[27]</sup>.

Our results indicated that platelets were significantly negatively correlated with the advancement of liver fibrosis stage ( $P < 0.0001$ ). Platelet count was reported previously to progressively decrease with the progression of liver fibrosis<sup>[28]</sup>, which makes it to be included in some currently available biomarker evaluations of liver fibrosis stage including Forn's index<sup>[23]</sup>, and Fib-4<sup>[24]</sup>, APRI test<sup>[25]</sup>, and Fibro index<sup>[26]</sup>.

Our univariate analysis results demonstrated a significantly increasing level of HOMA-IR with the progression of liver fibrosis stage ( $P < 0.0001$ ). Insulin resistance is a powerful promoter of fibrogenesis *via* direct HSC

stimulation, TNF- $\alpha$ , connective growth factor production and ductular reaction induction<sup>[29]</sup>. However, only the Sud index included insulin resistance as a variable to evaluate liver fibrosis<sup>[30]</sup>.

Our study is the first report of the correlation of the progressive rise of serum ACE levels with the advancement of liver fibrosis stage ( $P < 0.0001$ ). Multivariate analysis of ACE serum level significantly predicted the stage of liver fibrosis ( $P < 0.001$ ).

ACE is the key rate-limiting enzyme for activation of the RAS, which results in the production of angiotensin II. Angiotensin II induces the contraction and proliferation of the human HSCs that are responsible for hepatic fibrogenesis<sup>[31]</sup>. However, it was excluded from our discriminating analysis to avoid the possible confounding effect of some disease states that may alter ACE serum level.

Stepwise multiple discriminative functional analysis indicated that platelets, age, AST, and HOMA-IR variables, in this order of frequency, were independent predictors of liver fibrosis with highly significant values ( $P < 0.0001$ ).

Log AST, log platelet count, log HOMA-IR and age were introduced in a stepwise discriminant analysis model. Our discriminating index for the prediction of liver fibrosis was processed into three levels based on 2014 EASL recommendations for the management of HCV patients to discriminate fibrosis in chronic hepatitis C: 1-No to Mild Fibrosis = F0-F1. 2-Moderate fibrosis = F2 3-Advanced fibrosis = F3-F4 according to Metavir staging

score.

All variables were statistically significant before introduction into the model. The following discriminative outcome was obtained using multiple stepwise analysis: Outcome = 0.514 (age) + 0.373 (Log HOMA-IR) + 0.49 (Log AST) + (-0.532) Log platelet count.

Where the level of fibrosis was predicted using the following cut-off values: (1) mild fibrosis = -0.31 or more negative; (2) moderate fibrosis if outcome > -0.31 (more positive) and up to +0.86; and (3) advance fibrosis if outcome > 0.86.

Our index with a cut-off value  $\geq 0.86$  exhibited an AUROC of 0.91 for predicting advanced stages of liver fibrosis (F3-F4) with a sensitivity, specificity, positive predictive value, negative predictive value and positive likelihood ratio of 73%, 90.9%, 74.7%, 90.0% and 8.0, respectively. The diagnostic accuracy of our index for the predicting of advanced liver fibrosis (F3-F4) was more effective than other scores such as the Fibrotest, APRI, Fibrometere, Hepascore. Degos *et al.*<sup>[32]</sup> performed a large study ( $n = 1307$ ) that compared transient elastography with patented and non-patented biomarkers (e.g., Fibrotest, Fibrometere, Hepascore and APRI) compared to liver biopsy. They reported an AUROCs of 0.76 for transient elastography, which did not differ from the AUROCs of the serum markers (0.72-0.78) for the diagnosing of significant fibrosis (F2-F3). However, they reported an AUROC of 0.90 for transient elastography compared to 0.82, 0.86, 0.77 and 0.86 for the Fibrotest, Fibrometere, APRI and Hepascore respectively, for the diagnosing of F4.

Our discriminating index using a cut-off value < 0.31 exhibited an AUROC of 0.88 in the diagnosing of no or mild fibrosis (F0-F2) with a sensitivity, specificity, positive predictive value, negative predictive value, positive likelihood ratio of 67.2%, 86.3%, 83.6%, 69.5% and 4.9, respectively, which indicates high diagnostic performance in the diagnosing of this group of patients. Most currently available scores did not diagnose this group of patients. Poynard *et al.*<sup>[33]</sup> performed a meta-analysis of 30 studies that assessed the diagnostic value of the Fibrotest compared to liver biopsy and found that the AUROC for Fibrotest in the diagnosing of adjacent stages of fibrosis (F1 vs F2) was 0.77 (0.75-0.79), and the AUROC was 0.83 (0.81-0.85) for advanced fibrosis (F3-F4). These figures for Fibrotest in the diagnosing of mild and advanced fibrosis are lower in performance than in our index.

Koda *et al.*<sup>[26]</sup> formulated their Fibroindex and reported its accuracy compared to APRI and Forns indices. Their data indicated that the AUROCs of APRI, Forns index, and Fibronectin were 0.78, 0.78 and 0.83, respectively, in discriminating mild degrees of fibrosis (F0-F1) vs significant stages of fibrosis (F2-F3), but the AUROCs were 0.81, 0.83 and 0.85, respectively, for discriminating F3-F4.

These data indicate that our index exhibited higher AUROCs for predicting advanced and mild stages of fibrosis than the currently available scores with higher

performance accuracy.

Attallah *et al.*<sup>[34]</sup> reported the Fibronectin discriminant score (FDS), using fibronectin, APRI and albumin. FDS exhibited an AUROC of 0.91 in discriminating F0-F1 vs F2-F4 and an AUROC of 0.86 in discriminating F0-F2 vs F3-F4. These data are nearly equal to the values of our discriminating index.

However, one limitation of our index is the low performance in the diagnosing of F2. The AUROCs for the diagnosing of F2 was 0.64 with cut-off values of  $\geq -0.31$  up to +0.86 with a sensitivity, specificity, positive predictive value, negative predictive value, and a positive likelihood ratio of 53.1%, 74.1%, 33.0%, 86.8% and 2.0, respectively.

Crisan *et al.*<sup>[35]</sup> validated the performance of six blood scores (APRI, Forns, Fib-4, Hepascore, Fibrotest and Fibrometere) using transient elastography compared to liver biopsy. Their data indicated that significant fibrosis  $F > 2$  was predicted with AUROCs of 0.727, 0.680, 0.714, 0.778, 0.688, 0.797 and 0.751 for APRI, Forns, Fib-4, Fibrotest, Hepascore, Fibrometere and transient elastography, respectively, and AUROCs were 0.741, 0.737, 0.767, 0.705, 0.811, 0.782 and 0.809 in the diagnosis of severe fibrosis (F3-F4). These data provide further support to the higher performance of our index compared to these six serum scores.

Chisti *et al.*<sup>[36]</sup> performed a prospective study to validate three biological scores (Fibrotest, Fibrometere and Hepascore) and reported AUROCs for the predicting of mild to moderate fibrosis of 0.81, 0.85, and 0.77, respectively and AUROCs for the diagnosing of F4 of 0.84, 0.92 and 0.88 respectively. These figures approximate our discriminating scores in the predicting of mild and advanced stages of fibrosis.

Our discriminating index was validated *via* application to originally selected patients. The results indicated that the model correctly classified two-thirds of the cases (66.1%). This sensitivity increased to 67.2% and 73% in mild and advanced fibrosis, respectively, but dropped to 53.1% in moderate fibrosis.

Our discriminating score exhibited higher performance in the diagnosing of mild or no fibrosis and advanced stages of liver fibrosis than the currently available blood tests, but our study and others evaluations of biological scores used liver biopsy as the reference standard.

Poynard *et al.*<sup>[37]</sup> investigated the performance of liver biopsy itself compared to two non-invasive tests (Fibrotest and Fibroscan) in the absence of the gold standard. The authors reported a relatively lower level of performance for liver biopsy even with the use of 20 mm length for the diagnosis of significant fibrosis (F2-F3). The specificity and sensitivity were 0.67 and 0.63, respectively, for liver biopsy compared to 0.93 and 70 and 0.95 and 0.50 for the Fibrotest and Fibroscan, respectively. These reported data suggested that the discordance between a non-invasive blood test and liver biopsy may be due to the lower diagnostic efficiency of the liver biopsy itself.

The end point of treatment of patients with HCV infections is virus eradication, improvements in liver

histology and prevention of the development of complications. Lee *et al.*<sup>[38]</sup> recently reported on the regression, maintenance and progression of liver fibrosis after virological cure. Pyonard *et al.*<sup>[39]</sup> validated the use of non-invasive markers (Fibrotest and Fibroscan) in a prospective longitudinal study for the prediction of fibrosis regression and development of complications.

The current policy is to follow-up with hepatitis C patients even if these patients are cured virologically. Here, the availability of an easily assessed, less expensive, reproducible blood test with high performance may alleviate or reduce the need for liver biopsy.

In conclusion, our discriminating index for liver fibrosis in hepatitis C genotype 4 patients is a simple, easily reproducible test with accepted accuracy. The index is based on biomarkers that are related to the development and progression of liver fibrosis.

### Limitation of the study

The lack of external validation of the obtained discriminating index is a limitation of this study. Our index is a candidate for multicenter external validation. This index may also be subjected to longitudinal studies to validate its prediction of future complications in HCV patients. Other limitations are the lack of two pathological observers for each specimen and the lack of determination of elastin connective tissue added to collagens.

## COMMENTS

### Background

Hepatitis C virus (HCV) induces liver fibrosis through transforming hepatic stellate cells and other intrahepatic cells to fibrous tissue laying cells. The severity of liver fibrosis is related to multiple host and viral factors. These factors are reflected on changes on biological variables. Studying levels of serum levels of some of these biological markers may provide a non-invasive test that can predict the liver fibrosis stage.

### Research frontiers

Multiple studies have reported about the increased insulin resistance in HCV infections, possibly as a part of HCV-induced metabolic syndrome. Also, there are available data about the impact of increased activity of hepatitis on the development and progression of liver fibrosis. The authors studied multiple biological and host factors in a cohort of genotype 4 Egyptian patients to assess the predictive ability of these variables in diagnosis of liver fibrosis stage.

### Innovations and breakthroughs

This study identified insulin resistance as estimated by homeostasis model of insulin resistance, aspartate transaminase enzyme, platelet count, and age as significant predictors of liver fibrosis stage. A model could be obtained utilizing these markers that could predict liver fibrosis stage with accuracy performance higher than available biological tests. The index is easily applicable and with low expenses.

### Applications

The non-invasive test for diagnosis of liver fibrosis stage can alleviate or reduce the need of the invasive liver biopsy to determine the level of liver fibrosis at basal level before starting antiviral treatment. Because liver biopsy cannot be done sequentially to follow-up HCV patients with or without virus cure, the non-invasive test may provide acceptable tool to do this task.

### Terminology

HOMA-IR: Homeostasis model for insulin resistance, a mathematically calculated

formula; ACE: Angiotensin converting enzyme; AST: Aspartate transaminase enzyme; BMI: Body mass index; W/H: Waist/hip ratio.

### Peer-review

The study is interesting and shows a good bibliographic study.

## Abstract

### AIM

To make efficacy and safety comparison of telbivudine-roadmap and tenofovir-roadmap in hepatitis B e antigen (HBeAg)-negative chronic hepatitis B (CHB) patients.

### METHODS

This was the first prospective, randomised, two-arm, open-label, non-inferiority study in HBeAg-negative CHB patients that compared telbivudine and tenofovir administered as per roadmap concept. Patients were treated up to 24 wk and, depending on virologic response, continued the same therapy or received add-on therapy up to 104 wk. Eligible patients received an additional 52 wk of treatment in the extension period (*i.e.*, up to 156 wk). Patients who developed virologic breakthrough (VB) while on monotherapy also received add-on therapy. The primary efficacy endpoint was the rate of patients achieving hepatitis B virus (HBV) DNA < 300 copies/mL at week 52. Secondary efficacy endpoints included the rates of HBV DNA < 300 and < 169 copies/mL, HBV DNA change from baseline, alanine aminotransferase normalisation, hepatitis B surface antigen (HBsAg) loss, HBsAg seroconversion, VB, and emergence of resistance at various timepoints throughout the study. Safety and estimated glomerular filtration rate (eGFR) were also analysed.

### RESULTS

A total of 241 patients were randomised. Non-inferiority of telbivudine arm to tenofovir arm was demonstrated at week 52 ( $\pm 7$  d window), with over 91% of patients in each treatment arm achieving HBV DNA level < 300 copies/mL. Both arms were similar in terms of key secondary efficacy variables at weeks 104 and 156. The percentage of patients achieving HBV DNA < 300 copies/mL remained high and was similar in the telbivudine and tenofovir arms at both weeks 104 and 156. Over 82% of patients in both arms achieved alanine aminotransferase normalisation at week 52, and this percentage remained high at weeks 104 and 156. Telbivudine treatment progressively reduced serum HBsAg levels from baseline while no change was reported in quantitative HBsAg during therapy with tenofovir. Both treatments showed acceptable safety profiles. The telbivudine arm showed eGFR improvement unlike the tenofovir arm.

### CONCLUSION

Efficacy was shown for both telbivudine-roadmap and tenofovir-roadmap regimens in HBeAg-negative CHB patients over 156 wk. Telbivudine arm was associated with renal improvement.

**Key words:** Chronic hepatitis B; Glomerular filtration rate; Telbivudine; Tenofovir; Roadmap concept

**Core tip:** This was the first prospective, randomised, non-inferiority study in hepatitis B e antigen-negative chronic hepatitis B patients that compared telbivudine and tenofovir administered as per roadmap concept. Both treatments based on the roadmap approach were effective over a 156 wk treatment period. Non-inferiority of telbivudine arm to tenofovir arm was demonstrated at week 52, with over 91% of patients in each treatment arm achieving hepatitis B virus DNA level < 300 copies/mL. Both treatments showed acceptable safety profiles. Moreover, telbivudine showed an improvement in estimated glomerular filtration rate from baseline.

Telbivudine vs tenofovir in hepatitis B e antigen-negative chronic hepatitis B patients: OPTIMA roadmap study. *World J Hepatol* 2016; 8(32): 1402-1413 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i32/1402.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i32.1402>

## INTRODUCTION

Approximately 240-400 million people worldwide are chronically infected with hepatitis B virus (HBV), with a wide variation of prevalence among countries, and more than 780000 people die every year due to acute or chronic hepatitis B (CHB)<sup>[1-3]</sup>. Although CHB may be treated with interferon or nucleos(t)ide analogue (NA) antivirals, emergence of resistance due to prolonged NA therapy or incomplete suppression of HBV still remains an important concern<sup>[4]</sup>. Several studies have suggested that the use of response-guided add-on therapy is associated with a higher rate of virologic response and reduced antiviral resistance as compared to sequential monotherapy<sup>[5,6]</sup>.

Early virologic response has been used as a guide to predict better outcomes and to reduce the risk of antiviral resistance<sup>[7,8]</sup>. As previously reported<sup>[9,10]</sup>, the roadmap concept uses early virologic response at week 24 to individualize ongoing management of CHB patients. Patients with a complete response at week 24 can remain on their initial therapy, whereas treatment modification that may include the addition of a second drug is done for those with an inadequate virologic response. This strategy is relevant mainly in patients receiving NA with a low genetic barrier to resistance (clevudine, emtricitabine, lamivudine, telbivudine)<sup>[10]</sup>. In hepatitis B e antigen (HBeAg)-positive CHB patients treated with telbivudine, a response-guided treatment optimization strategy with telbivudine based on the roadmap concept has been demonstrated to improve the clinical outcomes of patients with a suboptimal antiviral response<sup>[11,12]</sup>.

The aim of this study, OPTIMA, was to assess the efficacy and safety of telbivudine and tenofovir regimens,

Figure 1 Study design. HBV: Hepatitis B virus.

when administered using the roadmap concept, in HBeAg-negative patients with CHB. This was the first study that compared efficacy of the 2 regimens in a prospective manner. The safety of the combination of telbivudine and tenofovir, for which limited data are currently available, was also evaluated.

## MATERIALS AND METHODS

### Study design and conduct

OPTIMA was a prospective, randomised, 2-arm, open-label study (ClinicalTrials.gov ID: NCT01379508) that enrolled patients between February 2011 and October 2012 in 8 countries (Austria, Bulgaria, Germany, Greece, Italy, Russia, Spain and Turkey). This study was approved by the Institutional Review Board at each participating centre, and was conducted in accordance with the Declaration of Helsinki and Good Clinical Practice guidelines. Written informed consent was obtained from each patient before enrolment.

Eligible patients were randomised *via* an interactive voice response system in a 1:1 ratio to either telbivudine arm (600 mg/d) or tenofovir arm (300 mg/d) (Figure 1). Randomisation was stratified by the screening HBV DNA level ( $< 7 \log_{10}$  copies/mL or  $\geq 7 \log_{10}$  copies/mL) and alanine aminotransferase (ALT) level [ $< 3 \times$  upper limit of normal (ULN) or  $\geq 3 \times$  ULN].

This study used the response-guided add-on strategy (roadmap concept). For patients with HBV DNA  $\geq 300$  copies/mL ( $\geq 51$  IU/mL) at week 24, tenofovir was added to telbivudine by week 26 in the telbivudine arm, and telbivudine was added to tenofovir by week 26 in the tenofovir arm. For patients with HBV DNA  $< 300$  copies/mL at week 24, telbivudine and tenofovir monotherapies in the respective arms were continued. Patients who developed virologic breakthrough (VB) while on monotherapy received add-on therapy. However, patients who developed VB after week 24 while on combination therapy were discontinued from the study.

### Patients

Eligible patients were male or female  $\geq 18$  years of age, with detectable hepatitis B surface antigen (HBsAg) for  $\geq 6$  mo, HBeAg-negative with positive hepatitis B e antibody, available liver histology report within 12 mo before screening compatible with CHB (patients without evaluable liver histology were eligible if they had clinical evidence of compensated liver cirrhosis or non-invasive methods that support the diagnosis of moderate to severe liver inflammation and/or fibrosis), serum HBV DNA  $> 2000$  IU/mL, and serum ALT level  $> 1 \times$  ULN and  $< 10 \times$  ULN at the screening visit. Patients with ALT  $\leq 1 \times$  ULN at screening were eligible if they had at least moderate liver inflammation or fibrosis, clinical evidence of compensated cirrhosis, or ALT level  $> 1 \times$  ULN within the last 6 mo.

Main exclusion criteria included co-infection with hepatitis C virus, hepatitis D virus or human immunodeficiency virus; hepatic decompensation; liver disease other than CHB; any nucleos(t)ide or interferon/immunomodulator treatment in the previous 6 mo; chronic renal insufficiency or serum creatinine clearance  $< 50$  mL/min; history of myopathy, myositis, or persistent muscle weakness; pregnant or nursing (lactating) women; or history of malignancy of any organ system (other than localized basal cell carcinoma of the skin).

Patients were allowed to receive an additional 52 wk of treatment in the extension period (*i.e.*, up to 156 wk) if they had HBV DNA  $< 300$  copies/mL at both weeks 92 and 104, and serum creatinine clearance  $\geq 50$  mL/min at two consecutive visits including week 104.

### Efficacy and safety analyses

The primary efficacy endpoint was the rate of patients achieving HBV DNA  $< 300$  copies/mL (51 IU/mL) at week 52. Secondary efficacy endpoints included the rates of patients with HBV DNA  $< 300$  copies/mL at weeks 104 and 156, and HBV DNA  $< 169$  copies/mL (29 IU/mL) (lower limit of detection) at weeks 24, 52, 104 and 156; change from baseline in HBV DNA; ALT normalisation at weeks 52, 104 and 156; HBsAg loss and HBsAg seroconversion; VB; and emergence of resistance. In addition, subgroup analyses were performed for secondary efficacy endpoints by baseline HBV DNA (*i.e.*,  $< 7 \log_{10}$  copies/mL or  $\geq 7 \log_{10}$  copies/mL).

VB was defined as an increase of HBV DNA by at least  $1 \log_{10}$  copies/mL (or  $1 \log_{10}$  IU/mL) above nadir on 2 consecutive visits, or at the last on-treatment visit in patients who did not have a primary non-response. Emergence of resistance was assessed as the rate of confirmed treatment-emergent genotypic resistance and was assessed at the time of confirmed VB and at week 24 in patients with viral load  $\geq 300$  copies/mL, it was calculated cumulatively at weeks 52, 104 and 156.

HBV DNA detection and quantification were performed at a central laboratory using the COBAS TaqMan real-time polymerase chain reaction assay (Roche Molecular Systems, Branchburg, NJ, United States).

Safety assessments included monitoring of adverse events (AEs), vital signs, and graded laboratory abnormalities. Estimated glomerular filtration rate (eGFR), calculated by the modification of diet in renal disease formula was recorded. AEs of special interest (muscle and renal function related events) were also reported.

### Statistical analysis

For the primary efficacy analysis, study treatments were compared for non-inferiority.

Based on the assumptions of 96% and 97% HBV DNA < 300 copies/mL at week 52 in the telbivudine arm and the tenofovir arm, respectively, and an approximately 10% dropout rate, it was estimated that 120 randomised patients per arm would provide 87% power for the non-inferiority testing on the primary analysis. Non-inferiority in efficacy of telbivudine arm to tenofovir arm was to be claimed if the lower limit of the 2-sided confidence interval (CI) for the difference was above the pre-determined non-inferiority margin (-10%).

A weighted Cochran-Mantel-Haenszel method, adjusting for randomisation strata [HBV DNA (< or  $\geq 7 \log_{10}$  copies/mL) and ALT (< or  $\geq 3 \times$  ULN) levels], was used to assess comparative therapeutic response rates.

For continuous variables, summary statistics of absolute value and of change from baseline, including mean, standard deviation (SD), median, minimum, and maximum were used. For dichotomous endpoints, statistical summaries included count and percentage of patients with a positive response (response rate) and also 95%CI for the response rate.

The intent-to-treat (ITT) population consisted of all patients who received at least one dose of study drug and had at least one post-baseline assessment of serum HBV DNA. The roadmap ITT (rITT) population consisted of all patients who did not discontinue before week 24 and did not deviate from the protocol defined rules of receiving add-on at week 24 (*i.e.*, patients who received the add-on therapy at week 24 if they had HBV DNA  $\geq 300$  copies/mL, or did not receive the add-on at week 24 if they had HBV DNA < 300 copies/mL). The modified ITT (mITT) population consisted of all patients in the ITT population who were eligible and enrolled in the extension period beyond week 104. The per-protocol population consisted of all patients in the ITT population who had no major protocol deviations.

All efficacy observations on or after censoring date were treated as missing. A patient's censoring date was the date of the first occurrence of: One day after the last dose of the study drug, the start of first prohibited CHB-related medication, pregnancy, or a specific major protocol deviation. To assess the robustness of the results due to missing data, the analysis of primary and all secondary efficacy endpoints were performed based on the rITT and ITT analysis populations. The mITT population was used only for the week 156 analysis.

The primary efficacy endpoint (week 52) analysis was performed on the rITT population. The analyses presented include: (1) assessments within the  $\pm 7$  d protocol-pre-

specified visit window around the scheduled week 52 date; (2) missing data at week 52 treated as failure; (3) missing data imputed using the earliest available assessment within the 28 d window starting from the scheduled week 52 date; and (4) missing data imputed using the last observation carried forward (LOCF).

Secondary efficacy parameters including HBV DNA, ALT normalisation, HBsAg loss, and HBsAg seroconversion were analysed using two imputation methods for missing data: (1) missing data treated as failure; and (2) missing data imputed using the earliest available assessment within the 28 d window starting from the scheduled visit for weeks 52 (except HBV DNA < 300 copies/mL), 104 and 156. VB and eGFR were analysed using the LOCF imputation method for missing data. Treatment-emergent genotypic resistance was analysed using cumulative imputation method for missing data. Missing eGFR assessments were imputed using the LOCF method.

Analyses of endpoints using LOCF imputation at weeks 104 and 156 are presented for the rITT and mITT populations, respectively.

## RESULTS

### Study patients

A total of 241 patients (121 in the telbivudine arm and 120 in the tenofovir arm) were randomised in this study. A total of 22 (18.2%) patients in the telbivudine arm and 13 (10.8%) patients in the tenofovir arm discontinued prematurely from the study. The most common reasons for discontinuation in the telbivudine arm were consent withdrawal ( $n = 7$ ), lost to follow-up ( $n = 5$ ), and administrative reasons ( $n = 4$ ). In the tenofovir arm, the most common reasons for discontinuation were AEs ( $n = 5$ ), consent withdrawal ( $n = 4$ ), and lost to follow-up ( $n = 3$ ).

Major protocol deviations were reported in 11 (9.1%) patients in the telbivudine arm and 8 (6.7%) patients in the tenofovir arm. The most commonly reported major deviations were patients on monotherapy with confirmed VB not starting add-on therapy within 2 wk of laboratory confirmation of VB ( $n = 9$ ), patients with a positive HBeAg result ( $n = 6$ ), and patients not completing 3 wk of treatment before the third visit ( $n = 4$ ).

The safety population comprised 120 patients in each of the 2 treatment arms. One patient in the telbivudine arm was excluded from the safety population as this patient did not receive any study treatment. Of the 241 randomized patients, 235 patients were included in the ITT population, with 117 (96.7%) in the telbivudine arm and 118 (98.3%) in the tenofovir arm. Six patients were excluded from the ITT population (4 patients in the telbivudine arm due to no post-baseline HBV DNA assessments, non-compliance with the study conduct, or no study treatment received; and 2 patients in the tenofovir arm because of no post-baseline HBV DNA assessments and viral resistance at baseline). A total of 113 (93.4%) patients in the telbivudine arm and 117 (97.5%) patients in the tenofovir arm comprised the

Creatine phosphokinase, mean (SD), IU/L	118.6 (64.4)	160.1 (299.3)
Median (min-max)	104.0 (35-430)	111.0 (36-2976)
eGFR <sup>1</sup> , mean (SD), (mL/min per 1.73 m <sup>2</sup> )	97.4 (17.9)	95.8 (16.4)
Median (min-max)	96.6 (60.9-147.1)	94.2 (60.5-138.4)

<sup>1</sup>eGFR: Estimated glomerular filtration rate (modification of diet in renal disease formula). HBV: Hepatitis B virus; SD: Standard deviation.

rITT population. Five patients (4 in the telbivudine arm and 1 in the tenofovir arm) that were included in the ITT population were excluded from the rITT population because they discontinued before week 24 and were not eligible for or enrolled into the roadmap concept period (weeks 24 to 104).

The per-protocol population consisted of 107 (88.4%) patients in the telbivudine arm and 111 (92.5%) patients in the tenofovir arm. A total of 17 patients (10 in the telbivudine arm and 7 in the tenofovir arm) were included in the ITT and rITT populations but were excluded from the per-protocol population because of major protocol deviations. The mITT population consisted of 79 (65.3%) patients in the telbivudine arm and 89 (74.2%) patients in the tenofovir arm.

Treatment arms were balanced with respect to demographics and baseline characteristics, with no clinically meaningful differences between the telbivudine and tenofovir arms (Table 1). Most (86.0% telbivudine, 91.7% tenofovir) patients were infected with HBV genotype D, and the mean HBV DNA at baseline was 6.2 log<sub>10</sub> copies/mL in the telbivudine arm and 6.0 log<sub>10</sub> copies/mL in the tenofovir arm, with 70.2% and 71.7% of patients, respectively, having a baseline HBV DNA < 7 log<sub>10</sub> copies/mL.

### Primary efficacy endpoint

Virologic response (HBV DNA < 300 copies/mL) at week 52 was achieved in more than 91% of patients in each treatment arm (Figure 2A). The primary endpoint

analysis showed that the antiviral efficacy of telbivudine-roadmap was non-inferior to that of tenofovir-roadmap application at week 52 in the rITT population; the lower bound of the 95%CI for the difference between the 2 treatment arms was above the non-inferiority margin of -10%: -9.4% (utilizing assessments within the ±7 d protocol-prespecified visit window); -8.3% for the 28 d window imputation; and -7.9% for the LOCF imputation. Using missing data as treatment failure, non-inferiority was not demonstrated (lower bound of the 95%CI: -10.5%, just below the protocol defined non-inferiority margin) (Table 2). In this analysis, HBV DNA samples from 6 patients (4 in the telbivudine arm and 2 in the tenofovir arm), although resulted in < 300 copies/mL, were considered as missing because they were not obtained at the week 52 visit date itself (*i.e.*, patients were counted as treatment failures).

The primary endpoint analysis at week 52 in the per-protocol population supported the non-inferiority of the telbivudine arm to the tenofovir arm (98.0% in the telbivudine arm and 99.0% in the tenofovir arm, lower bound of the 95%CI: -4.3%).

### Secondary efficacy endpoints

**Virologic responses:** Percentage of patients achieving HBV DNA < 300 copies/mL (51 IU/mL) at weeks 24 and 104, and by baseline viral load at weeks 24, 52 and 104 in the rITT population: The percentage of patients achieving HBV DNA < 300 copies/mL in the telbivudine and tenofovir arms at week 24 was 80.5% and 89.7%,

**Table 2** Virologic response, roadmap intent-to-treat population

Parameters	Telbivudine ( <i>n</i> = 113)	Tenofovir ( <i>n</i> = 117)	Difference between arms and 95%CI
Patients achieving HBV DNA < 300 copies/mL (51 IU/mL) at week 52, <i>n</i> (%)			
± 7 d protocol-prespecified visit window	104 (91.9)	111 (95.0)	-3.1% (-9.4%, 3.1%) <sup>1</sup>
Treating missing as failure	103 (91.0)	111 (95.0)	-4.0% (-10.5%, 2.5%) <sup>1</sup>
28 d imputation	105 (92.7)	111 (95.0)	-2.3% (-8.3%, 3.8%) <sup>1</sup>
Last observation carried forward	108 (95.4)	116 (99.2)	-3.8% (-7.9%, 0.4%) <sup>1</sup>
Change from baseline in HBV DNA levels (log <sub>10</sub> copies/mL) by visit, mean (SD)			<i>P</i> -value
Week 24	-4.001 (1.256)	-4.122 (1.165)	<i>P</i> < 0.0001 <sup>2</sup>
Week 52	-4.356 (1.473)	-4.305 (1.343)	<i>P</i> < 0.0001 <sup>2</sup>
Week 104	-4.281 (1.753)	-4.349 (1.382)	<i>P</i> < 0.0001 <sup>2</sup>

<sup>1</sup>Percentages and 95%CI were calculated using Mantel-Haenszel weighted estimates stratified by baseline HBV DNA and alanine aminotransferase levels;

<sup>2</sup>*P*-values were calculated using paired *t*-test comparing post-baseline timepoints to baseline timepoints. CI: Confidence interval; HBV: Hepatitis B virus; SD: Standard deviation.

**Figure 2** Proportions of patients achieving hepatitis B virus DNA < 300 (A) or < 169 copies/mL (B), by visit and by baseline hepatitis B virus DNA levels (< 7 or ≥ 7 log<sub>10</sub> copies/mL), roadmap intent-to-treat population. HBV: Hepatitis B virus.

and at week 104, 93.8% and 99.1%, respectively (Figure 2A).

In patients with lower baseline viral load (HBV DNA level < 7 log<sub>10</sub> copies/mL) at week 24, telbivudine and

tenofovir regimens were similar in terms of viral load reduction with 93.8% and 95.2% of patients achieving HBV DNA levels < 300 copies/mL in the telbivudine and tenofovir arms, respectively. At weeks 52 and

**Figure 3** Intensification with tenofovir (A) or telbivudine (B), virologic response and aminotransferase normalisation at week 104, roadmap intent-to-treat population. ALT: Alanine aminotransferase; HBV: Hepatitis B virus.

104, telbivudine and tenofovir regimens seemed to be similar in terms of viral load reduction, with over 92% of patients achieving HBV DNA levels < 300 copies/mL at weeks 52 and 104 (Figure 2A). The proportion of patients in each arm with higher baseline viral load ( $\geq 7 \log_{10}$  copies/mL) was relatively small to make any meaningful interpretation.

Change from baseline in HBV DNA levels from week 24 to week 104 in the rITT population: A statistically significant ( $P < 0.0001$ ) reduction in HBV DNA levels vs baseline was achieved in both treatment arms at week 24 and was sustained through week 104 (Table 2).

Intensification with tenofovir or telbivudine for HBV DNA  $\geq 300$  copies/mL at week 24 or for VB post week 24 through week 104 in the rITT population; response at week 104 (HBV DNA < 300 copies/mL) according to the requirement for add-on therapy at week 24: A greater number of patients in the telbivudine arm required add-on therapy compared with the tenofovir arm (35 patients in the telbivudine arm including 22 patients requiring add-on therapy at week 24 and 13 requiring add-on therapy post week 24 vs 11 patients in the tenofovir arm, all requiring add-on therapy at week 24).

The proportion of patients in the telbivudine arm achieving HBV DNA < 300 copies/mL at week 104 was greater in those who required tenofovir add-on therapy at week 24 (100%, 21/21 patients) than patients who

were in the telbivudine monotherapy group following the week 24 visit (92.4%, 85/92 patients) (Figure 3A).

The proportion of patients in the tenofovir arm achieving HBV DNA < 300 copies/mL at week 104 was similar in those who required telbivudine add-on therapy at week 24 (100%, 11/11 patients) to those who were in the tenofovir monotherapy group following the week 24 visit (99.1%, 105/106 patients) (Figure 3B).

Percentage of patients achieving HBV DNA < 169 copies/mL (29 IU/mL) at weeks 24, 52 and 104 in the rITT population: The rate of patients achieving HBV DNA < 169 copies/mL at weeks 24, 52 and 104 was consistent with that observed for the endpoint of HBV DNA < 300 copies/mL (Figure 2B).

Percentage of patients achieving HBV DNA < 169 copies/mL at week 104 in the rITT population according to the requirement for add-on therapy at week 24: The proportion of patients in the telbivudine and tenofovir arms achieving HBV DNA < 169 copies/mL at week 104 and receiving add-on therapy were 7.6 and 0.9 percentage points greater, respectively, than patients who received monotherapy (Figure 3).

Maintained virologic responses at week 156 in the mITT population: The percentage of patients who maintained HBV DNA < 300 copies/mL at week 156 was similar in the telbivudine and tenofovir arms: 91.1% (72/79 patients) and 100% (89/89 patients), respectively, using LOCF imputation. Similar results were found in patients maintaining HBV DNA < 169 copies/mL [91.1% (72/79 patients) and 96.6% (86/89 patients), respectively].

**HBsAg loss and HBsAg seroconversion:** HBsAg loss and HBsAg seroconversion were not observed in any patient from either treatment arm at weeks 52, 104 or 156. Telbivudine treatment progressively reduced serum HBsAg levels (mean  $\pm$  SD) from baseline in the rITT population [ $-0.116 \pm 0.581 \log_{10}$  IU/mL at week 52 ( $P = 0.0368$ ) and  $-0.179 \pm 0.633 \log_{10}$  IU/mL at week 104 ( $P = 0.0032$ )]. In contrast, no change was reported in quantitative HBsAg during therapy with tenofovir [ $-0.038 \pm 0.349 \log_{10}$  IU/mL at week 52 ( $P = 0.2399$ ) and  $-0.030 \pm 0.385 \log_{10}$  IU/mL at week 104 ( $P = 0.4063$ )]. At week 156, change from baseline in HBsAg levels in the mITT population was  $-0.204 \pm 0.759 \log_{10}$  IU/mL ( $P = 0.0193$ ) in the telbivudine arm and  $-0.031 \pm 0.412 \log_{10}$  IU/mL ( $P = 0.4760$ ) in the tenofovir arm.

**Biochemical response:** ALT normalisation at weeks 52 and 104 in the rITT population: ALT levels significantly improved vs baseline in both treatment arms, with over 82% of patients in both arms achieving ALT normalisation at week 52 that was sustained up until week 104 (89.7% and 85.9% in the telbivudine and tenofovir arms, respectively) (Figure 4).

The results at week 104 by baseline viral load are presented in Figure 4.

ALT normalisation at week 104 in the rITT population according to the requirement for add-on therapy at week 24: The proportion of patients who achieved ALT

**Figure 4** Proportions of patients achieving aminotransferase normalisation, by visit and by baseline hepatitis B virus DNA levels (< 7 or ≥ 7 log<sub>10</sub> copies/mL), roadmap intent-to-treat population. ALT: Alanine aminotransferase; HBV: Hepatitis B virus.

normalization at week 24 was higher (telbivudine arm) or similar (tenofovir arm) in patients who received add-on therapy (Figure 3).

Maintained biochemical response at week 156 in the mITT population: ALT normalisation was maintained in 92.0% of patients in the telbivudine arm and 91.1% of patients in the tenofovir arm.

#### Patients experiencing VB and emergence of resistance in the rITT and mITT populations:

At weeks 52 and 104, respectively, in the rITT population, cumulative rates of VB were reported in 2.7% (3/113) and 9.7% (11/113) of patients in the telbivudine arm (3.3% and 12.4% in the monotherapy group, none in the add-on treatment group). In the tenofovir arm, no patients developed VB cumulatively at week 52 and 1.7% (2/117) of patients developed VB cumulatively at week 104.

At week 52, cumulative emergence of resistance was reported in 2.7% (3/113) of patients in the telbivudine arm (3.3% in the monotherapy group, none in the add-on treatment group) and no treatment-emergent resistance was observed in the tenofovir arm. At week 104, cumulative emergence of resistance was reported in 7.4% (8/108) of patients in the telbivudine arm (9.2% in the monotherapy group, none in the add-on treatment group) and none in the tenofovir arm.

In the telbivudine arm, 10 patients experienced VB and 5 had emergence of resistance between weeks 104 and 156 in the mITT population. In the tenofovir arm, only 1 patient had VB and none developed viral resistance. The cumulative rate of VB at week 156 was 16.5% (13/79) in the telbivudine arm, and 1.1% (1/89) in the tenofovir arm. Cumulative rates of resistance were 10.8% (8/74) in the telbivudine arm (14.0% in the monotherapy group, none in the add-on treatment group) and none in the tenofovir arm.

#### Safety

No patients died or experienced ALT flare during the

study. The overall incidence of serious AEs (SAEs) was similar in the telbivudine arm and in the tenofovir arm [11 (9.2%) patients and 13 (10.8%) patients, respectively]. One patient in the tenofovir arm reported drug-related SAEs [moderately increased blood creatine phosphokinase (CPK), mild arthralgia, and moderate fatigue], which led to temporary interruption of the study drug (Table 3). There were no cases of myositis or myopathy.

Two patients in the telbivudine arm and 5 patients in the tenofovir arm discontinued due to AEs [myalgia and hepatocellular carcinoma (HCC) for telbivudine; headache, HCC, hepatic cirrhosis, cholestatic jaundice, and breast cancer for tenofovir], which were assessed by the investigator as unrelated to the study drugs. Most AEs were mild to moderate in severity. The proportion of patients reporting at least 1 AE, regardless of study drug relationship, was similar for telbivudine and tenofovir arms. The overall incidence of AEs suspected to be related to study drug was somewhat higher in the telbivudine arm compared with the tenofovir arm. The most frequent (≥ 2%) drug-related AEs reported in both arms are described in Table 3. Increased blood CPK levels [31 (25.8%) patients], myalgia [8 (6.7%) patients, and nausea 8 (6.7%) patients] were the drug-related AEs that were observed more frequently in the telbivudine arm compared with the tenofovir arm [16 (13.3%), 0, and 2 (1.7%) patients, respectively]. AEs of special interest were observed in 46 (38.3%) patients in the telbivudine arm and 27 (22.5%) patients in the tenofovir arm. These included elevated blood CPK and myalgia as the most commonly reported AEs in the telbivudine arm, and elevated blood CPK and ALT as the most commonly reported AEs in the tenofovir arm. Myalgia suspected to be drug related was reported in the telbivudine arm. The number of patients experiencing at least 1 muscle event along with 1 new-onset abnormal CPK episode during the study was greater in the telbivudine arm (Table 3).

The telbivudine arm showed a higher incidence of Grade 3/4 CPK elevations during the study than the tenofovir arm [19 (15.8%) patients vs 5 (4.2%) patients, respectively]. All Grade 3/4 CPK elevations were resolved (Table 3).

Telbivudine monotherapy (as of week 24) was associated with a significant improvement in eGFR as compared with tenofovir monotherapy (as of week 24). At week 24, the telbivudine monotherapy showed a statistically significant ( $P = 0.0798$ ) improvement from baseline in eGFR compared to worsening with tenofovir monotherapy, with least squares mean percentage changes from baseline of 2.46% vs -1.17%, respectively. Further improvement in eGFR in the telbivudine monotherapy group (as of week 24) was observed at weeks 52 (4.90% vs -2.68% with tenofovir,  $P = 0.0098$ ), 104 (5.54% vs -5.36%,  $P < 0.0001$ , respectively), and 156 (9.55% vs -6.23%,  $P < 0.0001$ , respectively) (Figure 5).

There was no significant change in vital signs from baseline for either treatment arm.

**Table 3** Summary of safety results, safety population *n* (%)

Safety parameters	Telbivudine			Tenofovir		
	Monotherapy ( <i>n</i> = 98)	Intensification with tenofovir ( <i>n</i> = 22)	Overall ( <i>n</i> = 120)	Monotherapy ( <i>n</i> = 109)	Intensification with telbivudine ( <i>n</i> = 11)	Overall ( <i>n</i> = 120)

## DISCUSSION

NAs given as a single daily oral dose are considered the mainstay of CHB treatment<sup>[13]</sup>. In clinical practice, attaining optimal efficacy with a low emergence of drug resistance remains an important goal<sup>[14]</sup>. The roadmap concept utilizing add-on therapy for patients who do not achieve HBV DNA < 300 copies/mL at week 24 (in particular for agents with lower barriers to resistance) has been identified as a strategy to achieve this goal. This study was the first prospective, randomised clinical trial using the roadmap concept in HBeAg-negative CHB patients comparing efficacy and safety of telbivudine with tenofovir. As previously reported<sup>[15]</sup>, early detection of virologic response may be a useful guide to individualize CHB treatment. This study confirmed that monitoring virologic response at week 24 is a strong predictor of the treatment response by week 104<sup>[16]</sup>. These data were consistent with an earlier study comparing telbivudine with lamivudine<sup>[15]</sup>.

In the real-world setting, use of the roadmap concept may offer several advantages such as early identification of patients with suboptimal responses to initiate an appropriate change in therapy<sup>[10,11]</sup>, and to provide clinicians with options for individualized treatment decisions<sup>[5]</sup>. Although emergence of resistance had been identified as

an issue for HBeAg-negative CHB patients treated with telbivudine monotherapy<sup>[15,17]</sup>, the data from our study suggest that the risk for resistance is lower if telbivudine is administered using the roadmap concept, as compared to the GLOBE trial showing higher rates of resistance<sup>[15]</sup>. Moreover, despite a somewhat higher percentage of patients requiring add-on therapy in the telbivudine arm, the overall efficacy profile of the 2 roadmap approach arms was comparable, as assessed by the percentages of patients achieving HBV DNA levels < 300 or < 169 copies/mL, and ALT normalisation at weeks 52, 104 and 156. Moreover, telbivudine treatment resulted in a statistically significant reduction in serum HBsAg levels from baseline while no change was reported in quantitative HBsAg during therapy with tenofovir.

Overall, both treatments based on the roadmap concept were well tolerated over the 156 wk treatment period in HBeAg-negative patients. Although myalgia and elevated blood CPK levels were reported in a higher number of patients in the telbivudine arm, the rates were consistent with the findings reported earlier in the literature<sup>[12,15,18,19]</sup>. It is recommended that serum CPK levels should be monitored closely during treatment with telbivudine<sup>[20]</sup>.

Renal safety issues with oral NAs have been well-documented<sup>[21-23]</sup>. Particularly, adefovir is considered to

**Figure 5** Changes in estimated glomerular filtration rate over time with telbivudine and tenofovir, safety population. eGFR: Estimated glomerular filtration rate; MDRD: Modification of diet in renal disease.

have high potential for nephrotoxicity and tenofovir has been associated with this risk<sup>[24]</sup>. In our study, telbivudine was associated with improvement in eGFR from baseline to week 156 compared to the increasing deterioration over time with tenofovir. The finding of improvement in eGFR with telbivudine treatment was consistent with that reported in previous studies where telbivudine significantly improved while adefovir and lamivudine worsened renal function<sup>[25,26]</sup>. CHB patients with impaired renal function at baseline have also shown an eGFR improvement after 1 year<sup>[27]</sup> and 2 years of treatment with telbivudine<sup>[11,28]</sup>. Similar results for telbivudine have also been reported in patients with cirrhosis, patients with compensated cirrhosis, or patients with no cirrhosis<sup>[29,30]</sup>. These findings imply that telbivudine may offer benefit in patients with known or at risk of renal impairment. Although telbivudine improves renal function, the mechanism of this renal protective effect remains to be determined<sup>[31]</sup>.

The main limitations of the study are related to its design (open-label) and the relatively small sample size.

In conclusion, this study was the first prospective, randomised, comparative study of telbivudine-roadmap vs tenofovir-roadmap concept in HBeAg-negative patients with CHB. Both treatments based on the roadmap concept were effective over the 156 wk treatment period. Moreover, telbivudine showed an improvement in eGFR from baseline while a deterioration was observed with tenofovir; this could be an important consideration for long term therapy in CHB patients especially in those with a high risk for renal impairment.

## ACKNOWLEDGMENTS

The authors acknowledge the work of the OPTIMA investigators and participating institutions located in various countries. The investigators included Peter Ferenci and Wolfgang Vogel (Austria); Rozalina Balabanska, Jordan Genov, and Krum Katarov (Bulgaria); Thomas Berg, Peter Buggisch, Heinz Hartmann, Hartwig Klinker, Jens Rasenack, Hans Wedemeyer, and Stefan Zeuzem

(Germany); Evangelos Akriviadis, Alexandra Alexopoulou, Ioannis Elefsiniotis, and Konstantinos Mimidis (Greece); Evangelista Sagnelli (Italy); Djamal Abdurakhmanov, Pavel Bogomolov, Vladimir Chulanov, Marina Maevskaya, Maria Matsievich, Igor Nikitin, Olga Znoiko, and Konstantin Zhdanov (Russia); Maria Buti Ferret, Jose Luis Calleja, Albert Pardo, and Ricard Sola Lamoglia (Spain); Ulus Akarca, Iftihar Koksak, and Fehmi Tabak (Turkey). ## COMMENTS

### Background

Hepatitis B virus (HBV) infection is the major cause of chronic hepatitis worldwide. Emergence of resistance due to prolonged nucleos(t)ide analogue use or incomplete suppression of HBV still remains an important concern. Therefore, early virologic response at week 24 of therapy has been used to predict better outcomes and to reduce the risk of antiviral resistance.

### Research frontiers

This study used the response-guided add-on strategy (roadmap concept). For patients with HBV DNA  $\geq 300$  copies/mL ( $\geq 51$  IU/mL) at week 24, tenofovir was added to telbivudine by week 26 in the telbivudine arm, and telbivudine was added to tenofovir by week 26 in the tenofovir arm. For patients with HBV DNA  $< 300$  copies/mL at week 24, telbivudine and tenofovir monotherapies in the respective arms were continued.

### Innovations and breakthroughs

This was the first prospective, randomised, 2-arm, open-label, non-inferiority study in hepatitis B e antigen (HBeAg)-negative chronic hepatitis B (CHB) patients that compared telbivudine and tenofovir administered as per the roadmap concept. The safety of the combination of telbivudine and tenofovir, for which limited data are currently available, was also evaluated.

### Applications

Efficacy was shown for both telbivudine-roadmap and tenofovir-roadmap regimens in HBeAg-negative CHB patients over 156 wk. Both treatments showed acceptable safety profiles. In addition, the telbivudine arm was associated with renal improvement.

### Peer-review

This is an extensive randomised study to compare the roadmap treatment strategy between telbivudine and tenofovir in patients with HBeAg-negative CHB patients. As antiviral treatment may be life-long, renal protection becomes an important consideration. The current manuscript should be of benefit to the hepatologists and liver transplantation specialists worldwide.

### Abstract

Polyarteritis nodosa (PAN) is one of the systemic vasculitis that affects the media wall of arteries of small and medium diameter. Diagnosis proves difficult due to the unspecific symptoms that dominate the clinical profile. Liver involvement is very diverse, ranging from the development of cirrhotic liver disease to acute abdomen presentation that requires surgery because of liver rupture. The management of these patients requires an expert multidisciplinary team. There are several cases in the literature that describe a sudden liver rupture as the first manifestation of a PAN. In this paper we present the case of a 75 years old patient without any previous disease, who is subjected to major hepatic resection for spontaneous liver rupture.

**Key words:** Polyarteritis nodosa; Spontaneous liver rupture; Liver surgery; Vasculitis; Rheumatology

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Spontaneous liver rupture is a rare entity with very few cases in the literature reviewed; even when it has an autoimmune disease such etiology and with no previous trauma. We present our experience managing an urgent abdominal hemorrhage caused by a liver rupture as a first manifestation of Polyarteritis in a 75-year-old woman.

Spontaneous liver rupture as first sign of polyarteritis nodosa. *World J Hepatol* 2016; 8(32): 1414-1418 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i32/1414.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i32.1414>

## INTRODUCTION

The first International Chapel Hill Consensus Conference of Rheumatological Diseases defined polyarteritis nodosa (PAN) as a systemic necrotizing vasculitis of arterial tunica media of small and medium sized arteries without the presence of any glomerulonephritis or vasculitis in arterioles, venules and capillaries or without association with anti-cytoplasmic neutrophil antibodies positivity<sup>[1]</sup>.

PAN is a common systemic vasculitis generally involving several organs such as kidneys, skin, central and peripheral nervous system and the gastrointestinal tract. The certain diagnosis is a complex task because of nonspecific laboratory tests and clinical features; therefore it must be based on histopathological analysis by biopsies.

The "American College of Rheumatology: Defined the criteria for the diagnosis of PAN in 1990<sup>[2]</sup>. To diagnose a PAN the patient must have 3 characteristics out of a list of 10 features, estimating a diagnostic sensitivity of 82.2% with a specificity of 86.6% (Table 1).

Liver involvement in this disease is uncommon and difficult to diagnose. Hepatomegaly (21%), jaundice (12%) and alteration of biochemical liver-function markers (6%) have been reported in the literature in different publications<sup>[3]</sup>. The development of this type of autoimmune disease has been associated to positive hepatitis B surface antigen (HBsAg), although the exact etiology is unclear. It is reported that HBsAg positive patients may have a better response to treatment and therefore better prognosis<sup>[4]</sup>. In addition, PAN may cause aneurysm development due to fibrotic arterial lumen occlusion and necrosis, including organs such as liver, spleen and kidneys. These may derive in chronic abdominal pain, gastrointestinal bleeding, stroke, intestinal perforation and even pancreatitis. In some cases infarction and hemorrhage may occur, causing hemoperitoneum bearing a poor prognosis.

Very few cases have been published to date in which spontaneous hepatic rupture would be the first clinical manifestation; even when it has an autoimmune disease such etiology and with no previous trauma.

We present our experience managing an urgent abdominal hemorrhage caused by a liver rupture as a first manifestation of PAN in a 75-year-old woman.

## CASE REPORT

A 75-year-old woman with no previous medical history except chronic anemia and well-controlled arterial hypertension with outpatient follow-up. She is referred for transfusion from another hospital because of a severe anemia. The patient reported feeling general malaise with unmeasured fever several days before. No nausea or gastrointestinal symptoms were noted.

On examination the patient's blood pressure was near the low end of normality without tachycardia. There was no neurological deficit, paraesthesia or loss of motor reflexes. The abdomen palpation proved pain predominantly in right quadrants, with some upper quadrant abdominal defense.

Blood tests found hemoglobin 6.7 g/dL with a hematocrit of 19.2% and white blood cell count of 18000 mm<sup>3</sup> (neutrophilia 70%). Coagulation tests showed an INR of 1.34 with a prothrombin activity of 54%. Liver function enzymes showed altered cytolysis enzymes (AST/ALT: 273/275 U/L) and cholestatic enzymes (GGT/FA: 90/159 U/L); bilirubin was within normal range. Other inflammatory parameters reflected reactive-C protein of 227.5 mg/dL.

With this scenario an abdominal computed tomography scan was performed (Figure 1) where liver damage was reported in the form of a right hepatic lobe lesion with poorly defined and confluent contours, heterogeneous density and hypodense predominance. There was also a heterogeneous subcapsular and subhepatic collection, with some hyperdense areas that could be a hematoma, along with a moderate amount of intraabdominal free fluid.

In this context an exploratory laparotomy was performed. There was a bleeding liver injury involving the inferior segments of the right hepatic lobe (segments V-VI), the source of this bleeding was difficult to identify. Hemoperitoneum was present in all abdominal quadrants. An urgent right hepatectomy was executed. The patient received four red cell concentrates in the perioperative care and no vasoactive drugs were necessary.

The postoperative was otherwise uneventful with only a persistent leukocytosis outstanding, without any other signs of sepsis. White blood cell count was normal at the time of discharge.

The pathology report described the existence of an inflammatory and haemorrhagic abscess with a volume of 10 cm × 7 cm × 2 cm as the cause of the hemoperitoneum. The remaining liver parenchyma appeared normal.

In the microscopic study, the liver specimen was compatible with nongranulomatous acute necrotizing vasculitis (Figure 2). The gallbladder sample (Figures 3 and 4) showed acute vasculitis with fibrinoid necrosis in

**Table 1** For classification purposes, a patient shall be said to have polyarteritis nodosa if at least 3 of these 10 criteria are present

Criteria diagnosis of polyarteritis nodosa	
Weight loss	Loss of 4 kg or more of body weight since illness began, not due to dieting or other factors
Livedo reticularis	Mottled reticular pattern over the skin or portions of the extremities or torso
Testicular pain or tenderness	Pain or tenderness of the testicles, not due to infection, trauma, or other causes
Myalgias, weakness or leg tenderness	Diffuse myalgias (excluding shoulder and hip girdle)
Mononeuropathy or polyneuropathy	Development of mononeuropathy, multiple mononeuropathies, or polyneuropathy
Diastolic BP > 90 mmHg	Development of hypertension with diastolic BP higher than 90 mmHg
Elevated BUN or creatinine	Elevation of BUN > 40 mg/dL or creatinine > 1.5 mg/dL, not due to dehydration or obstruction
Hepatitis B virus	Presence of hepatitis B surface antigen or antibody in serum
Arteriographic abnormality	Arteriogram showing aneurysms or occlusions of the visceral arteries, not due to arteriosclerosis, fibromuscular dysplasia, or other noninflammatory causes
Biopsy of small or medium-sized artery containing PMN	Histologic changes showing the presence of granulocytes or granulocytes and mononuclear leukocytes in the artery wall

BP: Blood pressure; BUN: Blood urea nitrogen; PMN: Polymorphonuclear neutrophils.

**Figure 1** Computed tomography scan of the liver.**Figure 2** Liver (hematoxylin and eosin; × 40 original magnification): Bleeding, abscesses and avascular necrosis.

muscular arteries of parietal medium caliber. All these findings are compatible with PAN type vasculitis.

In the year of follow-up after the surgery, the patient has been treated with prednisone and cyclophosphamide with good results. Outpatient blood tests were negative for HBsAg and the autoimmunity study revealed positive antinuclear antibodies. After two months cyclophosphamide was discontinued because of pancytopenia, with the patient reaching a full recovery after drug suspension. Currently, one year after diagnosis, treatment consists of 10 mg of prednisone once a day, the patient is asymptomatic.

## DISCUSSION

The diagnosis of PAN is presented as a challenge for the clinical practice. This is because it has mainly nonspecific symptoms, which may involve more than one organ and the absence of specific serological tests for this disease. PAN usually appears as a chronic disease with periods of remission and deterioration<sup>[5]</sup>.

Hepatic involvement may be of a PAN clinical profile. Different clinical entities have been described in the literature ranging from chronic liver failure and cirrhosis to acute hepatitis, hepatic regeneration

nodules and vascular and bile-duct complications. In most cases the pathogenesis involves immune complex depositions leading to obstruction in hepatic blood flow and obliteration of small vasculature resulting in aneurysm formation (13%-60%)<sup>[6-8]</sup>. These may cause complications of difficult diagnosis. Most patients are asymptomatic at the moment of diagnosis and only 10%-15% of patients with hepatic artery aneurysms have presenting symptoms, such as abdominal pain, gastrointestinal bleeding or cholestasis<sup>[9]</sup>.

Spontaneous intrahepatic hemorrhage caused by the rupture of a hepatic artery aneurysm is a rare complication of PAN, however it has a high mortality<sup>[10,11]</sup>. There are about fifteen reported cases in which the diagnosis of PAN was learned due to hemodynamic instability secondary to spontaneous hepatic rupture that required an urgent laparotomy, as in the case presented.

There are different options when deciding how to manage these patients. Some of the reported cases resolved the bleeding using vascular radiology techniques with selective artery embolization<sup>[12,13]</sup>. In other patients with hemodynamic stability expectant attitude was decided, administering blood transfusion after corticosteroid and immunosuppressive treatment<sup>[12,14-16]</sup>.

**Figure 3** Gallbladder (hematoxylin and eosin; × 40 original magnification): Acute vasculitis.

**Figure 4** Gallbladder (hematoxylin and eosin; × 100 original magnification): Acute vasculitis with fibrinoid necrosis in muscular arteries of parietal medium caliber.

In those cases in which surgical management was decided, most did not do any type of liver resection, opting for hepatic parenchyma hemostasis and packing<sup>[4,5]</sup> with high mortality rate.

In one case reported<sup>[17]</sup> a right hepatectomy surgery was performed on a 20-year-old with severe bleeding. This patient died after 12 wk because of several complications after surgery.

This article presents the first case in which an urgent major hepatectomy for treatment of a liver rupture secondary to a previously unknown PAN is performed. In this case the patient is still alive after approximately one year has passed without any kind of complication.

Early and proper diagnosis is decisive in this disease when it is not presented acutely as in the case presented. For this reason, a whole and exhaustive history is required. To confirm the diagnosis of PAN a pathological study is crucial. The biopsy can be obtained from muscle tissue. In cases where the biopsy can not be performed or it is assumed that it would be negative, arteriography is mandatory to confirm the presence of aneurysms<sup>[18]</sup>. After that, treatment with steroids and immunosuppressive drugs has been found to eliminate all clinical manifestations of the disease. Decrease of the aneurysm size and its risk of rupture has been described with this treatment<sup>[12]</sup>.

The paper was supported by Reina Sofía University Hospital, 14004 Córdoba, Spain (Andalusia Public Health Service).

## COMMENTS

### Case characteristics

The patient reported feeling general malaise with unmeasured fever and she feels pain predominantly in right quadrants on the abdomen.

### Clinical diagnosis

The most frequent at the beginning of disease symptoms are fever, weight loss, muscles pain, peripheral neuropathy, gastrointestinal disorders and skin lesions.

### Differential diagnosis

For diagnosis, the criteria established by the American College of Rheumatology are often used, a high clinical suspicion, a biopsy showing vasculitis or arteriography showing aneurysms.

### Laboratory diagnosis

The increased erythrocyte sedimentation rate and C-reactive protein is practically constant during the active phase of the disease. Other common findings are leukocytosis, eosinophilia, and normochromic anemia.

### Imaging diagnosis

Is useful to perform an arteriography or reconstructions high-quality computed tomography (CT)-scan imaging that showing the presence of aneurysms or occlusions of visceral arteries not display due to arteriosclerosis?

### Pathological diagnosis

Histological alterations show granulocytes or granulocyte and mononuclear leukocytes into the arterial wall of medium diameter.

### Treatment

The treatment has undergone major changes in recent years although cyclophosphamide remains the cornerstone despite its side effects, there are promising new therapies such as biologic therapies.

### Related reports

There are several cases in the literature related to liver rupture due to polyarteritis nodosa (PAN) them out various treatment are carried with different results. There is so far an established treatment for this type of clinical presentation. The decision is based on the clinical condition of the patient and therapeutics means available in the hospital.

### Term explanation

The patient had low suspicion of vasculitis, but had a history of hypertension, the presence of aneurysms in the CT-scan and a PAN conclusive biopsy. The hepatitis B surface antigen was negative and antinuclear antibodies were positive. It shows the difficult diagnosis of this disease and the need for a broad differential diagnosis.

### Experiences and lessons

In this case report, the authors show an uncommon PAN debuts with a spontaneous liver rupture as first symptom that requires urgent liver major resection in a patient without previous clinical manifestations.

### Peer-review

This case report describes spontaneous liver rupture due to polyarteritis nodosa

which was treated by surgical intervention. The paper is well written.

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

**FLYLEAF**

### Abstract

Primary biliary cholangitis (PBC), formerly referred to

as primary biliary cirrhosis, is an infrequent progressive intrahepatic cholestatic autoimmune illness that can evolve into hepatic fibrosis, hepatic cirrhosis, hepatic failure, and, in some cases, hepatocellular carcinoma. The disease itself is characterized by T-lymphocyte-mediated chronic non-suppurative destructive cholangitis and elevated serum levels of extremely specific anti-mitochondrial autoantibodies (AMAs). In this article, we will not only review epidemiology, risk factors, natural history, predictive scores, radiologic approaches (*e.g.*, acoustic radiation force impulse imaging, vibration controlled transient elastography, and magnetic resonance elastography), clinical features, serological characteristics covering biochemical markers, immunoglobulins, infections markers, biomarkers, predictive fibrosis marker, specific antibodies (including AMAs such as AMA-M2), anti-nuclear autoantibodies [such as anti-multiple nuclear dot autoantibodies (anti-sp100, PML, NDP52, anti-sp140), anti-rim-like/membranous anti-nuclear autoantibodies (anti-gp210, anti-p62), anti-centromere autoantibodies, and some of the novel autoantibodies], histopathological characteristics of PBC, diagnostic advances, and anti-diastole of PBC. Furthermore, this review emphasizes the recent advances in research of PBC in terms of therapies, including ursodeoxycholic acid, budesonide, methotrexate, obeticholic acid, cyclosporine A, fibrates such as bezafibrate and fenofibrate, rituximab, mesenchymal stem cells transplant, and hepatic transplant. Currently, hepatic transplant remains the only optimal choice with acknowledged treatment efficiency for end-stage PBC patients.

**Key words:** Autoimmune liver diseases; Primary biliary cholangitis; Primary biliary cirrhosis; Diagnosis; Therapy

**Core tip:** Primary biliary cholangitis (PBC), previously called primary biliary cirrhosis, is an autoimmune non-suppurative inflammatory disease of the bile duct

that is usually complicated by intrahepatic cholestasis and intrahepatic bile ductule damage, and eventually leads to liver fibrosis and cirrhosis. This review will focus on the clinical, serological and histopathological characteristics of PBC, as well as the advances in the diagnosis and treatment of the disease.

Huang YQ. Recent advances in the diagnosis and treatment of primary biliary cholangitis. *World J Hepatol* 2016; 8(33): 1419-1441 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i33/1419.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i33.1419>

## INTRODUCTION

Primary biliary cholangitis (PBC)<sup>[1-8]</sup> is a relatively rare chronic intrahepatic cholestatic illness characterized by a T-lymphocyte-mediated attack on small intralobular biliary ducts and the presence of elevated plasma concentrations of specific anti-mitochondrial antibodies (AMAs), resulting in hepatic fibrosis and, ultimately, hepatic cirrhosis or hepatic failure, with the potential for hepatic cellular carcinoma *via* complications<sup>[9-11]</sup>. PBC predominantly affects women, at a ratio of approximately 12:1 of women to men, who are normally diagnosed at middle-age, primarily in an initial symptomless early stage<sup>[9-12]</sup>. There is positive association between the national incidence of PBC and socioeconomic status, as estimated by the Human Development Index (HDI)<sup>[13]</sup>. Moreover, in less-developed countries, the incidence of PBC might be less common<sup>[13]</sup>. Fatigue and pruritus are incipient clinical manifestations that appear in approximately 20% of PBC patients<sup>[14]</sup>. Although the clinical presentation and natural disease history of PBC patients have progressively improved over the years due to the recognition of earlier widespread use of ursodeoxycholic acid (UDCA), about 1/3 of PBC patients display suboptimal biochemical responses to UDCA and a poor prognosis<sup>[9-12]</sup>. At present, hepatic transplant remains the most beneficial therapeutic modality for patients with end-stage PBC<sup>[9-12]</sup>. This article will focus on the epidemiology, risk factors, clinicopathologic characteristics, serological features, histopathological characteristics, radiologic evaluation approaches, diagnosis, and differential diagnosis, as well as recent advances in the therapy of PBC.

## ALTERED TERMINOLOGY FOR PBC: FROM “PRIMARY BILIARY CIRRHOSIS” TO “PRIMARY BILIARY CHOLANGITIS”

The disorder generally referred to currently as “primary biliary cirrhosis” was primitively depicted in 1851, but not formally named until 1950<sup>[1-8]</sup>. However, it was later rightly recognized that the application of the terminology “primary biliary cirrhosis” is for a catachresis

in patients in the presence of early-stage disease and histopathological characteristics of non-suppurative destructive cholangitis that are usually complicated with intrahepatic cholestasis and intrahepatic bile ductule damage. In recent decades, the prognosis of PBC patients has been observably ameliorated since the disease entity was first described more than 150 years ago due to the application of UDCA. Since a great number of PBC patients do not suffer from hepatic cirrhosis, this tag has perceptibly disrupted many PBC patients, who strive for more accurate nomenclature<sup>[1-8]</sup>. At the second European Association for the Study of the Liver (EASL) monothematic conference on “primary biliary cirrhosis” in 2014, representatives of multitudinous patient cohorts from a variety of countries worldwide requested altering the eponym “cirrhosis” to another that would more precisely represent the characteristics of the disorder<sup>[1-8]</sup>. From the point of view of the patient, the eponym “cirrhosis” is misdirecting in some ways, and may result in stigmatization and confusion with alcoholic cirrhosis, as well as a shortage of transparency with regards to the stage and prognosis of the disease. From the physician’s perspective, misapplication of the terminology “cirrhosis” is counter-productive to their job. In order to assist and cure patients both within and without the hospital setting who are trying to balance their private lives with their medical demands, it is vital that the term “cirrhosis” be changed<sup>[1-8]</sup>. The suggested change of “cirrhosis” to “cholangitis” was ratified by the EASL in November 2014, by the American Association for the Study of Liver Diseases in April 2015, and by the AGA in July 2015, respectively<sup>[1-8]</sup>. In order to inform more people worldwide regarding this change, an article was published in 2015 titled “Changing nomenclature for PBC: From “cirrhosis” to “cholangitis” ” in various well-known international medical journals, such as *Gastroenterology*, *Am J Gastroenterol*, *Gut*, *Hepatology*, *J Hepatol*, *Dig Liver Dis*, *Clin Res Hepatol Gastroenterol*, and *Clin Gastroenterol Hepatol*<sup>[1-8]</sup>. Adopting the terminology “primary biliary cholangitis” for the illness known by the acronym PBC is therefore long overdue, so as to bring it into correspondence with a very recent global consensus.

## Epidemiology

Epidemiology provides significant clues towards our comprehension of the unsearchable etiopathogenesis of PBC. In the past two decades, there have been a chain of epidemiological retrospective investigations concerning patients with PBC<sup>[15-22]</sup>. The epidemiology of PBC has not only changed significantly over the past twenty years, with a trend towards increasing prevalence in many places around the world<sup>[15-22]</sup>, but is also positively correlated with the national HDI<sup>[13]</sup>. There is a positive, but not significant, correlation between PBC incidence and HDI on a global level ( $r = 0.348$ ,  $P = 0.082$ )<sup>[13]</sup>. However, in Europe, a significantly positive correlation exists between PBC incidence and HDI ( $r = 0.455$ ,  $P = 0.044$ )<sup>[13]</sup>. Moreover, the PBC incidence

is positively related to the health index ( $r = 0.422$ ,  $P = 0.036$ ), but negatively related to the education index ( $r = -0.650$ ,  $P < 0.01$ )<sup>[13]</sup>. The prevalence and incidence rates of PBC patients have been reportedly augmenting annually worldwide, making changing the name “cirrhosis” vital<sup>[15-22]</sup>. A study in the United States showed that, during the period of 1975-1995, the overall age and sex-adjusted incidence rate of PBC was 27/1000000 per year, with the incidence in female and male populations being 45/1000000 and 7/1000000 per year, respectively<sup>[15]</sup>. In 1995, the age- and sex-adjusted prevalence was 654/1000000 for women, 121/1000000 for men, and 402/1000000 overall<sup>[15]</sup>. A study in Canada revealed that, from 1996 to 2002, the overall age and sex-adjusted incidence rate of PBC was 30.3/1000000 per year (female: 48.4/1000000, male: 10.4/1000000); the prevalence was 100/1000000 in 1996 and 227/1000000 in 2002<sup>[16]</sup>. A study in Lombardy, Italy and in Denmark suggested that during 2000-2009, the overall age and sex-adjusted incidence rate of PBC in Lombardy was 16.7/1000000 per year (female-to-male ratio 2.3:1), the point prevalence in Lombardy was 160/1000000 in 2009, the incidence of PBC in Denmark was 11.4/1000000 per year (female-to-male ratio 4.2:1), and the point prevalence in Denmark was 115/1000000 in 2009<sup>[17]</sup>. A study in Crete, Greece showed that, from 1990 to 2010, the incidence of PBC was 20.88/1000000, and the prevalence was 365/1000000<sup>[18]</sup>. A study in the Netherlands demonstrated that, between 2000 and 2008, the incidence of PBC was 11/1000000 (3/1000000 in men and 19/1000000 in women) and the point prevalence in 2008 was 132/1000000<sup>[19]</sup>. A study in Iceland indicated that the point prevalence in 2010 was 383/1000000, while the age-standardized rate of incidence for female patients in the 1<sup>st</sup> (1991-2000) and 2<sup>nd</sup> phases (2001-2010) were 34/1000000 and 41/1000000, respectively<sup>[20]</sup>. Overall incidence rates in the 1<sup>st</sup> and 2<sup>nd</sup> phases were 20/1000000 and 25/1000000, respectively<sup>[20]</sup>. Although the prevalence of PBC was higher in some regions of North America and northern Europe, it was rarely seen in Australia. A study in Australia demonstrated that the age-adjusted prevalence rate of PBC was 51/1000000<sup>[21]</sup>. A study in South Korea revealed that, between 2009 and 2013, the age and sex-adjusted incidence of PBC from 2011 to 2013 was 8.57/1000000 per year (ratio of female to male was 6.2:1), while the age and sex-adjusted prevalence rate from 2009 to 2013 was 47.50/1000000<sup>[22]</sup>. At the time of writing, there is still a notable lack of large, nationwide population-based solid epidemiological information concerning PBC in China. One study in China indicated that the point prevalence rate of adult PBC patients who received a health examination in southern China was 492/1000000, with the prevalence in women over 40 years old being up to 1558/1000000 (ELISA method)<sup>[23]</sup>. The overall prevalence of PBC reported by Liu *et al*<sup>[23]</sup> was much higher than previously reported in the literature, which was likely due to the methodology used in the study.

In general, the different prevalence and incidence rates of PBC reported in the aforementioned literature were mainly due to differences in assay methods, gender and age distributions of population groups, and geographic regions. There is presently no precise epidemiologic data on the prevalence of PBC in Africa, but it is speculated to be one of the lowest in the world.

## RISK FACTORS

To date, the pathogenesis of PBC remains largely unknown, although geographical distributions, genetic susceptibility, and environmental factors may be some potential risk factors for the disease<sup>[9-10]</sup>. Both familial clustering and monozygotic twins with an identical DNA sequence provided good evidence for its genetic susceptibility and high degree of consistency<sup>[11]</sup>. Environmental factors, such as smoking, drug abuse, and microbiome complexities, may play a vital role in breaking the immune tolerance of individuals with genetic susceptibility<sup>[9-11]</sup>. Furthermore, recent novel hypotheses on latent environmental triggers, such as chemical xenobiotics, which result in the breaking of self-tolerance within the unparalleled immunological environment of the liver, have also been suggested<sup>[11,12]</sup>. As PBC overwhelmingly affects females, factors such as major defects in sex chromosomes, abnormal genetic architecture, and epigenetic abnormalities strongly suggest an effect of genetic and epigenetic factors in the triggering and perpetuation of autoimmune aggression in PBC<sup>[9-12]</sup>. Several human leukocyte antigen (HLA) risk loci that provide prognostic information and a few non-HLA risk loci associated with the development of PBC have recently been confirmed by means of genome-wide association studies (GWAS)<sup>[24-31]</sup>. GWAS showed that *HLA-DQB1* (\*0402), *HLA-DRB1* genes (\*08,\*14), and *HLA-DPB1* gene (\*03:01) were predisposing risk alleles for PBC susceptibility<sup>[24,25]</sup>. Aside from the HLA locus, a number of non-HLA genes including *IL-12A* (*rs6441286*, *rs574808*), *IL-12RB2* (*rs3790567*), *STAT4*, *CD80*, *DENND1B*, *CXCR5*, *IL-7R*, *TNFRSF1A*, *NFKB1* and *CLEC16A* were also closely related to PBC susceptibility<sup>[24,26]</sup>. These data demonstrate not only that there are extraordinary associations between PBC and the usual heritable aberrance at HLA class II, *IL12A*, and *IL12RB2* loci, but also that the IL-12 immunoregulatory signaling axis plays an outstanding role in the physiopathology of PBC. Several recent GWAS have shown that some non-HLA genes, such as *STAT4* SNPs (*rs10168266*, *rs11889341*, *rs7574865*, *rs8179673*, *rs10181656*)<sup>[27]</sup>, *ESR2* *rs1256030* T allele<sup>[28]</sup>, *CLEC16A*, *SOC1*, *SPIB* and *SIAE* genes<sup>[29]</sup>, may also be significant risk factors for the progression of PBC. One study demonstrated that the downregulated expression of *IL-12A* in lymphoblastoid cell lines obtained from Han Chinese were markedly associated with the risk alleles of *rs4679868* and *rs6441286* ( $P = 0.0031$  and  $0.0073$ , respectively)<sup>[30]</sup>. Furthermore, the risk alleles of the 2 SNPs were observably related to a decreased expression

of *SCHIP1* gene that is 91.5 kb, located upstream of IL-12A and associated with susceptibility to celiac disease<sup>[30]</sup>. These data have disclosed the IL-12/JAK-STAT signaling pathway as a pivotal etiologic factor for PBC. In addition, the allele of rs79267778 was observably relevant to PBC<sup>[31]</sup>. The amino acid at position 1904 (NM\_001037335) from threonine (ACG) had been changed to methionine (ATG)<sup>[31]</sup>. This gene locus was exceedingly conservative in mammals and estimated to have the potential risk score of 0.469 by PolyPhen-2 (bioinformatics tools)<sup>[31]</sup>. PBC and gene expression were related to allele-specific transcription factor binding to usual and infrequent geno-variation<sup>[32]</sup>. DNA methylation analysis of the X chromosome exposes abnormal demethylation on CXCR3 promoter in PBC<sup>[33]</sup>. Furthermore, other associated risk factors include concurrent autoimmune disease, lifestyle factors (e.g., cigarette smoking), urinary tract infection, vaginal infection, and environmental influences (e.g., toxic and chemical exposure to such substances as nail polish and hair dye)<sup>[34-36]</sup>. In general, the close link between environment factors and genetic susceptibility may play a vital part in the epigenetic mechanisms of PBC.

### Clinical characteristics

Common clinical symptoms of PBC include fatigue, pruritus, weakness, daytime sleepiness, loss of weight, xanthelasma palpebrarum, jaundice, skin hyperpigmentation, upper abdominal discomfort, hepatosplenomegaly, osteodystrophy, osteoporosis, cholelithiasis, malabsorption syndrome, and extrahepatic manifestations of an autoimmune nature, although roughly 50% of PBC patients are asymptomatic at diagnosis<sup>[9-12]</sup>. Patients with PBC normally suffer from itching and fatigue, regardless of disease severity<sup>[14,37,38]</sup>. Serum fat-soluble vitamin D deficiency may be detected, particularly in advanced PBC patients<sup>[39,40]</sup>. Metabolic bone disease includes osteoporosis and, more rarely, osteomalacia, which have been considered important complications of PBC<sup>[41,42]</sup>. The extremely infrequent PBC complication of tubulointerstitial nephritis with Fanconi syndrome should be highly suspected in adult PBC patients in the presence of agnogenic haliteresis, even without the presence of abnormal liver function<sup>[41]</sup>. The serum levels of sclerostin were found to be observably increased in PBC patients in comparison with controls ( $P < 0.001$ ), while the hepatic mRNA overexpression of sclerostin and elevated serum levels of sclerostin were inversely related to osteogenesis and reabsorption biological markers<sup>[42]</sup>. In addition, liver sclerostin was mainly distributed in the bile ducts, was relevant to the seriousness of cholangitis ( $P = 0.02$ ), and was indirectly related to the extent of inflammation in the hepatic lobule ( $P = 0.03$ )<sup>[42]</sup>. These results indicated that sclerostin overexpression in the bile duct of patients with PBC in the presence of chronic intrahepatic cholestasis may affect metabolic osteopathia in PBC<sup>[42]</sup>. In general, although the main target organ is the liver, multiple systems may also be involved, such as interstitial lung

disease (ILD)-related pulmonary hypertension (PH) and esophageal dysfunction. PBC is also often accompanied by nephritis, connective tissue diseases (CTDs), hepatocellular carcinoma, and other rare diseases. The concurrence of these rare diseases often augments the difficulty in establishing an exact diagnosis. Specific clinical features are as follows.

### Fatigue

Fatigue is not an uncommon complaint of PBC patients, and is related to a lower quality of life<sup>[9-11]</sup>. In recent years, PBC is mainly diagnosed in the majority of patients who are asymptomatic<sup>[9-11]</sup>. However, fatigue is a significant problem in approximately 50% of PBC patients, with 20% of all PBC patients experiencing significant or life-altering fatigue<sup>[9-11]</sup>. The pathogenesis of fatigue in PBC has not been fully elucidated, although it isn't relevant to the seriousness of the underlying illness and is unresponsive to UDCA<sup>[9-11]</sup>. As the symptom of fatigue is non-specific, multifactorial, and potentially incapacitating, conditions such as anemia, diabetes, hypothyroidism, and depression should be considered and excluded<sup>[9-11]</sup>. Fatigue is typically identified with a subset of PBC patients who are predominantly young women who have particularly active illness, a suboptimal response to UDCA therapy, and are more likely to develop hepatic cirrhosis and its complications<sup>[37]</sup>. At present, there is no special drug therapy for the management of PBC-related fatigue and no significant improvement following liver transplantation<sup>[9-11]</sup>. The clinical efficacy of modafinil in the treatment of PBC-related fatigue for 12 wk has been proved to be secure and reasonably well-tolerated in randomized, placebo-controlled, phase II clinical trials<sup>[38]</sup>. Nevertheless, it did not give rise to an advantageous impact on fatigue when compared to a placebo-treated group<sup>[38]</sup>.

### Pruritus

Pruritus is a pre-eminent symptom in PBC patients with chronic cholestasis and is variably reported in PBC characterized by cholestasis<sup>[9-11,14]</sup>. More than two-thirds of PBC patients experience pruritus during the process of the illness<sup>[9-11]</sup>. Compared to asymptomatic PBC patients without pruritus, symptomatic PBC patients with pruritus more frequently suffer from hepatic cirrhosis and its related complications ( $P = 0.004$ )<sup>[37]</sup>, and are less likely to respond to UDCA treatment ( $P = 0.006$ ). The pathogenesis of cholestatic pruritus remains largely elusive<sup>[9-11]</sup>; its natural history, related pathogenesis, and molecular mechanisms are under continued investigation<sup>[9-11]</sup>. The autotaxin (ATX)-lysophosphatidic acid signaling axis may play a vital part in the nosogenesis of pruritus, and has lately has been connected with pruritus in PBC<sup>[14]</sup>. Several pieces of evidence have showed that a circulating pruritogen will take responsibility for it, but identification of the small molecule has yet to be ultimately identified<sup>[14]</sup>. In comparison, plasma ATX activity is observably associated with pruritus in PBC,

suggesting a new molecular targeting therapy<sup>[14]</sup>.

## FAT-SOLUBLE VITAMIN DEFICIENCY

Malabsorption, steatorrhea, and fat-soluble vitamin D deficiency are uncommon, except in cases of advanced liver disease and long-standing, severe cholestasis<sup>[9,10,39,40,43]</sup>. In addition to vitamin D deficiency, as luminal bile acid levels in severe cholestasis are below the critical concentration required for micelle formation and subsequent lipid absorption, clinically-relevant fat-soluble vitamin (vitamin A, E and K) deficiencies may also exist in PBC<sup>[43]</sup>. Deficiencies in fat-soluble vitamins A, D, E and K have been reported in 33.5%, 13.2%, 1.9% and 7.8% of PBC patients, respectively<sup>[43]</sup>. Vitamin A deficiency appears to be markedly associated with advanced PBC stage, decreased cholesterol, and increased Mayo risk score<sup>[43]</sup>. High Mayo risk score, low serum albumin level, and elevated total bilirubin have been shown to be independently related to vitamin D deficiency<sup>[43]</sup>. Baseline vitamin D deficiency was associated with severity of disease and response to UDCA treatment<sup>[39]</sup>. Serum 25(OH)D concentrations reduced with elevating histological grading of stage ( $P = 0.029$ ) and were inversely associated with serum bilirubin and alkaline phosphatase (ALP) concentrations in PBC<sup>[39]</sup>. Serum 25(OH)D concentration at baseline was observably reduced in non-responders to UDCA ( $P = 0.005$ )<sup>[39]</sup>. Baseline vitamin D deficiency was related to an elevated risk of an inappropriate response with no relationship to advanced histological stages ( $P = 0.047$ )<sup>[39]</sup>. Mean serum concentrations of vitamin D were observably reduced among PBC patients compared to the control group ( $P = 0.029$ ) and vitamin D deficiency ( $\leq 10$  ng/mL) was observed in 33% of PBC patients vs 7% of the control group ( $P < 0.0001$ )<sup>[40]</sup>. Vitamin D concentrations were negatively associated with advanced hepatic injury, as well as the existence of accompanying autoimmune disorders<sup>[40]</sup>. The potential role of vitamin D in PBC may involve genetic and cell signaling mechanisms. Relatively few PBC patients have vitamin E or K deficiencies<sup>[43]</sup>.

### **PBC complicated with portal-venous hypertension**

Portal-venous hypertension is not an uncommon aftermath of PBC, and may even occur before cirrhosis develops in PBC patients<sup>[9-11]</sup>; approximately 10% of PBC patients presented with characteristics of portal hypertension as an initial clinical symptom<sup>[9-11]</sup>. Gastroesophageal varices may occur in any of the different histological phases of PBC<sup>[9-11]</sup>. Signs of portal hypertension should therefore be carefully observed for in PBC patients at the moment of diagnosis, as well as during the observation period<sup>[9-11]</sup>. The pathogenesis of portal hypertension in PBC is still unclear<sup>[9,10]</sup>. A recent study suggested sinusoidal blockage as a potential physiopathology mechanism during the early phases of PBC, which was verified by the obvious intrahepatic portal vein in 3 non-cirrhotic PBC patients, with intrahepatic portal vein hepatica interflow being responsible for relieving the hepatic venous pressure

gradient<sup>[44]</sup>. Another study indicates that angiogenetic and fibrotic responses are presumably induced by aquaporin-1 (AQP-1), resulting in the enhanced perfusion of arterial blood flow to the sinusoids<sup>[45]</sup>. The result demonstrates that AQP-1 is related to arterial capillary wall proliferation and hepatic sinusoidal transformation facilitating portal-venous hypertension in PBC<sup>[45]</sup>. Esophageal varicosities (EV) can be found in PBC patients with early histological stages<sup>[46,47]</sup>. A study revealed that 6% (8/127) of early histological stage PBC patients suffered from EV and 95% of PBC patients in the presence of varices were required to meet at least one of the following criteria: Male sex, hypoalbuminemia ( $< 3.5$  g/dL), hyperbilirubinemia ( $\geq 1.2$  mg/dL), and/or prolonged prothrombin time (PT) ( $\geq 12.9$  s)<sup>[46]</sup>. Therefore, these parameters that include male sex, hypoalbuminemia, hyperbilirubinemia, and/or PT can be used as a tool for non-invasive prediction of EV<sup>[46]</sup>. A study demonstrated that among 256 cases of PBC with early histological stage, 22 cases suffered from EV at the time of diagnosis, with elevated serum ALP levels and decreasing platelet counts being markedly related to the presence of EV in early histological stage PBC<sup>[47]</sup>. The prominent relationship between these two factors with the development of EV was also disclosed, and PBC with early-stage and elevated ALP ratios  $\geq 1.9$  had an observably high risk of progressing EV<sup>[47]</sup>. In addition, another study has shown that quantitative parameters in the diagnosis of hepatic fibrosis in portal, septal and fibrillar areas may accurately predict gastroesophageal varices in PBC; the diagnostic specificity and sensitivity in PBC was 75% and 100%, respectively<sup>[48]</sup>.

### **PBC complicated with PH**

PH is generally complicated by heart or lung disorders, but it is also known to be related to PBC<sup>[49]</sup>. PH that suggests poor prognosis as a complication of PBC is not only common, but is closely related to portal-venous hypertension and immunological dysregulation<sup>[49]</sup>. PH is significantly more frequent than was previously assessed in PBC patients with portal hypertension<sup>[49]</sup>. The risk of progressing PH could be enhanced with the persistent time of portal hypertension without any explicit relationship with the degree of portal hypertension, liver failure, or amount of blood shunted<sup>[49]</sup>. The prevalence rate of PH in PBC patients with portal hypertension has been reported by McDonnell *et al*<sup>[50]</sup> as 0.61% in a clinical series of 2459 PBC patients with biopsy-proved cirrhosis of the liver. PH associated with PBC without portal hypertension is very infrequent; among 178 PBC patients, 21 (11.8%) suffered from PH<sup>[49]</sup>. Four cases (19.0%) suffered from medium to severe PH and one died of right ventricular dysfunction rather than hepatic dysfunction<sup>[49]</sup>.

### **PBC complicated with esophageal dysfunction**

Esophageal dysmotility can exist in some PBC patients<sup>[51]</sup>, particularly in those with scleroderma or Sjögren's syndrome in the absence of scleroderma<sup>[51]</sup>. As a result, some

esophageal motor disturbances could be considered associated with Sjögren's syndrome<sup>[51]</sup>. Esophageal motor dysfunction is by no means uncommon in Sjögren's syndrome or scleroderma; however, whether any esophageal dysmotility also exists in PBC without Sjögren's syndrome or scleroderma is still controversial. A recent study showed that, among 37 PBC patients, 17 (45.9%) had esophageal dysmotility (10 cases of non-specific esophageal motor disorder, 5 cases of esophageal hypomotility, 1 case of nutcracker esophagus, and 1 case of hypertensive lower esophageal sphincter)<sup>[51]</sup>. These results demonstrate that sub-clinical esophageal motor dysfunction is common in PBC patients<sup>[51]</sup>.

### **PBC complicated with ILD**

ILD is a frequent and major complication of PBC<sup>[52,53]</sup>. PBC patients who suffer from Raynaud's phenomenon and other CTDs were considered to have the greater possibility of developing ILD<sup>[52,53]</sup>. PBC with concomitant Sjögren's syndrome was considered to have a higher risk of developing ILD and presenting a poor prognosis<sup>[53]</sup>. A study showed that, among 178 PBC patients, 28 (15.7%) suffered from ILD, with 53.6% said patients suffering from difficult breathing and tussis, and 88.2% demonstrating restrictive and diffusing ventilation impairment by means of pulmonary function test<sup>[52]</sup>. Patients with PBC in the presence of ILD were older in age and displayed higher serum levels of sedimentation rate of erythrocyte compared to those without ILD ( $P < 0.05$ )<sup>[52]</sup>. Raynaud's phenomenon, as well as the coexistence of PBC and CTDs, were considered to be risk factors for PBC patients developing ILD ( $P = 0.04$ , OR = 3.12 and  $P = 0.01$ , OR = 3.18, respectively), although 42.9% of patients with PBC in the presence of ILD had not suffered from other CTDs<sup>[52]</sup>. There was much higher incidence rate of ILD in PBC patients with concomitant Sjögren's syndrome compared to those without the syndrome ( $P = 0.005$ )<sup>[53]</sup>. In some instances, ILD can even appear to precede PBC<sup>[54]</sup>.

### **PBC complicated with nephritis**

Symptomless distal renal tubular acidosis should be considered the main feature of PBC-related kidney damage, and can appear in approximately 1/3 of PBC patients<sup>[55]</sup>. However, various rarer methods of PBC-associated kidney damage have also been described in the literature, including: Fanconi syndrome, microscopic polyangiitis, membranous nephropathy, membranous glomerulonephritis, tubulointerstitial nephritis, fibrillary glomerulonephritis, interstitial nephritis, Goodpasture syndrome, anti-neutrophil cytoplasmic autoantibody (ANCA)-associated rapidly progressive glomerulonephritis, and focal segmental glomerulosclerosis<sup>[41,56-64]</sup>.

### **PBC complicated by CTDs**

PBC can be complicated by CTDs, more specifically systemic lupus erythematosus (SLE), systemic sclerosis (SSc), rheumatoid arthritis (RA), Sjögren's syndrome

(SS), polymyositis (PM), and dermatomyositis<sup>[65]</sup>. Moreover, combined PBC and CTDs often enhance the difficulty in making an exact diagnosis and treatment of PBC<sup>[65]</sup>. One study showed that, among 322 patients with PBC, 150 cases (46.6%) suffered from CTDs, of which 11 cases (3.4%) suffered from two or more CTDs<sup>[65]</sup>. SS should be considered the most common CTD (122 cases, 36.2%)<sup>[65]</sup>. Other CTDs in this group of patients, in order of rarity from high to low, were as follow: 12 cases of SLE (3.7%), 10 cases of PM (3.1%), 9 cases of SSc (2.8%), and 9 cases of RA (2.8%)<sup>[65]</sup>.

### **PBC complicated by hepatocellular carcinoma**

It is by no means uncommon for PBC patients to suffer from hepatocellular carcinoma (HCC)<sup>[66-69]</sup>. Of two retrospective studies in China, one demonstrated an incidence of HCC in PBC patients of 4.13% (52/1255)<sup>[66]</sup>, while the other found it to be 3.75% (70/1865)<sup>[67]</sup>; this incidence was observably higher in men (9.52%) than in women (3.31%)<sup>[66]</sup>. Risk factors for PBC-related HCC in China for the two studies were found to be body mass index (BMI)  $\geq 25$ , male sex and a history of drinking alcohol for the first study<sup>[66]</sup> and age  $> 54$  years, male sex, co-existence of diabetes, and previous hepatitis B virus (HBV) infection for the second study<sup>[67]</sup>. A retrospective Japanese study found the incidence of HCC in PBC patients to be 5.2% (11/210), with the only risk factor for PBC-associated HCC being associated with advanced histological stage<sup>[68]</sup>. Recently, a multicenter international study demonstrated that incidence rates of HCC in PBC patients were 2.69% (123/4565), with markedly higher rates in male PBC patients compared to female patients ( $P < 0.0001$ ). Univariate analysis of potential risk factors in establishing diagnosis of PBC related to HCC progression were: Male sex ( $P < 0.0001$ ), increased aspartate aminotransferase (AST) ( $P < 0.0001$ ), progressing liver illness ( $P = 0.022$ ), platelet decline ( $P < 0.0001$ ), and decompensated hepatic function ( $P < 0.0001$ )<sup>[69]</sup>. According to the Paris-I criteria, one year stratification by inappropriate biochemical response with UDCA therapy was markedly related to risk factors of progressing HCC ( $P < 0.0001$ )<sup>[69]</sup>. Biochemical non-response to UDCA therapy predicted future trends of HCC in early stage PBC (stages I - II) ( $P = 0.005$ ) and advanced stage PBC (stages III - IV) ( $P = 0.02$ )<sup>[69]</sup>. The international multicenter study clearly demonstrates that one year biochemical non-response to UDCA is related to incremental future risk factors of progressing HCC in PBC<sup>[69]</sup>. In addition, another study showed that repeat liver resection for recurrent HCC complicating PBC is an option and may provide and improved outcome<sup>[70]</sup>. In general, PBC with hepatic cirrhosis or non-response to one year of UDCA therapy are at incremental risk of HCC.

### **PBC with concurrent viral hepatitis**

The difficulty in identifying hepatitis C virus (HCV) and/or HBV infections in PBC patients is such that an accurate diagnosis of PBC is usually observably delayed in this particular patient cohort<sup>[71]</sup>. In PBC patients with

accompanying HCV infection, impact therapy might be approved in consideration of the relevant and more serious cirrhosis<sup>[72]</sup>. A retrospective Greek study showed that, among 1493 HBV and 526 HCV patients, 17 were confirmed as having a coexistence of viral hepatitis and PBC (8 cases of HCV and 9 cases of HBV)<sup>[71]</sup>. It is very difficult to make an exact diagnosis of PBC in HBV or HCV-infected patients, meaning that a precise diagnosis is usually delayed<sup>[71]</sup>. Cholestasis should therefore be an important indication of PBC for physicians<sup>[71]</sup>. A study in Taiwan showed that, among 76 patients with PBC, 9 cases were confirmed as having a coexistence of HCV infection and PBC, and suffered from more serious hepatic cirrhosis on the basis of Child-Pugh ( $P = 0.019$ ) and the Model for End-Stage Liver Disease (MELD) ( $P = 0.01$ ) scores<sup>[72]</sup>. One case report showed that a patient with chronic HBV infection was later found to have active, asymptomatic PBC due to a persistently elevated ALP level after optimal HBV DNA suppression on antiviral therapy<sup>[73]</sup>. This report emphasizes the significance of keeping a high clinical index of suspicion for potential PBC, even after a patient with HBV has been successfully treated for a primary liver condition<sup>[73]</sup>. Clinical vigilance, particularly in atypical clinical manifestations, can result in earlier accurate diagnosis and prompt treatment of PBC<sup>[73]</sup>.

#### **PBC with concurrent rare diseases**

Although uncommon, the coexistence of PBC and some rare diseases are frequently believed to enhance the difficulty in making an exact diagnosis of PBC, as well as its treatment, due to the very complicated clinical manifestation of diseases with coexistence conditions. PBC is occasionally associated with some rare diseases, including Guillain-Barré syndrome, warm autoimmune hemolytic anemia, primary hepatic mucosa-associated lymphoid tissue lymphoma, ANCA-associated vasculitis, pseudolymphoma, hereditary hemorrhagic telangiectasia, generalized morphea, myasthenia gravis, hepatic inflammatory pseudotumor, idiopathic retroperitoneal fibrosis, celiac disease, Wilson's disease, bullous pemphigoid, idiopathic granulomatous hepatitis, CREST syndrome, Crohn's disease, hepatic sarcoidosis, Evans syndrome, and Hürthle cell adenoma<sup>[74-92]</sup>.

## **SEROLOGICAL FEATURES**

#### **Serum antibody specific for PBC**

**AMAs:** AMAs, including AMAs-M2, are a specific and sensitive marker for the diagnosis of PBC<sup>[9,10,93,94]</sup>. The existing evidence shows that AMAs and AMAs-M2 have excellent diagnostic value, with high specificity and sensitivity for PBC<sup>[93]</sup>. Compared with AMAs-M2, AMAs is a faster and more comprehensive diagnostic marker<sup>[93]</sup>. AMAs consist of nine subtypes, four of which are associated with PBC: AMA-M2, AMA-M4, AMA-M8, and AMA-M9<sup>[9-11]</sup>. Although these four AMA subtypes have comparatively specific diagnostic value for PBC, AMA-M2

remains the foremost subtype applied as a routine diagnostic marker for PBC<sup>[9-11]</sup>. AMAs are present in 95% of PBC patients; however, 5% of patients with PBC are still AMA-negative<sup>[94]</sup>. AMA-negative PBC patients had an observably worse prognosis in comparison with AMA-positive PBC patients<sup>[94]</sup>; however, an obvious distinction between positive and negative PBC AMAs should not have been found on the basis of clinical manifestation, serum biochemical features, histopathological characteristics, disease process, or response to UDCA treatment<sup>[94]</sup>. Notably, AMA-negative PBC patients had an observably decreased free survival of liver-associated complications covering liver transplant and death in comparison with AMA-positive PBC patients ( $P = 0.0182$ )<sup>[94]</sup>.

**Anti-nuclear antibodies:** Besides AMAs, PBC patient serum is able to demonstrate other PBC-related autoantibodies, especially anti-nuclear antibodies (ANAs) covering anti-multiple nuclear dot autoantibodies (anti-sp100, PML, NDP52, anti-sp140), anti-nuclear envelope protein autoantibodies (lamin, lamin B receptor), and anti-rim-like/membranous anti-nuclear autoantibodies (anti-gp210, anti-p62)<sup>[95-103]</sup>. Determination of AMAs and PBC-specific ANAs identified them as being associated with PBC severity<sup>[9,10]</sup>. Elevated serum concentrations of ANAs should be found in approximately 50% of PBC patients and 85% of AMA-negative PBC patients<sup>[96]</sup>. In short, 44% of PBC patients had anti-sp100, 15.1% had PML, 25% had anti-gp210 and 25% had ACAs<sup>[97-100]</sup>. AMAs and ANAs (anti-gp210, anti-sp100, ACAs) are particularly prevalent in PBC<sup>[101]</sup>. Although changes in most autoantibodies that occur naturally with the passage of time do not appear to associate with clinical results in PBC, changes in serum anti-sp100 antibody levels can be used as an evaluation of prognostic factors with regard to the progress of liver fibrosis diagnosed via hepatic biopsy<sup>[102]</sup>. Sp140L is the phylogenetically nearest family member to anti-sp100 protein, and serves as an autologous antigen in PBC patients<sup>[103]</sup>. The polymerization of anti-p62 is significantly augmented in the impaired biliary ducts of PBC and may reflect the inappropriate autophagy and subsequent senescence of biliary ducts cells in the etiopathogenesis of biliary duct injury in PBC<sup>[104]</sup>. In clinical practice, it is vital to detect these autoantibodies in order to establish PBC diagnosis, assess disease severity, determine the PBC clinical phenotype, and calculate the long-term outcome<sup>[101]</sup>. Positive anti-gp210 antibody and elevated vanishing biliary duct score were observable risk factors for elevated ALP predicted worsened response<sup>[105]</sup>. Positive anti-gp210 antibody and elevated hepatitis score were observable risk factors for elevated IgM predicted worsened response<sup>[105]</sup>. Elevation of ALP and IgM worsened response were observable risk factors for development to end-stage liver illness in the absence of jaundice<sup>[105]</sup>. Therefore, in the classical or typical form of PBC, characterized by the chronic progressive disappearance of small intrahepatic biliary ducts with a simultaneous augment in hepatic fibrosis, anti-gp210 autoantibodies are a powerful risk factor for development

to icterus and liver failure<sup>[101,105]</sup>. Age, positive anti-gp210 antibody, and positive ACAs were observable risk factors for elevated of alanine aminotransferase (ALT) worsened response<sup>[105]</sup>. Elevation of ALT worsened response was an observable risk factor for development to end-stage hepatic illness with persistent icterus<sup>[105]</sup>. Of PBC patients with ACAs positivity, 30% had serious bile duct damage and portal hypertension<sup>[106]</sup>. Therefore, the presence of ACAs is a risk factor for development to hepatic cirrhosis and portal-venous hypertension<sup>[101,105,106]</sup>. Biochemical response to UDCA therapy at two years, which is affected by the serum autoantibody status of ACAs, anti-gp210, and histological and morphometric variables at baseline, may predict long-term clinical results in PBC patients<sup>[105]</sup>. By contrast, another study showed that continuous variations of anti-sp100 titers, rather than anti-gp210 titers, might be effective for the surveillance of disease procession and UDCA treatment outcome<sup>[107]</sup>. The study revealed a reduced rate of eGFR, an elevated possibility of chronic kidney disease (CKD), and an elevated rate of annual eGFR decline in PBC patients with ACAs compared to those without ACAs ( $P < 0.05$ , separately)<sup>[108]</sup>. ACAs may serve as an independent predictor for CKD in patients with PBC<sup>[108]</sup>; therefore, it is important to assess ACAs and renal function in order to deter CKD evolution in PBC<sup>[108]</sup>.

**New autoantibodies:** The recognition of novel autoantibodies as a non-invasive serum hallmark is still an important area of PBC research<sup>[109]</sup>. Hu *et al*<sup>[109]</sup> created a PBC-focused microarray with 21 of these recently affirmed alternatives, as well as 9 supererogatory familiar PBC autoantigens<sup>[109]</sup>. By screening the PBC-focused microarrays with PBC patients, 6 proteins were identified as new PBC autoantigens in the presence of high specificities and sensitivities, covering hexokinase-1 (HK 1, and isoforms I and II), Kelch-like protein 7 (KLHL7), KLHL12, zinc finger, BTB domain-containing protein 2, and eukaryotic translation initiation factor 2C, subunit 1<sup>[109]</sup>. In addition, both anti-KLHL12 and anti-HK1 antibodies with higher specificity and sensitivity were more likely to be detected in PBC in comparison with controls without PBC ( $P < 0.001$ )<sup>[110]</sup>. Anti-HK1 in combination with anti-KLHL12 in the presence of usable signs (*i.e.*, MIT3, gp210 and sp100), improved the sensitivity of PBC diagnosis<sup>[110]</sup>. Importantly, both anti-KLHL12 and anti-HK1 autoantibodies had been detected in 10% to 35% of AMA-negative patients with PBC, and increasing both biomarkers in routine PBC tests significantly increased the sensitivity in AMA-negative patients with PBC from 55% to 75% by means of immunoblot and from 48.3% to 68.5% with the ELISA method<sup>[110]</sup>. Supplementing both anti-KLHL12 and anti-HK1 autoantibodies with highly specific assays for AMAs and ANA serological tests observably enhanced the serological surveillance effect and PBC diagnosis, particularly for AMA-negative patients<sup>[110]</sup>.

**Serum biochemical sign in PBC:** The enhanced serum activity of ALP, gamma-glutamyltransferase

( $\gamma$ -GT), ALT, AST, total bilirubin (TBIL), and bile acids can be detected in most patients with PBC<sup>[9,10,47,111-113]</sup>. Evidence from several studies has shown that the presence of elevated serum activity of ALP is not only an obvious guidepost of intrahepatic cholestasis, but also a pronounced succedaneous hallmark PBC severity<sup>[111-113]</sup>. A Japanese study showed that elevated serum ALP levels were not only markedly related to the presence of esophageal varicosities in PBC patients with early histological stage, but also associated with the progression of esophageal varicosities during the follow-up period<sup>[47]</sup>. In addition, a meta-analysis of individual patient information from 4845 PBC cases covering 15 European and North American countries demonstrated that serum levels of ALP and TBIL detected at research enrollment and every year for 5 years were significantly related to clinical results<sup>[111]</sup>. The study result showed that serum levels of ALP and TBIL may predict clinical results (*i.e.*, hepatic transplant or dying) of PBC patients, and could serve as alternative terminal points in treatment tests<sup>[111]</sup>. In addition, a study in China showed that, among serum biolabeling in PBC patients, the serum concentrations of bile acids were augmented with the development of PBC, while the concentrations of carnitines were reduced with the development of PBC<sup>[113]</sup>; these factors, high serum levels of ALP, TBIL, and bile acids, are markedly associated with progressive PBC and worsened outcomes.

**Serum immunoglobulins in PBC:** PBC patients characteristically show elevated serum levels of IgM<sup>[9,10]</sup>. Environmental factors, but not genetic ones, are considered to play an important role in the pathogenesis of high serum IgM in PBC<sup>[114]</sup>. In addition, serum IgG2 and IgG3 levels were most prominently increased in PBC<sup>[115]</sup>. However, evidence of decreased serum levels of IgA, IgM, and IgG in a PBC patient seems to demonstrate that immunoglobulin-mediated etiopathogenesis may be unessential for the development of PBC<sup>[116]</sup>.

**Serum markers of infection in PBC:** As a screening test, serum from 69 PBC patients were detected for IgG-antibodies against *Toxoplasma gondii* (anti-*T. gondii*), *Helicobacter pylori* (anti-*H. pylori*), Epstein-Barr virus (anti-EBV), cytomegalovirus (anti-CMV), anti-HBV and anti-HCV<sup>[117]</sup>. The results demonstrated that the prevalence rates of 4 anti-infectious agent antibodies: Scilicet anti-*T. gondii* ( $P < 0.0001$ ), anti-*H. pylori* ( $P < 0.01$ ), EBV early antigen ( $P < 0.0001$ ), and anti-CMV ( $P < 0.05$ ) in PBC patients was observably higher than in the controls<sup>[117]</sup>. The coexistence of the 4 anti-infectious agent antibodies was comparatively ordinary in PBC, but the infection burden was infrequent in normal controls ( $P < 0.0001$ )<sup>[117]</sup>. In addition, peculiar contagion reciprocities that potentially accelerate PBC patient risk were also pointed out. Seropositivity of ammodytotoxin A was negatively related to hepatic cirrhosis among patients with PBC ( $P < 0.05$ )<sup>[117]</sup>.

**Serum biomarkers in PBC:** Serum microRNAs (miRNAs), which are sufficiently steady and control RNase-mediated

degeneration in body fluids, have been used as novel potential biomarkers for many illnesses. However, the expression spectrum of serum miRNAs in patients with PBC is poorly understood. Recently, a miRNA panel (hsa-miR-122-5p, hsa-miR-141-3p, and hsa-miR-26b-5p) was confirmed to have prominent diagnostic accuracy for PBC (sensitivity = 80.5%, specificity = 88.3%)<sup>[118]</sup>. There was a remarkable difference between expression profiles of the miRNA panel, those of serum ALP ( $P < 0.001$ ), and those of serum ANAs ( $P = 0.0282$ )<sup>[118]</sup>. Seventeen miRNAs were confirmed to be distinctively expressed in peripheral blood mononuclear cells from PBC patients<sup>[119]</sup>. In addition, the downregulated expression of hsa-miR-505-3p and miR-197-3p can be used as biological markers of PBC<sup>[120]</sup>. Functional bioinformatics analysis showed prediction of microRNA target genes involved in multiple signaling passageways and biological processes<sup>[119]</sup>. In general, serum biological markers for inchoate diagnosis of PBC are a new subject of ongoing research.

**Serum predictive marker in PBC:** Non-invasive predictive markers of hepatic fibrosis in PBC patients should be used for predicting illness development. The Wisteria floribunda agglutinin-positive Mac-2-binding protein [WFA (+)-M2BP] could serve as an effortless and dependable non-invasive succedaneous serum glycol-biomarker for the diagnosis of hepatic fibrosis in PBC<sup>[121]</sup>. Serum WFA (+)-M2BP was not only considered to be better than the other non-invasive markers in determining the important and serious fibrosis stages of PBC, but was also forcefully and separately related to clinical result<sup>[121]</sup>. Serum FGF19 is related to hepatic illness severity, and can also be used as a potential predictive marker of chronic cholestatic hepatic lesion in PBC<sup>[122]</sup>. Serum ANAs, total cholesterol, and bile acids are predictors of liver failure in PBC<sup>[123]</sup>. Elevated serum levels of fractalkine in patients with PBC could serve as predictive markers of cholangitis activity at early stages<sup>[124]</sup>. Comparative proteomics analysis demonstrated not only obvious elevated serum levels of vitronectin in AMA-negative PBC patients compared to those of AMA-positive PBC ( $P < 0.01$ ), but also a potential association with the more serious bile duct destruction found in this group<sup>[125]</sup>. Serum hyaluronan is considered a hopeful hallmark for the estimation of hepatic fibrosis in PBC<sup>[126]</sup>. In addition, serum cartilage oligomeric matrix protein might be a novel non-invasive biomarker for estimating PBC and the risk of HCC<sup>[127]</sup>.

## PREDICTIVE SCORES IN PBC

A retrospective analysis showed that PBC predictive scores, covering the European and Yale model, MELD score, and Child-Pugh score, should be interpreted prudently, with the Mayo Risk Score being deemed beneficial in predicting a helpful result<sup>[128]</sup>. As current approaches for risk stratification of PBC patients are limited and single-center-based, as well as often

dichotomous, the novel prognostic tool of GLOBE score was recently proposed by the Global PBC Study Group on the basis of an international meta-analysis of 4119 PBC patients receiving UDCA<sup>[129]</sup>. A GLOBE score to forecast transplant-free survival of PBC patients receiving UDCA therapy within 1 year was formulated and confirmed by means of clinical and biochemical variables, and the prognostic capacity of the GLOBE score was assessed along with those of the Paris-1, Barcelona, Toronto, Rotterdam, and Paris-2 criteria<sup>[129]</sup>. Serum levels of ALP, albumin, and hematoidin, as well as blood platelet counts and age, were all independently related to patient mortality or hepatic transplant<sup>[129]</sup>. There were significantly reduced times of transplant-free survival in patients with risk scores  $> 0.30$  compared to matched normal subjects ( $P < 0.0001$ )<sup>[129]</sup>. The 5-year and 10-year survival rates for patients with positive predictive values verified by the GLOBE score were 98% and 88%, separately<sup>[129]</sup>. The GLOBE score can therefore not only be considered predictive of the transplant-free survival of PBC patients treated with UDCA, but may also be used to choose the therapy and nursing scheme<sup>[129]</sup>.

## RADIOLOGIC APPROACHES TO ASSESSING FIBROSIS IN PBC

At present, there are three proposed important radiologic prediction approaches for assessing hepatic fibrosis: Acoustic radiation force impulse (ARFI), vibration controlled transient elastography (VCTE), and magnetic resonance elastography (MRE)<sup>[130-132]</sup>. The diagnostic value of the degree of liver fibrosis by means of ARFI together with the 4 serum prediction markers of hepatic fibrosis covering laminin, hyaluronan (HA), type III collagen, and type IV collagen is of a satisfying effect and has significant practical value<sup>[130]</sup>. ARFI elastography correlated observably with hepatic histological stage ( $r = 0.74$ ,  $P < 0.001$ ) in PBC patients<sup>[131]</sup>. The area under the receiver operating curve of ARFI elastography for predicting histological stage equal to or higher than II or III and equal to IV were 0.83, 0.93 and 0.91, respectively<sup>[131]</sup>. The optimal cut-off values of ARFI elastography were 1.51 m/s, 1.79 m/s, and 2.01 m/s for PBC stage equal to or higher than II or III and equal to IV, respectively<sup>[131]</sup>. ARFI elastography is therefore an acceptable and powerful technique for the quantitative assessment of PBC stage<sup>[131]</sup>. Dependable VCTE consequences can exclude advanced hepatic fibrosis and avoid the need for biopsy in the lowest 45% of patients<sup>[132]</sup>. A recent prospective study in the United States has demonstrated that three-dimensional (3D)-MRE at 40 Hz has supreme diagnostic precision in diagnosing advanced hepatic fibrosis<sup>[133]</sup>. Both 2D-MRE and 3D-MRE at 60 Hz, the standard shear-wave frequency, are also reasonably precise in diagnosing advanced hepatic fibrosis<sup>[133]</sup>. MRE has obvious diagnostic precision in advanced hepatic fibrosis and cirrhosis in hepatic transplantation receivers, independent of the extent of inflammation

**Figure 1** Histology of primary biliary cholangitis (hematoxylin and eosin staining; × 200 liver biopsy). An absence/paucity of bile ducts is seen with focal chronic inflammation in a portal area consistent with late-stage primary biliary cholangitis<sup>[9]</sup>.

and BMI<sup>[134]</sup>. Magnetic resonance imaging (MRI) has potential diagnostic value for PBC, and the periportal halo sign and signal strength contribute to assessing the extent of hepatic fibrosis<sup>[135]</sup>. In addition, Gd-EOB-DTPA-enhanced MRI might offer beneficial detection approaches for hepatopathy in PBC patients<sup>[136]</sup>. In general, none of the radiologic approaches have perfect accuracy in any published study to date; however, VCTE outperformed all other non-invasive current surrogate markers of hepatic fibrosis in PBC. Due to its high acceptability and ability to predict hepatic decompensation, VCTE could be a useful tool in allocating PBC patients into different categories of risk.

## HISTOPATHOLOGICAL FEATURES

Histopathologically, PBC is not only characterized by predominantly different stages of hepatic fibrosis that eventually result in cirrhosis of the liver or hepatic failure, but also as a granulomatous lymphocytic cholangitis that consequently leads to such small bile duct loss such as vanishing bile duct syndrome and cholestasis (Figures 1 and 2)<sup>[9,137]</sup>. The typical dendritic-cellular CD11c marker has markedly effective expression and significant sensitivity compared with classical hematoxylin and eosin (H and E) staining in discovering hepatic granulomatous lesions related to PBC and other illnesses<sup>[137]</sup>. There are significantly elevated serum concentrations of IgM and earlier stages of illness in PBC patients in the presence of CD11c-positive expression hepatic granulomas<sup>[137]</sup>. There are hallmarks of immature dendritic cells, namely CD11b, decreased expression of MHC II, IL23, CD83 and CCR7, and increased expression of C1q in granulomatous lesions from PBC and other illnesses<sup>[137]</sup>. PBC-related granulomatous lesions largely represented by B lymphocytes and IgM-positive plasmacytes together with macrophages<sup>[137]</sup>. Put simply, dendritic cells play a pivotal role in the etiopathogenesis of granulomas, regardless of their origin<sup>[137]</sup>. More specifically, hepatic granulomas may be caused by the reciprocities between IgM and immature dendritic cells in PBC<sup>[137]</sup>. In addition, spleen tissue samples from PBC demonstrated accumu-

lation of IgM-positive cells, along with CXCL13-positive cells, in CD21-positive lymph follicles<sup>[138]</sup>. CXCL13-positive follicular dendritic cells might be conducive to the production of excess IgM from the spleen<sup>[138]</sup>. The deviant expression of mitochondrial autoantigens and subsequent autoimmune mechanism in PBC may be closely associated with deregulated autophagy and the following cellular senescence in biliary epithelial cells (BECs)<sup>[139]</sup>. Activated NKT cells may prompt BEC death, leading to the development of PBC<sup>[140]</sup>. A novel hepatic histological grading system for PBC, proposed by Japanese scholars, includes the degree of chronic cholangitis activity (CA 0-3), which is associated with clinic-laboratory characteristics of cholangitis, and hepatitides activity (HA 0-3), which is related to the progression of cirrhosis-related conditions<sup>[141]</sup>. French scholars proposed another novel histological scoring system for PBC, which covers assessment of hepatic fibrosis, leukomonocyte interface hepatitides, and absence of biliary ducts<sup>[142]</sup>. Abnormal expression of K-7 in hepatic cells may serve as an accessional hallmark for predicting rapid development to hepatic failure in diagnosed asymptomatic patients with PBC<sup>[143]</sup>. In other words, the histological features of PBC, in addition to typical non-suppurative destructive cholangitis and hepatic granulomatous lesions, include portal inflammation, chronic cholestasis, hepatic changes (interface hepatitides or lobular hepatitides), and bile duct loss. The two histological classifications by Ludwig's and Scheuer's stages have been used globally for PBC staging since the 1960s, and are based on the histopathological findings of PBC. In addition, two novel histological scoring systems for PBC have been proposed by Japanese and French scholars, respectively.

## DIAGNOSIS

Cholestasis, which is a general clinical manifestation in hepatic illnesses that gives rise to reactive hyperplasia of the bile ducts, is the main complication in PBC patients. PBC diagnosis can be made in a patient *via* high serum AMAs in the presence of significantly elevated serum ALP, after ruling out other common or rare causes of cholestasis, such as viral hepatitides, drug-induced hepatic damage, alcoholic liver disease, intrahepatic cholestasis of pregnancy, progressive familial intrahepatic cholestasis, autoimmune hepatitides (AIH), primary sclerosing cholangitis (PSC), immunoglobulin G4-associated sclerosing cholangitis (IgG4-SC), and autoimmune hepatic illnesses overlap syndrome (PBC/AIH, PSC/AIH, PBC/PSC, PBC/IgG4-SC), as well as biliary obstructions such as biliary calculi, biliary ascariasis, biliary tract inflammation, postoperative bile duct benign stricture, pancreatic pseudocyst, cholangiocarcinoma, and pancreatic head carcinoma. PBC diagnosis requires two of the three following objective criteria: (1) biochemical proof of intrahepatic cholestasis based primarily on elevated levels of serum ALP greater than or equal to 1.5 times the upper limit of normal (ULN) for more than

**Figure 2** Histology (hematoxylin and eosin staining) and immunochemical staining of primary biliary cholangitis. A: Magnification  $\times 400$ ; B: Magnification  $\times 400$ ; C, D: Magnification  $\times 400$  (left); Magnification  $\times 200$  (right). PBC livers demonstrated observably stronger portal area immunostain for CD11c, the position of CD11c sedimentation scored on a 0-4 scale to be compared among PBC, AIH and CHB patients ( $^aP < 0.05$ ,  $^bP < 0.01$ ) (A); PBC hepatic granulomatous lesions were classically situated within portal areas, generally near or around the impaired bile duct (B); Hepatic granulomatous lesions were also occasionally detected in the liver lobule or close to the germinal center (C)<sup>[137]</sup>. PBC: Primary biliary cholangitis; AIH: Autoimmune hepatitis; CHB: Chronic hepatitis B.

24 wk; (2) presence of serum titers of AMAs greater than or equal to 1:40; and (3) liver histology characterized by non-suppurative cholangitis and granulomatous destruction of interlobular bile ducts<sup>[9,10,144]</sup>. Furthermore, patients with PBC frequently have elevated serum levels

of ALT, AST and IgM<sup>[144]</sup>.

## DIFFERENTIAL DIAGNOSIS OF PBC

Autoimmune liver diseases (AILDs) cover PBC, PSC,

**Figure 3** Histology characteristic of autoimmune hepatitis (hematoxylin and eosin staining). The inflammatory cell infiltration feature of autoimmune hepatitis is composed of leukomonocytes, monocytes/macrophagocytes, and plasmacytes (interface hepatitis, arrows) in the portal and periportal areas<sup>[145]</sup>.

IgG4-SC and AIH; PBC should therefore be distinguished from AMA-positive AIH, PSC, or IgG4-SC. In addition, some AILDs patients present with features of PBC or PSC and AIH or IgG4-SC, either simultaneously or consecutively. They are traditionally deemed as obvious entities, although shared modes in so-called “overlap syndrome” have been recognized across the spectrum. The diagnosis of such overlap syndromes as PBC/AIH, PSC/AIH, PBC/PSC, and PBC/IgG4-SC is still challenging, but it is indispensable to diagnosis due to its rapid progression to cirrhosis and liver failure. Overlap syndromes should be considered in AIH patients with cholestatic findings, concurrent inflammatory bowel disease (IBD), or steroid-refractory disease. Clinical, biochemical, immunological, histological, and bile duct imaging characteristics contribute to the diagnosis of AILD overlap syndrome.

#### AMA-positive AIH

AIH is an immune-mediated severe hepatopathy characterized by elevated serum levels of ALT, AST and IgG, a high percentage of circulating non-organ-specific autoantibodies, and histologically with interface hepatitis (Figure 3)<sup>[145]</sup>. The incidence rates of AIH display a positive correlation with the national HDI ( $r = 0.638$ ,  $P = 0.014$ ) and the income index ( $r = 0.649$ ,  $P = 0.012$ )<sup>[13]</sup>. AIH is divided into type 1, which is defined according to the seropositivity of smooth muscle autoantibody (SMA) and/or ANAs, and type 2, which is defined according to the seropositivity of liver-kidney microsome type 1 and/or liver cytosol type 1<sup>[145]</sup>. The non-classical clinical phenotypes of AIH, particularly AMA-positive AIH, should be distinguished from PBC. In general, AMAs-M2 antibody is specific to PBC patients, but may also be occasionally discovered in certain AIH patients<sup>[146]</sup>. Efficient means of discriminating between AIH and PBC are required, due to the fact that their clinical process and treatment are disparate<sup>[146]</sup>. One recent study has shown that antibodies to filamentous-actin (anti-F-actin) protein can not only be considered the serological marker of type 1 AIH, but may also predict AIH recurrence<sup>[147]</sup>.

Furthermore, the application of repetition hepatic biopsy is an efficient method for AIH diagnosing comorbid liver conditions<sup>[148]</sup>. Although certain AIH patients were detected to be AMAs-M2 (+), the titers were markedly reduced compared to PBC patients<sup>[146]</sup>. During the follow-up period, the serum titers of AMAs-M2 were reduced in AIH patients<sup>[146]</sup>.

#### PSC

PSC is an immune-mediated chronic idiopathic cholestatic hepatobiliary illness characterized by progressive fibrosis and the stricturing of medium and large-sized extrahepatic and/or intrahepatic bile ducts (Figure 4)<sup>[9]</sup>. PSC is related to an elevated risk of cholangiocarcinoma and when IBD is present for colorectal carcinoma. Approximately 75% of PSC patients suffer from IBD; primarily ulcerative colitis (UC)<sup>[9]</sup>. Although no statistical correlation between PSC incidence and HDI was discovered ( $r = 0.116$ ,  $P = 0.706$ ), the income index was positively related to PSC incidence ( $r = 0.599$ ,  $P = 0.031$ )<sup>[13]</sup>. PSC classically evolves slowly over 10 to 15 years, eventually leading to biliary cirrhosis and premature death due to decompensated hepatic illness in the majority of patients<sup>[149]</sup>. Additional complications of PSC include hepatic osteodystrophy, dominant bile duct stenosis, recurrent cholangitis, and such disease-related malignancies as hepatobiliary (especially cholangiocarcinoma), pancreatic, and colorectal (especially with IBD) carcinoma<sup>[149]</sup>. In one recent study, 65% of patients with long-term IBD had subclinical PSC related to progressive IBD, with no biochemical anomalousness and mild illness, based on magnetic resonance cholangiography findings<sup>[150]</sup>. There is currently no specific biomarker for PSC, although the prevalence of p-ANCA has been reported to range from 33% to 85% in patients with PSC<sup>[149]</sup>. Other non-specific autoantibodies in PSC cover ANAs and SMA<sup>[149]</sup>.

#### IgG4-SC

IgG4-SC is an immune-mediated peculiar sclerosing cholangitis of unknown etiopathogenesis that is frequently related to autoimmune pancreatitis (AIP)<sup>[151]</sup>. The diagnosis of IgG4-SC is performed on the basis of a combination of the following four standards: (1) distinctive cholangiography features; (2) elevated serum levels of IgG4; (3) concurrence of IgG4-associated illnesses, excluding those of the bile duct; and (4) typical histopathological characteristics<sup>[151,152]</sup>. Moreover, the efficiency of corticosteroid treatment is a selectable additional diagnostic standard to affirm a precise diagnosis of IgG4-SC<sup>[151,152]</sup>. Typical characteristics of IgG4-SC may be divided into four types on the basis of the stenosis regions disclosed by endoscopic retrograde cholangiography and anti-diastole (Figure 5)<sup>[152]</sup>.

#### PBC/AIH overlap syndromes

PBC/AIH overlap syndrome patients, including both characteristics of PBC and AIH, were diagnosed based on the Paris diagnostic criteria proposed by Chazouillères

**Figure 4** Histology of primary sclerosing cholangitis. Trichrome  $\times 40$ , liver biopsy. Low power view demonstrating a focal lesion typical for primary sclerosing cholangitis. Periductular layered fibrosis (featuring “onion skin” pattern) is found with edema and inflammation around the interlobular bile ducts in the center of the field<sup>[9]</sup>.

*et al*<sup>[153]</sup>. Characteristics of PBC were the following: (1) serum ALP levels more than twice the ULN value and/or  $\gamma$ -GT five or more times the ULN value; (2) serum AMA positivity; and (3) histopathological evidence of bile duct damage<sup>[153]</sup>. Characteristics of AIH were: (1) ALT elevation at a minimum of five times the ULN value; (2) levels of IgG at a minimum of twice the ULN value and/or SMA positivity; and (3) hepatic biopsy revealed interface hepatitis in the presence of moderate to serious periportal lymphocyte infiltration<sup>[153]</sup>. Diagnosis of PBC/AIH overlap syndrome was considered with the presence of 2/3 of the criteria<sup>[153]</sup>. According to the Paris diagnostic criteria: (1) PBC/AIH overlap syndromes are uncommon; (2) flares of AIH can appear either voluntarily or under UDCA; and (3) a combination of corticosteroids and UDCA is requested in the majority of patients in order to achieve the best efficient biochemical response<sup>[153]</sup>. In addition, the revised and simplified diagnostic criteria for AIH were established by the International Autoimmune Hepatitis Group (IAIHG) in 1999<sup>[154]</sup> and 2008, respectively<sup>[155]</sup>. The latter is constructed on the basis of four clinical components that appear to be more peculiar in PBC/AIH patients<sup>[156]</sup>. The simplified diagnostic criteria seem to be more effective in comparison with the Paris diagnostic criteria and revised diagnostic criteria for patients with PBC/AIH overlap syndrome<sup>[157]</sup>. However, the IAIHG’s position statement on this controversial issue suggests that patients with AILDs should be classified on the basis of their dominant characteristics as PBC, AIH or PSC/small duct PSC, and that those with overlapping characteristics should not be referred to as unique diagnostic entities<sup>[158]</sup>. Combination treatment with budesonide and UDCA was more efficacious than UDCA monotherapy for PBC/AIH overlap syndrome<sup>[159]</sup>. Furthermore, combination treatment with immunosuppression and UDCA offered better short-term responses in PBC/AIH overlap syndromes<sup>[160]</sup>.

#### **PSC/AIH overlap syndrome**

PSC/AIH overlap syndrome is a comparatively infrequent variant of PSC<sup>[161]</sup>. There were remarkable distinctions

in the below listed arguments, such as mean age ( $P < 0.01$ ), serum levels of AST ( $P < 0.005$ ), ALT ( $P < 0.005$ ), and IgG ( $P < 0.0001$ ) in PSC/AIH overlap syndromes compared with “typical” PSC patients<sup>[161]</sup>; the former seemingly profits from combination treatment with UDCA and immunosuppression, while survival is distinctly superior in the latter<sup>[161]</sup>. In addition, the clinical course of PSC/AIH overlap syndrome appears to be superior to typical PSC, suggesting that immunosuppression likely has an active efficacy on the development of PSC composition<sup>[162]</sup>.

#### **PBC/PSC overlap syndromes**

PBC/PSC overlap syndromes demonstrating the clinical manifestations of both PBC and PSC are an exceedingly uncommon condition that has been reported in a mere eight published cases, including the previously mentioned two cases<sup>[163]</sup>.

#### **PBC/IgG4-SC overlap syndromes**

IgG4-SC and PBC are two distinct autoimmune liver diseases. Approximately 90% of IgG4-SC patients have AIP, so therefore the presence of AIP may contribute to the diagnosis of IgG4-SC<sup>[151,152]</sup>. Nevertheless, PBC/IgG4-SC overlap syndrome is an extremely rare condition that has been reported in very few published cases to date, with the diagnosis of PBC/IgG4-SC overlap syndromes without the coexistence of AIP being particularly difficult<sup>[164]</sup>. Serum IgG4 concentrations may be worthwhile detecting in patients with PBC intractable to routine therapy<sup>[164]</sup>.

### **NATURAL HISTORY OF PBC**

The natural history pattern of PBC has observably changed over the past 20 years due to earlier diagnosis and the introduction of UDCA treatment. However, little is known about the natural history of PBC patients without efficient therapy. Hence, an epidemiological survey of the natural history of PBC patients in the absence of treatment might contribute to a greater understanding of the natural history of patients with UDCA-resistant PBC and in developing criteria for estimating UDCA response. A recent study demonstrated greatly reduced serum levels of ALP and very slight fluctuations in the other biochemical parameters of PBC patients treated with placebo at the 2 year follow-up period<sup>[165]</sup>. There was histological development in 39.4% of patients treated with placebo and a mild worsening of histological grade after 2 years of research<sup>[165]</sup>. In the meantime, histological progression was observed in 39.4% of the placebo-treated patients, with a moderate deterioration in histological scores noted after 2 years. Furthermore, the pooled 2 year rates of death, transplant, and progression of varicosities were 11.4%, 8.7% and 10.6%, respectively, in patients treated with placebo<sup>[165]</sup>. The natural history of PBC patients with AIH characteristics significantly differs from those without AIH characteristics<sup>[160]</sup>. In addition, although considered to possess a higher prevalence

**Figure 5** Endoscopic retrograde cholangiography classification of IgG4-SC and anti-diastole. Stricture is distributed only in the distal choledoch in type 1; stricture is widely spread throughout in the intrahepatic and extrahepatic biliary ducts in type 2. Type 2 is once more divided into two. Expanded stenosis of the intrahepatic biliary ducts in the presence of pre-stenotic expansion is diffusely spread all over in type 2a. Stenosis of the intrahepatic biliary ducts in the absence of pre-stenotic expansion and decreased biliary tree are diffusely spread throughout in type 2b; stricture is found in both porta hepatis damage and the distal choledoch in type 3; stenosis of the biliary ducts are found only in the porta hepatis damage in type 4. IDUS: Intraductal ultra-sonography; EUS-FNA: Endoscopic ultrasonography-guided fine-needle aspiration<sup>[152]</sup>; IBD: Inflammatory bowel disease.

rate of AMAs, first-degree relatives of PBC patients have a lower risk of developing PBC over time, especially in those without baseline biochemical test evidence of intrahepatic cholestasis<sup>[166]</sup>.

## THERAPY OF PBC

### UDCA

The optimal dosage for UDCA of 13-15 mg/kg per day is the standardized treatment for PBC<sup>[9,10]</sup>, as it can postpone its development, improve long-term clinical outcomes, and is extremely safe and well-tolerated. Therefore, reliable identification of so-called treatment non-response to UDCA is very important, not only for selecting PBC patients who could benefit from new therapeutic approaches, but also for discerning those who are at low risk of developing end-stage PBC. The biochemical response to UDCA after 1 year of treatment in PBC has been deemed to be a powerful predictive indicator of long-term clinical outcomes and thus facilitate the rapid recognition of patients requiring novel treatment methods. However, another study demonstrated that, in comparison with biochemical responses assessed after 12 mo of UDCA treatment, biochemical responses at the 6 mo mark showed higher positive predictive value and negative predictive value, as well as lower negative likelihood ratio according to all criteria used in the Paris, Toronto, Barcelona, and Ehime definitions<sup>[167]</sup>. Therefore, the biochemical responses at the 6<sup>th</sup> month may be served as a new standard of prediction substitute for those assessed after 12 mo of UDCA treatment<sup>[167]</sup>. In addition, the UK-PBC risk scores (composed of baseline albumin, bilirubin, platelet count, ALT, AST and ALP) after 1 year of UDCA treatment might not only be available for identification in higher risks patients for rigorous surveillance and 2<sup>nd</sup>-line treatments, as well as lower risks patients who could possibly be tracked after observation during initial treatment, but the 5-, 12- and 15-year risk scores might also be considered extremely precise<sup>[168]</sup>.

### Budesonide

Budesonide is a corticosteroids receptor/pregnane X receptor (PXR) agonist<sup>[9,10]</sup>. Treble treatment with budesonide (6 mg/d), UDCA (13-15 mg/kg per day), and mycophenolate mofetil (1.5 g/d) may afford an advantage in non-cirrhotic PBC patients with characteristics of serious illness without biochemical response to UDCA<sup>[169]</sup>. Combination therapy of budesonide (6 mg/d) and UDCA (15 mg/kg per day) was able to ameliorate the plasma biochemical index of hepatic function and hepatic histology, particularly in PBC patients with hepatic fibrosis (grade I - III), whereas the treatment effectiveness of UDCA alone was principally on lab results<sup>[170]</sup>. Although larger studies are still required, the preparatory results of agents targeting PXR, such as budesonide, have been encouraging, particularly in subsets of patients with PBC, and may mark a new therapeutic era<sup>[169,170]</sup>.

### Methotrexate

The immunosuppressive agent methotrexate (MTX) has a long history in the treatment of PBC, however little is known about its action mechanisms and roles, if any<sup>[9,10]</sup>. MTX was assessed for PBC treatment, which is currently recommended only in patients for whom PBC failed to respond adequately to UDCA and in AIH/PBC overlap syndromes<sup>[171,172]</sup>. PBC patients with characteristics of AIH should be considered for immunosuppressive therapy<sup>[158]</sup>, with the therapeutic goal being to attain normal serum aminotransferase levels and histological improvement<sup>[158]</sup>. In patients who responded improperly to UDCA, MTX observably improved hepatic enzyme tests and hepatic histology<sup>[171]</sup>. Combination therapy of UDCA and MTX brought about continuous clinical anesis in a subgroup of PBC patients, and the response to a combination of MTX and UDCA appears to be more time-proof<sup>[172]</sup>.

### FXR agonist

FXR is the receptor for primary bile acids expressed in enterohepatic tissues, where it regulates bile acid uptake, metabolism, and disposal, and has been considered

a significant target for intrahepatic cholestatic illness therapy<sup>[173-176]</sup>. Obeticholic acid (OCA) is a semi-synthetic bile acid analogue for 6 $\alpha$ -ethyl-chenodeoxycholic acid that is nearly 100-fold more potent than chenodeoxycholic acid (CDCA) and is a powerful, first class alternative FXR agonist derived from primary human bile acid CDCA, the natural endogenous FXR agonist<sup>[173]</sup>. OCA is being developed by Intercept Pharmaceuticals for the treatment of a variety of intrahepatic cholestatic illnesses, and has lately been permitted expedited approval in the United States for the treatment of PBC in combination with UDCA in adults with inappropriate response to UDCA or as monotherapy in adults unable to tolerate UDCA<sup>[174]</sup>; OCA (Ocaliva<sup>TM</sup>) is in preregistration for this function in the European Union<sup>[174]</sup>. A randomized controlled clinical trial showed that treatment with OCA (10-50 mg/d) observably decreased the serum concentrations of  $\gamma$ -GT, ALP and ALT in PBC patients with inappropriate response to UDCA, in comparison with placebo<sup>[175]</sup>. Furthermore, PBC patients treated with OCA (10 mg/d) had the lowest incidence rates and seriousness of itching<sup>[175]</sup>. Clinical trials demonstrated the treatment effectiveness of OCA in PBC without biochemical response to UDCA, as evidenced by changes in laboratory parameters substituted for long-term clinical outcomes<sup>[176]</sup>. Dose-dependent itching is a usual side-effect of OCA, but can be overcome *via* dose-titration<sup>[176]</sup>. Furthermore, INT-767, which is another steroidal semi-synthetic bile acid analogue, has been testified to be able to modulate the activity of monocytes and macrophages, decrease inflammation through the inactivation of NF- $\kappa$ B *via* a protein kinase A dependent pattern, and decrease hepatic damage by promoting biliary bicarbonate excretion as a dual FXR and TGR5 agonist<sup>[173]</sup>.

### Cyclosporine A

Recurrence of PBC after hepatic transplant has been proven to adversely influence transplant and patient survival. Protective potencies of cyclosporine A (CyA) against PBC recurrence after hepatic transplant have been reported<sup>[177]</sup>. Changing from tacrolimus to CyA was possible without sequelae, with no patients demonstrating recurrence of PBC<sup>[177]</sup>. Therefore, CyA might be serviceable for the prevention of PBC recurrence after living-donor hepatic transplant<sup>[177]</sup>. However, a retrospective multicenter study in Japan showed that although there was no influence on patient survival, original immunosuppression with CyA was considered to be major risk for PBC recurrence after hepatic transplant<sup>[178]</sup>. However, in subset analysis, switching from tacrolimus to CyA within 12 mo reduced recurrence<sup>[178]</sup>.

### Fibrates

Fibrates, including bezafibrate and fenofibrate, may be useful for treating asymptomatic patients with PBC who exhibit inappropriate response to UDCA<sup>[179-183]</sup>. A nationwide retrospective survey in Japan demonstrated that normalizing serum ALT concentrations with accessional

bezafibrate therapy observably reduced the occurrence of hepatic illness-associated clinical signs in symptomless patients, with PBC responding incompletely to UDCA<sup>[179]</sup>. Moreover, long-term combined bezafibrate and UDCA treatment in PBC not only observably ameliorated the Mayo risk score and serum concentrations of ALP, but also observably elevated the serum concentrations of creatinine<sup>[180]</sup>. Hence, it is very important to consider adverse drug reaction associated with long-term combination treatment<sup>[180]</sup>. Although the treatment effectiveness of fenofibrate has been confirmed to be related to obvious improvement in ALP, decompensation amelioration, and hepatic transplantation-free survival in patients with PBC who reveal inappropriate responses to UDCA, fenofibrate should be more prudently applied in PBC, with frequent supervision for biochemical/clinical maladjustment<sup>[181]</sup>. Long-term fenofibrate therapy as a second-line auxiliary drug in PBC patients without appropriate response to UDCA was considered to be safe and efficient in ameliorating ALP, but did not markedly decrease the evaluated possibility of hepatic-associated death or demand for hepatic transplant<sup>[182]</sup>. In addition, the optimal dosage for fenofibrate (100-200 mg/d) seems to be efficient for assistant treatment in PBC patients without optimal biochemical response to UDCA<sup>[183]</sup>.

### Rituximab

Rituximab, an anti-CD20 monoclonal antibody that selectively depletes B cells, which are precursors of the autoantibody-producing plasmocytes, may be successfully used in autoimmune-mediated hepatic illnesses<sup>[184]</sup>. Selective depletion of B-cells with rituximab was safe and related to an obvious reduction in autoantibody product, but had limited biochemical effect in PBC patients without optimal biochemical response to UDCA<sup>[184]</sup>. The efficacy of B-cell depletion with rituximab therapy and the significant improvement in both biochemical and immunologic markers that it provides has been found in PBC patients with inappropriate biochemical response to UDCA<sup>[185]</sup>. The results of these studies demonstrate that depletion of B-lymphocyte affects the induciveness, maintenance, and activation of both B- and T-lymphocytes, and offers an underlying principle for the treatment of PBC patients with incomplete response to UDCA<sup>[184,185]</sup>.

### Mesenchymal stem cells

Mesenchymal stem cell (MSC) transplantation is considered to be safe, and has been diffusely tested in autoimmune hepatic disease clinical trials with encouraging results<sup>[186,187]</sup>. MSC transplantation could modulate the systemic immune response and promote recovery in hepatic inflammation of PBC<sup>[186,187]</sup>. One single-arm clinical trial has shown that umbilical cord-derived MSC (UC-MSC) transplantation is viable and well-tolerance in patients with PBC, who response only partly to UDCA therapy, hence the need for a new treatment method for PBC patients in this subset<sup>[186]</sup>. However, the exact effect of UC-MSC transplantation in patients with PBC

still requires confirmation by a larger placebo-controlled randomized clinical trial<sup>[186]</sup>. In addition, allogeneic bone marrow MSC transplantation has been confirmed to safely improve histologic fibrosis and hepatic function in UDCA-resistant PBC patients<sup>[187]</sup>.

### Liver transplantation

At present, liver transplantation (LT) is still a lifesaving approach with outstanding results for end-stage PBC patients<sup>[177,178]</sup>. Although the 15 year survival of PBC patients was confirmed as 52.6% after LT, regrettably, the recurrent rates of PBC were 21%-37% and 43% at 10 and 15 years after LT, respectively<sup>[178,188]</sup>. Though there is still no specific treatment for recurrent PBC (rPBC), cyclosporine A and UDCA may be useful for the prevention of rPBC after LT<sup>[177,188,189]</sup>. Furthermore, the expression of mitochondrial proteins in small biliary ducts may be a beneficial diagnostic hallmark for both end-stage PBC and rPBC after LT<sup>[190]</sup>.

## CONCLUSION

In the past decade, recent advances in PBC have attempted to improve the accuracy of the disease's diagnosis and prognosis, as well as affording the chance to refine therapeutic methods. Promising novel therapies, including budesonide, fibrates, and rituximab, are being tested in PBC patients on the basis of understanding thoroughly the cellular and molecular mechanisms touched upon in all histological stages of PBC, from the early autoimmune-mediated bile duct epithelial cell damage to the destructive and illness-persistent influences of intrahepatic cholestasis, and finally giving rise to hepatic fibrosis and hepatic cirrhosis progression. Although much progress has been seen in the last 5 to 10 years, including in the diagnosis and treatment of PBC, the ultimate challenge for physicians is reducing UDCA non-responders and recurrent PBC after liver transplantation. Some novel therapeutic agents, including FXR agonists like OCA, FXR/TGR5 agonists like as INT-767, and PPAR-alpha have been identified as novel targets for drug development, with further investigation in PBC-related clinical trials still being implemented. Results of ongoing clinical trials and burgeoning therapeutic paradigms for PBC patients will likely further improve medical management and stride toward accurate treatment in the near foreseeable future.

Basic Study

# Performance of cold-preserved rat liver Microorgans as the biological component of a simplified prototype model of bioartificial liver

María Dolores Pizarro, María Gabriela Mediavilla, Alejandra Beatriz Quintana, Ángel Luis Scandizzi, Joaquín Valentín Rodríguez, María Eugenia Mamprin

María Dolores Pizarro, Joaquín Valentín Rodríguez, Centro Binacional de Criobiología Clínica y Aplicada, Rosario 2000, Argentina

María Gabriela Mediavilla, Instituto de Biología Molecular y Celular de Rosario, Rosario 2000, Argentina

María Gabriela Mediavilla, Joaquín Valentín Rodríguez, María Eugenia Mamprin, Consejo Nacional de Investigaciones Científicas y Técnicas, Caba C1033AAJ, Argentina

Alejandra Beatriz Quintana, Morfología, Facultad de Ciencias Bioquímicas y Farmacéuticas, Rosario 2000, Argentina

Ángel Luis Scandizzi, María Eugenia Mamprin, Área Farmacología, Facultad de Ciencias Bioquímicas y Farmacéuticas, Universidad Nacional de Rosario, Rosario S2002 LRK, Argentina

**Author contributions:** Pizarro MD performed the majority of experiments and analyzed the data; Mediavilla MG and Mamprin ME have designed research, performed research, contributed new reagents, analyzed data, wrote the manuscript; all the authors were involved in reviewing the literature for latest contributions in the field, writing, and edition of the manuscript; Mediavilla MG and Mamprin ME have equally contributed to this work.

**Supported by** Universidad Nacional de Rosario (UNR), No. 677/2013.

**Institutional review board statement:** The study was reviewed and approved by the National University of Rosario Institutional Review Board (Resol. C.S., No. 677/2013).

**Institutional animal care and use committee statement:** All procedures involving animals were reviewed and approved by the Institutional Animal Care and Use Committee of the Faculty of Biochemical and Pharmaceutical Sciences-UNR (Resol. No. 139/2011).

**Conflict-of-interest statement:** No potential conflicts of interest relevant to this article were reported.

**Data sharing statement:** No additional data are available.

**Open-Access:** This article is an open-access article which was selected by an in-house editor and fully peer-reviewed by external reviewers. ## Abstract

### AIM

To develop a simplified bioartificial liver (BAL) device prototype, suitable to use freshly and preserved liver Microorgans (LMOs) as biological component.

### METHODS

The system consists of 140 capillary fibers through which goat blood is pumped. The evolution of hema-

tocrit, plasma and extra-fiber fluid osmolality was evaluated without any biological component, to characterize the prototype. LMOs were cut and cold stored 48 h in BG35 and ViaSpan® solutions. Fresh LMOs were used as controls. After preservation, LMOs were loaded into the BAL and an ammonia overload was added. To assess LMOs viability and functionality, samples were taken to determine lactate dehydrogenase (LDH) release and ammonia detoxification capacity.

## RESULTS

The concentrations of ammonia and glucose, and the fluids osmolalities were matched after the first hour of perfusion, showing a proper exchange between blood and the biological compartment in the minibioreactor. After 120 min of perfusion, LMOs cold preserved in BG35 and ViaSpan® were able to detoxify  $52.9\% \pm 6.5\%$  and  $53.6\% \pm 6.0\%$ , respectively, of the initial ammonia overload. No significant differences were found with Controls ( $49.3\% \pm 8.8\%$ ,  $P < 0.05$ ). LDH release was  $6.0\% \pm 2.3\%$  for control LMOs, and  $6.2\% \pm 1.7\%$  and  $14.3\% \pm 1.1\%$  for BG35 and ViaSpan® cold preserved LMOs, respectively ( $n = 6$ ,  $P < 0.05$ ).

## CONCLUSION

This prototype relied on a simple design and excellent performance. It's a practical tool to evaluate the detoxification ability of LMOs subjected to different preservation protocols.

**Key words:** Rat liver Microorgans; Cold preservation; BG35 preservation solution; Bioartificial liver device; Acute liver failure

**Core tip:** This work describes the development of a simplified bioartificial liver prototype (BAL, suitable to use rat liver Microorgans (LMOs) as biological component, and the evaluation of these tissue slices performance in this new model. We demonstrate that the minibioreactor constructed allows a good performance of fresh and cold preserved LMOs, showing the importance of architecture and model configuration on these devices design. Besides its application as BAL, this minibioreactor could serve as a suitable laboratory tool to evaluate the behavior and functionality of LMOs subjected to different preservation protocols due to its simple design and the utilization of standard materials.

Performance of cold-preserved rat liver Microorgans as the biological component of a simplified prototype model of bioartificial liver. *World J Hepatol* 2016; 8(33): 1442-1451 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i33/1442.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i33.1442>

## INTRODUCTION

To date, acute liver failure continues to be a defeating syndrome in the clinical practice due to its rapid development and its high risk of mortality. Patients always require a multidisciplinary approach for adequate management and subsequent organ transplantation. Unfortunately, the scarcity of donor organs often limits liver transplantation in time. Among the different approaches that have been tested to maintain the patients until transplantation and/or to facilitate self-regeneration of the damaged liver is the bioartificial liver (BAL)<sup>[1]</sup>. In BAL devices, the plasma of the patient is treated by its circulation through a bioreactor that accommodates a biologically active component which performs the diminished or lacking hepatic metabolic functions. Ammonia detoxification is one key task this biological component must carry out because increased blood levels of this metabolite are toxic to the central nervous system<sup>[2]</sup>.

Investigations concerning the development of BAL devices containing normal hepatocytes are still being conducted<sup>[3,4]</sup>. Some researchers have chosen to employ immortalized hepatocytes<sup>[5]</sup> while others have focused their efforts in preparing bioreactors housing isolated hepatocyte with or without extra-cellular matrix and structural components<sup>[6,7]</sup>.

Our group has already reported the construction of a minibioreactor (MBR) consisting in a hollow fiber based cartridge with blood flowing through the fiber lumens. Rat isolated hepatocytes were used as the biological component, showing an effective ammonia depuration rate<sup>[8]</sup>. Since it is thought that the "ideal" biological component for a BAL should contain all the constituents present in a liver lobule in order to obtain maximal function, we became interested in evaluating the performance of rat liver Microorgans (LMOs). These are thin fragments of tissue that retain the basic micro-architecture of the liver lobe, including cell to cell contact and cell to cell communication<sup>[9,10]</sup>.

On the other hand, in order to become a useful clinical tool, any BAL device must be ready to use when a patient needs it. This means the biological component should be not only available but viable and functional. In a previous work we have presented BG35 [Bis-Gluconate-Polyethyleneglycol (PEG) 35 kDa], a novel preservation solution, that exhibited an efficacy similar to that of the ViaSpan® to give protection to LMOs against injury produced by the ischemia followed by reoxygenation suffered as a consequence of cold preservation<sup>[11]</sup>.

The objectives of this work were to develop a simplified prototype BAL suitable to use LMOs as biological component, and to evaluate the performance of fresh and cold preserved rat LMOs in this model.

## MATERIALS AND METHODS

### MBR

The MBR (Figure 1) was constructed using a 25 cm<sup>2</sup>

**Figure 1 Minibioreactor device.** BC: Biological compartment; Lp: Loading port; O<sub>2</sub>/CO<sub>2</sub>: Carbogen supply line; Ox: Silicone tube oxygenator; Bsp: Blood sample port.

culture flask, adding a loading port (Lp) on top, a Y-polypropylene connector (Nalgene cat. 6152-0375) onto its lid and a simple connector at one side. One hundred and forty Polyamix™ hollow fibers (Gambro, Hechingen, Germany) are assembled to these two connectors and sealed with epoxy glue. The diverse parts that made up the MBR can be appreciated in Figure 1.

In the MBR, two main compartments can be distinguished: The hollow fibers internal lumen constitutes the blood compartment, while the biological compartment (BC) comprises the space outside the hollow fibers (total volume of 50 cm<sup>3</sup>). A silicone tube (Ox, oxygenator) enters to the BC through the Y connector and allows the oxygenation of the BC fluid. The LMOs were placed in the biological compartment through the Lp port and released on the flat surface of the device. This allows a homogeneous distribution of LMOs and a better oxygenation and exchange of solutes.

### Components of the perfusion system and its manipulation

The components of the perfusion system used are detailed in Figure 2. The blood reservoir, that contains a clot filter, and the MBR are immersed in a water bath at 37 °C. The peristaltic pump (model 7554-60, Cole Parmer, United States) allows the recirculation of heparinized goat blood (total volume: 35 mL) through all the system at a constant flow of 9 mL/min.

In all the experiments performed, we first filled the system with goat blood *via* the inlet tube and then inoculated 1 g of LMOs into the BC (or Krebs-Henseleit Reoxygenation media (KHR) alone, in the experiments done to characterize system operation, which composition is shown in page 11). The silicone tube was used to oxygenate the BC compartment with carbogen gas (95% O<sub>2</sub>/5% CO<sub>2</sub>) at a stable pressure of 85 mmHg. The blood pH was kept at 7.40 ± 0.50 adding 8.4% sodium bicarbonate if necessary.

To test ammonia detoxification capability of the rat LMOs, we added an aliquot of an ammonium chloride solution (approximate concentration: 350 mmol/L) to

**Figure 2 In vitro perfusion system.** A: Peristaltic pump; B: Minibioreactor; C: Blood reservoir; D: External oxygen supply.

the blood in order to achieve an initial ammonia plasma concentration of 1.06 ± 0.12 mmol/L, *n* = 6 (blood sample *t* = 0). Then, we initiated blood perfusion and took blood and BC fluid samples after 60 and 120 min of operation to perform the different assays detailed below.

### Characterization of the MBR perfusion system

In order to characterize the operation of the system “*in vitro*”, *i.e.*, without LMOs, different MBR were perfused for 120 min with only KHR solution inside the BC compartment and the following parameters were evaluated:

Hematocrit, to determine the probable rupture of some fibers with the concomitant passage of blood to the BC, and to study the possible hemolytic action of the peristaltic pump. Blood samples were taken from blood sample port at different perfusion times and were centrifuged (1000 × *g* - 3 min, Rolco CH24 centrifuge). The hematocrit was calculated using the next equation:

Hematocrit (%) = red blood cells volume/blood total volume.

Plasma and extra-fiber fluid osmolality, were measured in order to monitor the correct transfer of fluids between blood and the BC, using a freezing point osmometer (Osmomat 030, Gonotec, GmbH, Berlin, Germany).

Protein analysis using fast protein liquid chromatography (FPLC), in order to study the diffusive properties of the hollow fibers used in the construction of the MBR and to determine the possible passage of plasmatic proteins towards the BC, especially those belonging to the immune system that could damage the biological component (described below).

Metabolite concentration in both compartments, such as glucose and ammonia, to determine their correct distribution in the MBR (described below).

### Hemolysis determination

Samples of plasma were taken after 0, 60 and 120 min of perfusion and hemoglobin concentration was determined using the oxyhemoglobin method<sup>[12]</sup>.

**Table 1** Composition of the preservation solutions ViaSpan® and BG35

	ViaSpan®	BG35
Impermeants (mmol/L)		
Lactobionate	100

PEG 35000		40
pH	7.40	7.40
Osm (mOsm/kg water)	320 ± 4	339 ± 4

Dexamethasone 16 mg/L, insulin 40 UI/L and penicillin G 200000 UI/L were added to ViaSpan® before use. Streptomycin 0.25 mg/mL and penicillin G 10 UI/mL were added to BG35 before use. All the solutions were bubbled with 100 % N<sub>2</sub> for 45 min at 0 °C before use. BES: N, N-bis (2-hydroxyethyl)-2-aminoethanesulfonic acid; HES: Hydroxyethyl starch; PEG: Polyethyleneglycol.

To calculate the percentage of hemolysis, we used the following equation, described by Arnaud<sup>[13]</sup>:

$$\text{Hemolysis (\%)} = 100 \times \{[\text{Hbs} \times (1 - \text{Ht})] \div \text{Hbr}\}$$

where Hbs is the hemoglobin content, expressed in g/100 mL, of the different samples; Hbr is the total hemoglobin content (in whole blood), and Ht is the hematocrit value measured after 0, 60 or 120 min of perfusion.

### FPLC analysis

Samples of basal plasma and BC fluid were taken after 60 and 120 min of perfusion and analyzed by Gel Filtration Chromatography. They were centrifuged (12100 × *g* - 5 min), filtered and 100 µL were seeded in a Tricorn Superdex-200 column (30 × 1 cm, GE Healthcare, Sweden), equilibrated with 50 mmol/L Tris, 150 mmol/L NaCl buffer, pH 7.00, previously degassed by vacuum filtration. The column was manipulated using an ÄKTA-Prime equipment (GE Healthcare, Sweden), at a constant flow of 0.5 mL/min. Each sample was analyzed in duplicate. Chromatograms were registered measuring absorbance at 280 nm and, to determine the protein molecular weight, a standard calibration curve was made using a "Molecular Weights 29000-700000" kit, following the supplier's instructions (Sigma-Aldrich, St Louis, Missouri, United States).

### Animals

The livers were obtained from male Wistar rats weighing 250-300 g. Animals had access to regular laboratory food for rodents and water *ad libitum*. Animals were cared in conformity with the principles and recommendations for

the care and utilization of laboratory animals, suggested by the National Academy of Sciences. The rats were adapted to experimental laboratory environment for fourteen days before to experimentation. All experimental procedures were authorized by the School of Biochemical and Pharmaceutical Sciences Institutional Animal Care and Use Committee (Res No. 139/2011).

### Preparation of rat LMOs

LMOs were manually cut from rat livers into slices of 338 ± 27 µm thickness, *n* = 25. They were cut using a microtome blade attached to a plastic handle. We performed all the manipulations on ice (at 0 °C) to decrease tissue injury, and on top of a paper filter to avoid the pieces of livers from sliding what could impede the correct cutting of the tissue<sup>[14]</sup>.

Subsequently, LMOs were allocated in various solutions. Control group (non-preserved or fresh) LMOs were suspended in KHR and directly put in the MBR perfusion. KHR buffer was composed as follows: 114 mmol/L NaCl, 25 mmol/L NaHCO<sub>3</sub>, 1.2 mmol/L KH<sub>2</sub>PO<sub>4</sub>, 1.2 mmol/L MgSO<sub>4</sub>, 4.8 mmol/L KCl, 1.5 mmol/L CaCl<sub>2</sub>, 10 mmol/L HEPES, 25 mmol/L glucose, 5 mmol/L fructose, 1 mmol/L allopurinol, 3 mmol/L glycine, 10 µmol/L adenosine, 6 mmol/L ornithine, 10 mmol/L sodium lactate; pH 7.40, 328 ± 7 mOsm/kg water (*n* = 6)<sup>[15]</sup>. Preserved LMOs were stored 48 h in BG35 and ViaSpan® solutions (Table 1) before MBR perfusion as explained in the next section.

### Preservation of LMOs

As it was stated, in the case of the preserved groups, LMOs were stored in two different preservation solutions. Fifty LMOs were preserved during 48 h at 0 °C<sup>[11]</sup> in a crystal flask immerse in 50 mL of one of these preservation solutions: (1) ViaSpan® (Bristol-Myers Squibb Pharmaceutical Limited; ViaSpan® group); and (2) BG35 (Bes-Gluconate plus 4% PEG 35 kDa; BG35 group).

The composition of the preservation solutions used are shown in Table 1. A period of 48 h of preservation was selected since in initial investigations (data not exposed) the viability evaluated by lactate dehydrogenase (LDH) leakage was modestly changed by 1 d of cold ischemia, but a pronounced increase was observed after 2 d.

After 48 h of cold preservation, LMOs were completely rinsed with a flush solution earlier reported by our group<sup>[16]</sup> to fully eliminate residual cold preservation solution. After that, LMOs were placed into the MBR.

### LDH release

Viability of LMOs was tested by LDH release. LDH activity was determined in the BC fluid and the slices as earlier explained<sup>[17]</sup>. Data are shown as the percentage of the total enzyme activity released into the incubation medium.

### Measurement of plasma and BC fluid ammonia concentrations

Samples of blood and BC fluid were taken at different

**Table 2** Time course evolution of minibioreactor functional parameters during 120 min of perfusion

Perfusion time	(Osm) <sub>B</sub> /((Osm) <sub>BC</sub>	Hto (%)	Hemolysis (%)	(Glucose) <sub>B</sub> /((Glucose) <sub>BC</sub>	(NH <sub>4</sub> <sup>+</sup> ) <sub>B</sub> /((NH <sub>4</sub> <sup>+</sup> ) <sub>BC</sub>	QNH <sub>4</sub> <sup>+</sup> (μmol)
0 min	0.94 ± 0.02	47 ± 3	0.27 ± 0.09	0.09 ± 0.04	52.8 ± 4.0	36.3 ± 1.6
60 min	1.00 ± 0.02	44 ± 5	0.59 ± 0.10	0.77 ± 0.07	1.1 ± 0.1	36.1 ± 1.6

B: Blood; BC: Biological compartment.

periods of time (0, 60 and 120 min), blood samples were centrifuged (12000 × *g*, 3 min) and all samples were conserved in liquid nitrogen until the determinations were performed. Ammonia was measured using the van Anken enzymatic determination in a volume of 0.8 mL consisting of 66.7 mmol/L phosphate buffer, pH 8.30, 0.14 mmol/L, NADPH, 6.5 mmol/L sodium-ketoglutarate, 2.5 mmol/L ADP, 120 UI/mL glutamate dehydrogenase (cat. #G2626, Sigma Aldrich St. Louis, MO, United States)<sup>[18]</sup>.

The following equations were then used to calculate ammonia mass balance:

$$Q_{B,t} = [(A)_{B,t} \times V_{B,t}] - [(A)_{B,Bas} \times V_{B,t}]$$

$$Q_{BC,t} = [(A)_{BC,t} \times V_{BC,t}] - [(A)_{BC,Bas} \times V_{BC,t}]$$

$$Q_{T,t} = Q_{B,t} + Q_{BC,t}$$

Where:  $Q_{B,t}$  and  $Q_{BC,t}$  represent the ammonia mass at time *t* in blood and the BC fluid respectively;  $(A)_{B,t}$  and  $(A)_{BC,t}$  are the ammonia concentrations in blood and BC fluid at different times;  $(A)_{B,Bas}$  is basal blood ammonia concentration;  $V_{B,t}$  and  $V_{BC,t}$  are the blood and BC fluid volumes, and  $Q_{T,t}$  is the total ammonia mass at different times.

The ammonia detoxification capacity is expressed as the % of the initial dose detoxified at different times and was calculated using the following equation.

$$\% \text{ Dose} = 100 - [(Q_{T,t} \times 100)/Q_{T,0}]$$

Where  $Q_{T,0}$  is total ammonia mass at time 0.

### Determination of plasma and BC fluid glucose concentrations

Glucose was determined using a commercial kit ("Glicemia Enzimática AA", Wiener Laboratories, Rosario, Argentina) and following the manufacturer's instructions.

### Histology

Samples of livers from all experimental groups were fixed in 10% formaldehyde, dehydrated, embedded in paraffin, sectioned with a micrometer, stained with hematoxylin-eosin and mounted. Sections were microscopically analyzed and some aspects of the hepatic parenchyma were taken into consideration: Hepatic cell plate organization, the form of endothelial cells and hepatocytes, presence of necrotic areas and blebs in the plasmatic membrane of the hepatocytes. To perform the analyses, we used a light field microscope (Olympus Co, LTD. Model U-MDOB), equipped with a digital camera (Olympus model D-360 Zoom-3.2 megapixels of resolution).

### Materials

Chemicals were purchased from Sigma (St. Louis,

Missouri, United States) and were analytical grade pure.

### Statistical analysis

Results are presented as mean ± SD. We performed a one-way or multifactor analysis of variance with Scheffé's multiple range test as post-test to establish the statistical significance of the differences between means. *P* values smaller than 0.05 were taken as statistically significant. The statistical review of the study was performed by a biomedical statistician.

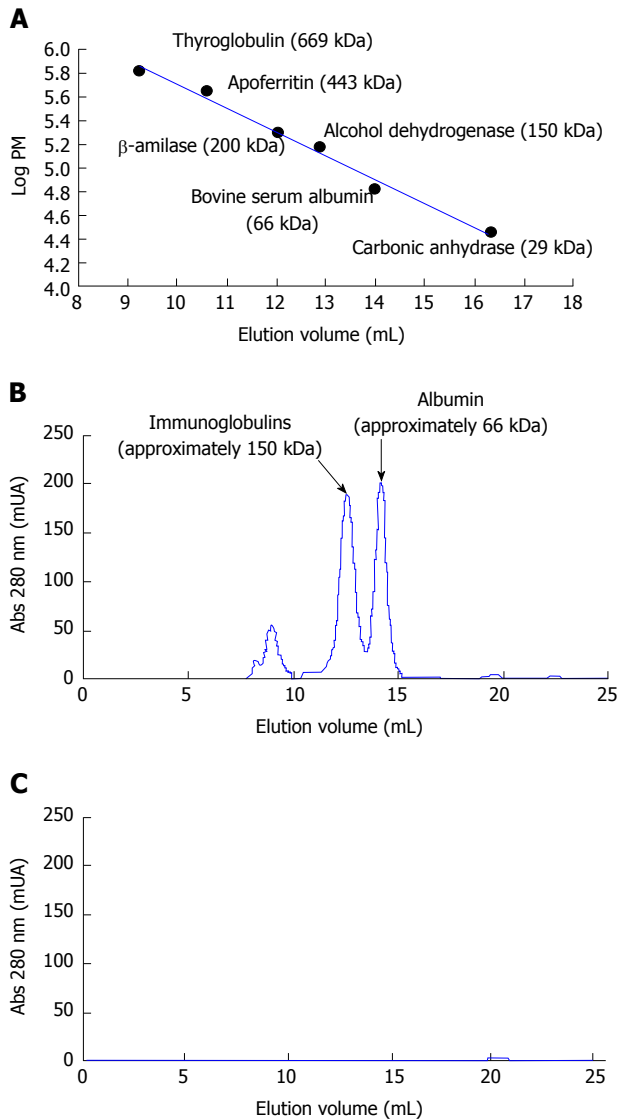

## RESULTS

### Time course evolution of MBR functional parameters during 120 min of perfusion

In order to characterize the "in vitro system" operation, different MBR were perfused for 120 min, without any biological component. The mean data of six individual runs are shown in Table 2. The plasma/BC relationship did not change during the experiments. Plasma and KHR solution osmolalities were arrived to equilibrium after the first hour of perfusion, demonstrating a proper exchange of solutes between the two compartments. No significant variation of the hematocrits was observed during the function of the system, but a minimum breakup of the erythrocytes was generated after 120 min of perfusion by the activity of the peristaltic pump. Ammonia concentration became equal in both compartments after the first hour of perfusion and the total mass (*Q*) of this metabolite remained constant during the whole experiment, indicating that no loss or interactions with any system component occurred. Similar behavior was observed for glucose distribution.

### FPLC analysis

The protein analysis by gel filtration chromatography is shown in Figure 3. In the chromatogram obtained for a sample of basal plasma (Figure 3B) we can observe the presence of two main peaks. Based on the calibration curve obtained (Figure 3A), they can be assigned to the major plasma proteins: Albumin [elution volume (*Ve*) = 14.15 mL] and immunoglobulins (mainly IgG, *Ve* = 12.52 mL). Two minor peaks are also appreciated (*Ve* < 9 mL) that correspond to proteins of high molecular weight (*MW* > 700 kDa). These could be α2-macroglobulin (*MW* = 725 kDa, *Ve* = 8.92 mL) and the pentameric form of IgM (*MW* = 950 kDa, *Ve* = 8.22 mL). Figure 3C shows the chromatogram obtained for a sample of the BC fluid after 120 min of blood perfusion (the same result was obtained after 60 min). It can be noticed that none of the

**Figure 3 Protein analysis by gel filtration chromatography.** A: Calibration curve carried out with molecular weight markers; B: Chromatogram obtained for a sample of basal plasma; C: Chromatogram obtained for a sample of biological compartment, taken after 120 min of perfusion  $n = 5$ .

plasma proteins was capable of crossing the membrane of the hollow fibers used in the construction of the MBR.

#### Evolution of the amount of LDH released by fresh LMOs and LMOs cold preserved in BG35 and ViaSpan® solutions after two hours of MBR perfusion

Figure 4 exposes the time changes in LMOs viability (determined by LDH release) throughout the two hours of the experiments performed. One gram of fresh LMOs (controls) or LMOs cold preserved in BG35 and ViaSpan® solutions was loaded into the BC and the MBR was then perfused during 120 min. The amount of enzyme released by fresh LMOs and LMOs cold preserved in BG35 showed a minor increase after two hours of perfusion. However, LMOs preserved in ViaSpan® solution showed a statistically significant raise in this parameter as perfusion time increased. The values of LDH release reached after 120 min in the MBR were:  $6.0\% \pm 2.3\%$  for controls;

**Figure 4 Time course of lactate dehydrogenase release during 120 min of minibioreactor perfusion determined for fresh and cold preserved liver microorgans in BG35 and ViaSpan® solutions.** Data are expressed as mean  $\pm$  SD for 6 liver microorgans (LMOs) preparations. Different from control,  $^aP < 0.05$ ; Different from all the other reoxygenation times,  $^cP < 0.05$ ,  $n = 6$  LMOs independent preparations for each condition. LDH: Lactate dehydrogenase.

$6.2\% \pm 1.7\%$  for LMOs cold preserved in BG35 and  $14.3\% \pm 1.1\%$  for the group cold preserved in ViaSpan®, ( $P < 0.05$ ,  $n = 6$ ).

#### Evolution of ammonia detoxification for fresh LMOs and LMOs cold preserved in BG35 and ViaSpan® solutions

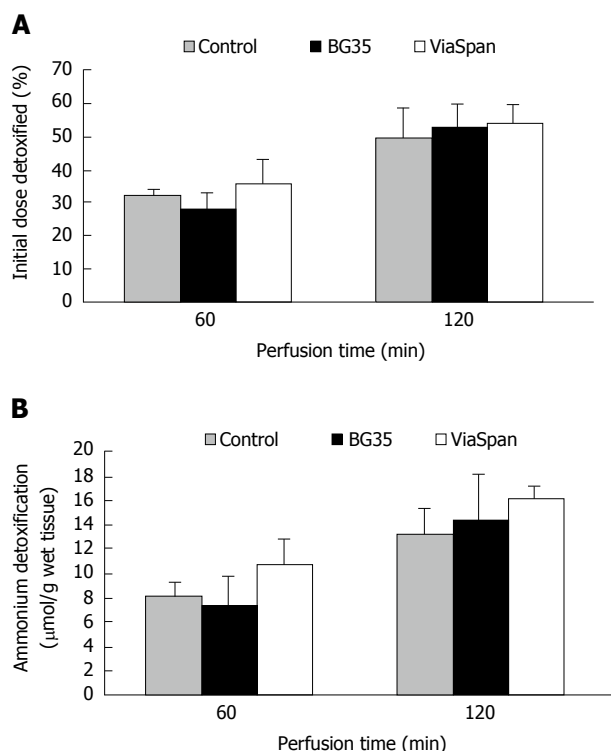

The ammonia detoxification capability of the device was evaluated by measuring the time course evolution of plasma ammonia concentration: An ammonia overload was added to the blood to obtain an ammonia plasma concentration of  $1.06 \pm 0.12$  mmol/L,  $n = 6$ . We determined the ammonia content in blood and BC fluid samples obtained before initiating the perfusion (time 0) and after the first and second hour of operation (time 60 and 120 min, respectively). In Figure 5A it can be appreciated the LMOs ammonia detoxification capacity during two hours of MBR functioning. It can be observed that both preserved groups were able to detoxify a percentage of ammonium initial doses similar to control group, during the whole experiment. After two hours, the percentage of the initial dose detoxified (Figure 5A) was  $49.3\% \pm 8.8\%$  for controls LMOs;  $52.9 \pm 6.5$  for BG35 and  $53.6 \pm 6.0$  for ViaSpan® preserved LMOs ( $n = 6$ ). To get a better knowledge about the amount of ammonia that LMOs were able to metabolize in the MBR, Figure 5B shows the  $\mu$ mol of this compound detoxified per gram of wet tissue. The values reached at the end of the perfusion period were: Control:  $13.2 \pm 2.2$ ; BG35:  $14.2 \pm 3.8$ , and ViaSpan®  $16.0 \pm 1.1$   $\mu$ mol of  $\text{NH}_4^+$  detoxified/g wet tissue ( $n = 6$ ).

#### Histology

Control and cold preserved LMOs (48 h in BG35 and ViaSpan® solutions) were morphologically analyzed to assess hepatic tissue integrity, at the beginning and after 2 h of perfusion in the MBR.

Control LMOs showed normal hepatocyte cords with fusiform endothelial cells attached to the extracellular matrix of perisinusoidal space (EMPS), both at 0 min and at 120 min of perfusion period in the MBR (Figure

**Figure 5** Evolution of (A) initial dose of ammonium detoxified (%) (B) detoxification of ammonia ( $\mu\text{mol/g}$  wet tissue) for fresh cold preserved liver Microorgans in BG35 and ViaSpan® solutions used as a biological component in the minibioreactor. Data are expressed as mean  $\pm$  SD,  $n = 6$  liver Microorgans independent preparations for each condition.

6A and B).

LMOs preserved in BG35 had organized hepatocyte cords with sinusoids slightly dilated and endothelial cells with two different morphology patterns: Fusiform or rounded, both attached to EMPS (Figure 6D) at 0 min. After 120 min, morphological features changed. Hepatocyte cords continued to be organized but sinusoids were dilated with abundant rounded endothelial cells either attached to EMPS or seen inside sinusoidal lumen (Figure 6E).

At 0 min, LMOs preserved in ViaSpan® solution showed balonized hepatocytes and abundant rounded endothelial cells. Endothelial cells were attached to EMPS and sinusoidal lumen was dilated (Figure 6D). At 120 min LMOs had abundant blebs and areas of disrupted hepatocyte cords (Figure 6E).

## DISCUSSION

The goal of this study was the development of a simplified BAL prototype suitable to use LMOs as biological component, and the evaluation of fresh and cold preserved rat LMOs performance in this model.

Our simple hollow fiber MBR was constructed to enable the control of LMOs performance (*i.e.*, viability and detoxification, but also suitable for the measurement of other parameters such as synthesis functions specific of liver) and sampling of blood and BC fluid during operation. In a first stage, we characterized this simplified prototype by setting different functional para-

meters without the biological component. We observed an optimum exchange of fluids and metabolites. The Polyamix™ hollow fibers used allow adequate diffusive and convective mass transport. In order to evaluate the performance of these fibers against large size molecules we determined their permeability to plasma proteins. The experiments using FPLC showed that the pore size of the membranes used, with a cutoff value of 50 kDa, blocks the transfer of plasma proteins into the BC thus preventing damage of LMOs by the hypothetical patient's immune system proteins (antibodies, complement system).

After checking the system operation without any biological component, as a final step of the "*in vitro*" characterization of our BAL model, a validation step was performed, evaluating the performance of control and preserved LMOs in the MBR designed. The architecture chosen for the BAL we present here was not trivial; the BAL system in use in our laboratory, with isolated hepatocytes as biological component, was not suitable for LMOs which almost did not detoxify ammonia when applied to it (data not shown). As LMOs detoxification of ammonia on flat plates<sup>[11]</sup> was satisfactory, we decided to construct a "flat bottom" BAL to allow accommodating the tissue slices in a less crowded manner. In BAL devices designed to use LMOs, it is essential that the bioreactor architecture ensures a good viability of this biological component during the blood detoxification performance.

We observed that LDH releasing from LMOs cold preserved in Viaspan® was increasing with the perfusion time and this phenomenon was not observed for LMOs preserved in BG35 solution or controls. This fact can be attributed to a protective effect exerted by PEG 35000 kDa (key component of BG35 solution) on cell membranes<sup>[14,19,20]</sup>.

Observation of ammonia depuration is an evidence of hepatic synthetic function and is an important feature to propose the device we present here for clinical application<sup>[21,22]</sup>. When this MBR was challenged with an ammonia overload it showed an effective detoxification of this detrimental metabolite, either when cold preserved or fresh LMOs were examined. LMOs cold preserved in both preservation solutions were able to detoxify a similar percentage of the initial dose as compared to the control group. Although LMOs cold preserved in ViaSpan® showed higher levels of LDH release after 120 min of reperfusion they were able to detoxify an ammonium overload as well as control and cold preserved in BG35 solution LMOs did. Our group had already shown that, immediately after 48 h of cold preservation, ATP levels were severely decreased but they were actively replenished during reperfusion<sup>[23,24]</sup>. This fact can explain the good ammonium detoxification performance observed and constitute an indication of LMOs conserved mitochondrial function after cold preservation. Histological evaluation of LMOs showed that although BG35 protect hepatic morphology better than ViaSpan® solution, both cold preservation solutions proved to be useful to preserve the biological component integrity in our flat-plate model of MBR.

To provide a clear idea of the amount of ammonia that

**Figure 6 Liver microorgans histology.** Hematoxylin-eosin. Samples were taken from control and preserved groups at the beginning (A, C and E) and at the end ( $t = 120$  min) (B, D and F) of the experiment. Controls (A and B) showed normal hepatic parenchyma with fusiform endothelial cells (arrows) attached to perisinusoidal extracellular matrix and conserved hepatocyte cords. Sinusoids appeared dilated (bold arrow head) after 120 min. Liver microorgans (LMOs) preserved in BG35 (C and D) presented conserved hepatic architecture with fusiform (arrows) and rounded (bold arrows) endothelial cells. Sinusoids were dilated (bold arrow heads). LMOs preserved in ViaSpan® (E and F) had fusiform (arrows) and rounded (bold arrows) endothelial cells, dilated sinusoids (bold arrow head), and balonized hepatocytes (b) at the beginning of the experiment. F: After 120 min, blebs (a) and areas of hepatocyte trabecular disruption (d) were also found. Central Vein (CV). Magnification  $\times 200$ .  $n = 6$  LMOs independent preparations for each condition. c: Central vein.

LMOs were able to metabolize, we also determined the amount ( $\mu\text{mol}$ ) of this compound detoxified per gram of wet tissue during reperfusion. Once again we found similar levels of ammonium detoxification between control LMOs and LMOs cold preserved in Viaspan® or BG35 solution. The ammonium concentration in blood of patients with acute liver failure (ALF) could be greater than  $0.2 \text{ mmol/L}$  and it should be considered that also there is a continuous infusion of this metabolite to blood flow. In our *in vitro* experiments we used a higher concentration ( $1 \text{ mmol/L}$ ) since we worked with a single initial dose of ammonium. In addition, Calligaris *et al.*<sup>[25]</sup> showed that neither cell viability nor ammonium detoxification capacity of freshly isolated hepatocyte suspensions were affected by the

concentration of the initial ammonium overload.

It is important to consider that in this work we tested two preservation solutions: ViaSpan® which is the gold standard in liver preservation<sup>[26,27]</sup> and BG35 that was design by our group specifically to suit cold preservation of LMOs, and the entire liver in the future. The use of BG35 solution for the cold storage of LMOs may facilitate liver research since one litter of ViaSpan® is about 3 time more expensive than the same volume of BG35<sup>[11,14]</sup>.

The experimental MBR presented in this study relied on a simple design and was constructed using standard materials available in most laboratories. Due to these facts we foresee its employment as a useful tool to study the performance of LMOs submitted either

to preservation protocols or any other treatment or condition. Taking into account all the results previously shown, we have demonstrated that LMOs could be used as the biological component of the MBR designed, showing an adequate capacity to detoxify ammonia. We have also optimized the techniques to cold preserve this biocomponent to ensure its continuous availability, which is essential for any BAL to become a useful therapeutic tool for patients with ALF. As future prospects, these results encourage us to study other important liver functions, as transcription of albumin and clotting factors during reperfusion and to challenge it to treat acute liver failure of small animal models which will allow the measurement of bilirubin conjugation, blood clotting functions or intracranial pressure all important clinical prognostic predictors for ALF patients<sup>[28-30]</sup>. Also, to scale this MBR up and evaluate it in big animal models of ALF such as pigs.

## ACKNOWLEDGMENTS

The authors would like to thanks Dr. German Rosano for his technical support in FPLC analysis.

## COMMENTS

### Background

Acute liver failure is a condition that sometimes is resolved spontaneously but in most cases requires liver transplantation. The regeneration capacity of the liver seems to be behind the cases were, after the first insult has disappeared, the organ recovers by itself. This has been shown to be a consequence of the amount of viable mass remaining in terms of tissue capacity to cope with the detoxification of harmful metabolites produced by the damage and to provide the needed quantities of essential liver produced molecules and factors. This is why many attempts have been pursued to help the patient's liver to transit this acute failure and either recover or extend the time frame for a liver transplantation to be practical. In this sense, bioartificial liver (BAL) is thought as the better choice to accomplish this job but till now it is only performed by medical care teams that are able to obtain the biological component in the same unit making the practice limited to very few centers in the world.

### Research frontiers

A choice for the optimal biological component for BAL devices, as looking forward to develop a tool ready to use worldwide, is not straightforward. Hepatic derived cell lines, whole animal livers (even "humanized" organs) and primary human or animal hepatocytes have been proposed and tested but none have proven to be easily translatable to health centers reality. The work presented here proposes the use of tissue slices [liver Microorgans (LMOs)] and their preservation for at least 48 h in a preservation solution designed by their group. The obtainment of this biological component presents much less technical difficulty than isolation of viable hepatocytes and it bares all the cellular types and a conserved micro-architecture compared to the liver itself. The authors also show the extension of the period of use of these LMOs from few hours to 2 d and they are certain that it could be increased more by tuning the composition of their BG35 solution further.

### Innovations and breakthroughs

To date the reports found in the literature inform the use of isolated cells, either primary hepatocytes or continuous cell lines, or even whole pig livers and attempts have been made to cultivate the cellular component on artificial scaffolds mimicking extracellular matrices and micro-architecture. This biological components are used either fresh isolated or obtained directly by *in vitro* culturing. To the best of our knowledge, the authors are the only group using and combining tissue slices and cold preservation techniques to

successfully apply these LMOs onto BAL devices. The authors are still working with the dimensions of a mini-prototype that should be scaled up to be used for human patients and this is the future challenge the authors have to undertake.

## Applications

It follows that the application of their results would be the design of a BAL accessible on demand at low cost in health care centers for the treatment of patients, with either acute or chronic liver failure, for their recovery, or as a support until organ transplantation, and to ameliorate their quality of life in the process.

## Peer-review

This is an *in vitro* study for demonstration of the bio-artificial liver with detoxification. An interesting study for research design and innovation of the device.

### Abstract

#### AIM

To examine the relationship between pancreatic hyperechogenicity and risk factors for metabolic syndrome.

#### METHODS

A general population-based survey of lifestyle-related diseases was conducted from 2005 to 2006 in Japan. The study involved 551 participants older than 40 year of age. Data for 472 non-diabetic adults were included in the analysis. The measures included the demographic factors, blood parameters, results of a 75 g oral glucose tolerance test, and abdominal ultrasonography. The echogenicity of the pancreas and liver was compared, and then the subjects were separated into two groups: cases with pancreatic hyperechogenicity ( $n = 208$ ) and cases without (controls,  $n = 264$ ). The differences between both groups were compared using an unpaired  $t$ -test or Fisher's exact test. Multiple logistic regression analysis was used to determine the relationship between the pancreatic hyperechogenicity and clinical and bio-

chemical parameters.

## RESULTS

Subjects with pancreatic hyperechogenicity had decreased serum adiponectin concentration compared to control subjects [8.9 (6.5, 12.8) *vs* 11.1 (7.8, 15.9),  $P < 0.001$ ] and more frequently exhibited features of metabolic syndrome. Logistic regression analysis showed that the following variables were significantly and independently associated with pancreatic hyperechogenicity: Presence of hypoadiponectinemia, increased body mass index (BMI), higher homeostasis model assessment of insulin resistance (HOMA-IR) score, and presence of fatty liver. Similar associations were also observed in subjects with pancreatic hyperechogenicity without fatty liver. Multivariate association analysis of data from participants without fatty liver showed that hypoadiponectinemia was significantly associated with pancreatic hyperechogenicity (OR = 0.93, 95%CI: 0.90 - 0.97,  $P < 0.001$ ). This association was independent of other confounding variables. Additionally, an increased BMI and higher HOMA-IR score were significantly associated with pancreatic hyperechogenicity.

## CONCLUSION

Pancreatic hyperechogenicity is independently associated with increased BMI, insulin resistance, and hypoadiponectinemia in the general population.

**Key words:** Pancreatic hyperechogenicity; Metabolic syndrome; Obesity; Adiponectin; The Takahata study

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Pancreatic hyperechogenicity is related to aging. Several recent studies have reported that hepatic steatosis and increased body mass index (BMI) are predictors of a hyperechogenic pancreas. In the present study, fatty liver was also significantly associated with pancreatic hyperechogenicity. We performed additional analyses excluding participants with fatty liver in order to account for the effect of this condition. Our analyses showed that an increased BMI, higher homeostasis model assessment of insulin resistance score, and decreased adiponectin were also significantly associated with pancreatic hyperechogenicity.

Pancreatic hyperechogenicity associated with hypoadiponectinemia and insulin resistance: A Japanese population study. *World J Hepatol* 2016; 8(33): 1452-1458 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i33/1452.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i33.1452>

## INTRODUCTION

Pancreatic hyperechogenicity may be related to the

aging process<sup>[1-3]</sup>. Previous studies have reported that increased echogenicity of the pancreas is associated with pancreatic lipomatosis<sup>[4,5]</sup>. Additionally, recent ultrasound studies have demonstrated pancreatic hyperechogenicity is correlated with obesity, hepatic steatosis<sup>[6,7]</sup>, and insulin resistance<sup>[8]</sup>. To our knowledge, there are a limited number of reports examining the relationship between pancreatic hyperechogenicity and lifestyle-related risk factors.

Recent studies have demonstrated that adipose tissue not only stores fat but also functions as an endocrine organ by producing various adipocytokines such as adiponectin. Adiponectin is a peptide hormone that plays a key role in the development of insulin resistance associated with metabolic syndrome<sup>[9]</sup>. Adiponectin levels are correlated directly with insulin sensitivity and are decreased in obese individuals and patients with type 2 diabetes<sup>[10,11]</sup>. Recent studies have shown that there is an association between low concentrations of adiponectin and cancer development<sup>[12,13]</sup>. However, no report has examined the relationship between adiponectin concentration and pancreatic hyperechogenicity.

The aim of the present study was to examine the associations between pancreatic hyperechogenicity and risk factors for metabolic syndrome, including adiponectin concentration, in the general Japanese population.

## MATERIALS AND METHODS

### Study population

The study was part of an ongoing molecular epidemiological project utilizing the regional characteristics of the 21<sup>st</sup> Century Centers of Excellence program in Japan, which has been previously described<sup>[14]</sup>. The surveyed population was the entire population of adults aged over 40 year in the town of Takahata, Yamagata prefecture, located in northeastern Japan. There were 551 participants enrolled in the study between 2005 and 2006. All participants received a physical examination, blood tests, a 75-g oral glucose tolerance test (OGTT), and abdominal ultrasonography (US). We excluded 79 of the 551 participants for the following reasons: Poor US images of the pancreas (43 individuals); blood samples collected in a non-fasting state (27 individuals); or OGTT-diagnosed diabetes mellitus based on the American Diabetes Association criteria (9 individuals)<sup>[15]</sup>. Exclusion criteria included a history of diabetes or pancreatic disease. However, no participants met the exclusion criteria. The data collected from 472 subjects (201 males and 271 females) were included in the final analysis.

### Measurements

We obtained information on current medication and lifestyle-related characteristics from all participants using a questionnaire. Trained study staff measured height, weight and systolic and diastolic blood pressure (BP) using standard methods. Body mass index (BMI) was calculated as weight (in kilograms) divided by height (in meters squared). Insulin resistance was evaluated using

the homeostasis model assessment of insulin resistance (HOMA-IR) method with the following equation:  $\text{HOMA-IR} = \text{fasting insulin } (\mu\text{U/mL}) \times \text{fasting glucose (mg/dL)} / 405$ . Venous blood was drawn the morning after an overnight fast. The serum and plasma were separated immediately and stored at  $-80^\circ\text{C}$  until analysis. The serum adiponectin concentrations were measured by an enzyme-linked immunosorbent assay as described previously<sup>[9]</sup>. The other biochemical blood parameters were determined by standard laboratory procedures in the General Laboratory of BML, Inc. (Saitama, Japan). All laboratory personnel were blinded to the status of the samples.

All participants underwent US and an OGTT during a single visit at the research center and within 2 mo of the physical examination and initial blood collection. Blood samples were obtained to determine plasma glucose in the basal period and 120 min after an oral glucose load in the morning following an overnight fast.

The participants fasted overnight for the US study, and the scans were performed by one of four experienced operators using either a Toshiba Nemio™ scanner or an Aloka SSD-3500 scanner with a 3.5-MHz convex transducer. The participants were scanned while lying supine. The images were recorded on a standard computer hard disk drive. The recorded images were analyzed and judged simultaneously by four experienced physicians blinded to the details of the subjects, as described in a previous report<sup>[5]</sup>. The echogenicity of the pancreatic body was compared with the liver. The subjects were separated into cases with pancreatic echogenicity higher than hepatic echogenicity ( $n = 208$ ) and controls whose pancreatic echogenicity was equal to or lower than the liver ( $n = 264$ ). The presence of fatty liver was defined as a US pattern consistent with evidence of increased ultrasonographic contrast between the hepatic and renal parenchyma, vessel blurring, and narrowing of the lumen of the hepatic veins. We used these criteria to divide the subjects into cases with ( $n = 206$ ) or without ( $n = 266$ ) fatty liver.

### Statistical analysis

The distribution of the continuous variables was assessed for normality. If a normal distribution was evident, then the data were expressed as the means  $\pm$  standard deviation. The data with a non-normal distribution were log-transformed for analysis and expressed as the median with 25<sup>th</sup>/75<sup>th</sup> percentiles. The case and control groups were compared using the unpaired *t* test or Fisher's exact test. The relationship between pancreatic hyperechogenicity and clinical and biochemical parameters was determined using multiple logistic regression analyses with the backward elimination method. The odds ratio (OR) and 95%CI were then calculated.

The parameters in the multiple logistic regression analysis were categorized using the following cutoff values: BMI ( $< 25 \text{ kg/m}^2$ ,  $\geq 25 \text{ kg/m}^2$ ), systolic BP ( $< 130 \text{ mmHg}$ ,  $\geq 130 \text{ mmHg}$ ), diastolic BP ( $< 85 \text{ mmHg}$ ,  $\geq 85 \text{ mmHg}$ ), fasting plasma glucose ( $< 110 \text{ mg/dL}$ ,

$\geq 110 \text{ mg/dL}$ ), HOMA-IR score ( $< 2.0$ ,  $\geq 2.0$ ), high-density lipoprotein (HDL) cholesterol ( $< 40 \text{ mg/dL}$ ,  $\geq 40 \text{ mg/dL}$ ), triglyceride ( $< 150 \text{ mg/dL}$ ,  $\geq 150 \text{ mg/dL}$ ), glutamic pyruvic transaminase (GPT) ( $< 35 \text{ IU/L}$ ,  $\geq 35 \text{ IU/L}$ ), pre-load plasma glucose in the OGTT ( $< 110 \text{ mg/dL}$ ,  $\geq 110 \text{ mg/dL}$ ) and post-load 2-h plasma glucose in the OGTT ( $< 140 \text{ mg/dL}$ ,  $\geq 140 \text{ mg/dL}$ ). The median values for serum insulin and pancreatic isoamylase were used as the cutoff points. Serum adiponectin was analyzed as a continuous variable. All data were analyzed using SPSS software (version 15.0, SPSS Inc., Chicago, IL, United States). All differences with  $P < 0.05$  were considered statistically significant. The statistical methods of this study were reviewed by Yuko Nishise from the Faculty of Medicine, Yamagata University.

## RESULTS

The baseline clinical and biochemical data for the cases and controls are shown in Table 1. The serum adiponectin levels were markedly lower in the cases than in the controls [8.9 (6.5-12.8) vs 11.1 (7.8-15.9),  $P < 0.001$ ]. In addition, there were significant differences between the cases and controls for the following variables: Age, presence of fatty liver, weight, BMI, systolic BP, diastolic BP, serum insulin, fasting plasma glucose, HOMA-IR score, HDL cholesterol, total cholesterol, triglyceride, pancreatic isoamylase, GPT, pre-load plasma glucose in the OGTT, and 2-h plasma glucose.

Each parameter was dichotomized according to the cutoff points to further explore the relationship between pancreatic hyperechogenicity and other parameters. We then conducted multiple logistic regression analyses with the backward elimination method.

We first used an age-adjusted model to exclude the influence of aging. The results indicate that there was a significant negative association between decreased adiponectin levels and pancreatic hyperechogenicity (OR = 0.92, 95%CI: 0.88-0.95,  $P < 0.001$ ). In addition, the presence of fatty liver, higher values of BMI, systolic BP, diastolic BP, serum insulin, HOMA-IR score, 2-h plasma glucose and lower pancreatic isoamylase levels were significantly associated with pancreatic hyperechogenicity (Table 2).

We next performed the analysis after adjustment for age, presence of fatty liver, BMI, systolic and diastolic BP, adiponectin, serum insulin, HOMA-IR, triglyceride, pancreatic isoamylase, GPT, and 2-h plasma glucose. The analysis showed that hypoadiponectinemia was significantly associated with pancreatic hyperechogenicity (OR = 0.9, 95%CI: 0.91-0.98,  $P = 0.004$ ), independent of the other confounding variables. The presence of fatty liver, increased BMI, and higher HOMA-IR score were also significantly associated with pancreatic hyperechogenicity. In addition, decreased pancreatic isoamylase showed a weak relationship with pancreatic hyperechogenicity (Table 2).

We then performed further analyses to exclude the influence of fatty liver. The baseline clinical and

2-h plasma glucose (OGTT) (mg/dL), < 140/≥ 140	170/38	244/20	2.4 (1.3-4.3)	0.003		

<sup>1</sup>Serum adiponectin was analyzed as a continuous variable; <sup>2</sup>The median values for serum insulin and pancreatic isoamylase were used as the cutoff points;

<sup>3</sup>Adjusted for the age, presence of fatty liver, BMI, systolic BP, diastolic BP, adiponectin, serum insulin, HOMA-IR, triglyceride, pancreatic isoamylase, GPT and 2-h plasma glucose. Odds ratios and 95%CI were estimated using the multiple logistic regression model with backward elimination. BMI: Body mass index; BP: Blood pressure; HOMA-IR: Homeostasis model assessment of insulin resistance; HDL: High-density lipoprotein; GPT: Glutamic pyruvic transaminase; OGTT: Oral glucose tolerance test.

biochemical data for cases and controls without fatty liver are shown in Table 3. The serum adiponectin levels were lower in cases than in controls [10.3 (7.6-14.6) vs 12.0 (8.6-17.0), *P* = 0.022]. Furthermore, there were significant differences between cases and controls for the following parameters: Age, weight, BMI, serum insulin, fasting plasma glucose, HOMA-IR score, HDL cholesterol, triglycerides, and preload plasma glucose in the OGTT.

We next performed multivariate association analyses of data from participants without fatty liver. The multi-

variate analysis showed that hypoadiponectinemia was significantly associated with pancreatic hyperechogenicity (OR = 0.93, 95%CI: 0.90-0.97, *P* < 0.001), independent of the other confounding variables. Additionally, an increased BMI and higher HOMA-IR score were also significantly associated with pancreatic hyperechogenicity (Table 4).

## DISCUSSION

Studies examining digestive organ disease and altered

**Table 3** Comparison of baseline characteristics between the pancreatic hyperechogenicity and control groups excluding participants with fatty liver

Clinical parameters	Pancreatic hyperechogenicity (n = 95)	Control (n = 171)	P value
Age (yr)	62 ± 9	58 ± 10	0.001
Sex (male/female)	44/51	76/95	0.769
Height (cm)	158.0 ± 8.0	158.1 ± 9.0	0.960
Weight (kg)	59.5 ± 9.4	53.9 ± 8.5	< 0.001
BMI (kg/m <sup>2</sup> )	23.7 ± 2.6	21.5 ± 2.5	< 0.001

CI: Confidence interval; BMI: Body mass index; HOMA-IR: Homeostasis model assessment of insulin resistance.

secretion of adipocytokines caused by metabolic syndrome will improve our understanding of the mechanisms involved in pathophysiological conditions. It is possible that such investigations might lead to the development of preventive measures for diseases linked to metabolic syndrome.

Pancreatic hyperechogenicity is thought to be related to the aging process<sup>[1-3]</sup>. Our data showed that several features of metabolic syndrome, such as higher BMI, increased HOMA-IR score, and hypoadiponectinemia, were also independently associated with pancreatic hyperechogenicity.

This is the first study conducted in a general population that investigated the relationship between pancreatic hyperechogenicity and risk factors of metabolic syndrome, such as insulin resistance and serum adiponectin concentration. The main study findings were: (1)

that serum adiponectin concentrations were markedly lower in subjects with pancreatic hyperechogenicity than in controls [8.9 (6.5-12.8) vs 11.1 (7.8-15.9), *P* < 0.001]; and (2) that decreased adiponectin levels were associated independently with pancreatic hyperechogenicity (OR = 0.9, 95%CI: 0.91-0.98, *P* = 0.004). Adiponectin is produced by adipose tissue, and a low adiponectin concentration is considered to be a key factor in the development of insulin resistance underlying metabolic syndrome<sup>[9-11]</sup>.

Several studies have reported that increased echogenicity of the pancreas is related to lipomatosis of the pancreatic parenchyma<sup>[4,5]</sup>. Pancreatic lipomatosis is the most common histological change in the pancreas associated with age, obesity, and insulin resistance<sup>[6-8,16-19]</sup>. Recently, Raeder *et al.*<sup>[5]</sup> evaluated the pancreatic fat content using US and magnetic resonance imaging and showed that pancreatic lipomatosis may reflect early events involved in the pathogenesis of diabetes and exocrine pancreatic dysfunction in non-diabetic children with mutations in carboxyl-ester lipase. In addition, Tushuizen and co-workers<sup>[20]</sup> measured the pancreatic fat content using proton magnetic resonance spectroscopy and found that pancreatic fat was inversely associated with β-cell function parameters in non-diabetic men. However, there was no association in their diabetic counterparts. The authors suggested that pancreatic fat content may contribute to β-cell dysfunction<sup>[20]</sup>. In our logistic regression analysis, we adjusted for age and pancreatic hyperechogenicity, which is a potential marker of lipomatosis. We found that these parameters were associated with higher serum insulin, HOMA-IR, and 2-h plasma glucose levels in the OGTT. There was

no association with fasting and preload plasma glucose concentrations in the OGTT (Table 2). It is possible that pancreatic hyperechogenicity with insulin resistance precedes the development of diabetes in the non-diabetic general population. Thus, further large-scale prospective studies are necessary to investigate whether pancreatic hyperechogenicity is an early pathological event in the diabetes disease process.

Several recent studies have reported that hepatic steatosis and increased BMI are predictors of a hyperechogenic pancreas<sup>[6,7]</sup>. In the present study, fatty liver was also significantly associated with pancreatic hyperechogenicity (OR = 1.77, 95%CI: 1.15-2.72, *P* = 0.009) (Table 2). Therefore, we performed additional analyses excluding participants with fatty liver in order to account for the effect of this condition in our results. The adjusted analysis showed that increased BMI, higher HOMA-IR score, and decreased adiponectin were also significantly associated with pancreatic hyperechogenicity (Table 4). This is the first study investigating the relationship between pancreatic hyperechogenicity and risk factors for metabolic syndrome by excluding the influence of fatty liver.

In this study, we used a simple and traditional method of assessing the severity of pancreatic hyperechogenicity, which was the comparison of echogenicity between the pancreatic body and the liver. However, this approach can potentially result in misdiagnosis of pancreatic hyperechogenicity if the extent of fatty liver is severe. We also performed additional analyses to exclude the influence of fatty liver. As shown in Tables 2 and 4, the results of our analyses that either included or excluded fatty liver, respectively, were similar and both showed increased BMI, higher HOMA-IR scores, and decreased adiponectin levels. However, our study had a limitation: No histological confirmation of pancreatic fat was possible.

There may be unknown factors that may cause the histological changes associated with obesity in addition to fat accumulation, fibrosis and functional changes in the exocrine pancreas. We recently demonstrated that intra-lobular fat accumulates in exocrine pancreatic tissue and that lipid droplets in acinar cells increase in Zucker diabetic fatty rats, which is an animal model of type 2 diabetes caused by the chronic intake of a high-fat diet. These conditions appear cause acinar cell injury and fibrosis<sup>[21]</sup>. Thus, additional clinical and experimental studies of the interrelationships between diabetes, metabolic syndrome and pancreatic injury should be conducted to clarify the pathogenesis of "non-alcoholic fatty pancreatic disease".

In conclusion, our study of a non-diabetic general population showed that pancreatic hyperechogenicity was independently associated with increased BMI, insulin resistance and hypoadiponectinemia.

## ACKNOWLEDGMENTS

We are grateful to all the participants and volunteers who enrolled in this study. We also thank Ms. Miho Ishii

and Dr. Mitsuru Emi for helpful advice.

## COMMENTS

### Background

Pancreatic hyperechogenicity is thought to be related to the aging process. However, little is known about the association between pancreatic hyperechogenicity and other life-style related risk factors.

### Research frontiers

Prior studies have reported that increased echogenicity of the pancreas is associated with pancreatic lipomatosis. Recent ultrasound studies have shown that pancreatic hyperechogenicity is correlated with obesity, hepatic steatosis, and insulin resistance.

### Innovations and breakthroughs

This is the first study investigating the relationship between pancreatic hyperechogenicity and risk factors for metabolic syndrome by excluding the influence of fatty liver.

### Applications

Pancreatic hyperechogenicity is independently associated with increased body mass index, insulin resistance, and hypoadiponectinemia in the general population. Pancreatic hyperechogenicity could be a useful marker of the metabolic syndrome.

### Peer-review

### Abstract

#### AIM

To investigate in non-alcoholic-fatty-liver-disease (NAFLD), with ultrasound (US)-detected fatty liver, and in a group of non-alcoholic and otherwise healthy subjects, relationship of neglected features of lifestyle with NAFLD and obesity.

#### METHODS

Five hundred and thirty-two NAFLD and 667 non-NAFLD healthy subjects, age 21-60 years were studied. Severity of liver steatosis was assessed by US bright liver score. The adherence to mediterranean diet score (AMDS) was assessed on the basis of a 1-wk recall computerized questionnaire which included a detailed physical activity reports (Baecke questionnaire). The western dietary profile score, as a simplified paradigm of unhealthy diet, a questionnaire quantifying sun exposure score and a sleep habits questionnaires provided a further comprehensive lifestyle assessment.

#### RESULTS

Body mass index (BMI), insulin resistance (HOMA), and triglycerides, poorer adherence to a mediterranean diet profile, sedentary habits, minor sun exposure and use of "western diet" foods are greater in NAFLD. Multiple

linear regression analysis, weighted by years of age, displays BMI, HOMA and AMDS as the most powerful independent predictors of fatty liver severity; however, also the physical activity score, the western diet habit and the sun exposure score are acting inside the model with significant independent effects.

### CONCLUSION

Articulated clinical intervention, according to our results, are justified in NAFLD and can be pursued addressing by focused intervention nutritional profile, physical exercise mainly in open-air subsets for enhancing sun exposure and healthier sleep duration and rhythm.

**Key words:** Fatty liver; Ultrasound; Diet; Malnutrition; Sleep; Clinical risk management; Health psychology; Sun exposure; Obesity

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Non-alcoholic-fatty-liver-disease (NAFLD) is a multifactorial condition associated with malnutrition and, mainly, with obesity, sedentary life and insulin resistance; some neglected factor, such as sleep and sun exposure curtailment, along with D vitamin deficiency, are associated with NAFLD; articulated clinical intervention, according to our results, is justified in NAFLD and can be pursued addressing by focused intervention nutritional profile, open-air physical exercise for enhancing sun exposure and healthy behaviour targeted to improved sleep duration and rhythm.

Neglected features of lifestyle: Their relevance in non-alcoholic fatty liver disease. *World J Hepatol* 2016; 8(33): 1459-1465 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i33/1459.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i33.1459>

## INTRODUCTION

Liver diseases, already in the past, were considered at least partly a consequence of unhealthy lifestyles and adverse environmental conditions, a concept that was very well addressed also by pathologists<sup>[1]</sup>. Lifestyle regards the use of the body functions related to physical exercise, exerted in work, love, leisure or sport, the quality and quantity of food, the sleep and rest rhythms, the exposure to hostile or unhealthy environmental factors, and other aspects, including fashion, clothing and non-sport leisure activity<sup>[2,3]</sup>. As in the past, the impact of the fashions and of beliefs based on alleged scientific statements and commercial information, namely publicity, is the key factor<sup>[4]</sup>. This framework, also by conditioning different lifestyles, reasonably affects the "establishment and maintenance of several diseases, including liver disease"<sup>[5]</sup>. In a very simplified manner today we tend to describe the lifestyles in medicine especially in terms

of diet and physical inactivity or sedentary life, with a synergistic effect on body size - obesity - and on disease related with excessive food intake (atherosclerosis and liver disease)<sup>[6]</sup>. Marketing strategies focus much on some related aspects that have an influence on nutrition and physical activity, but also with trade repercussions, while neglecting and avoiding other modes of social behavior. Some of these factors, such as sleep duration<sup>[7,8]</sup>, the sleeping patterns<sup>[9-12]</sup>, including shift-work related effects<sup>[7]</sup>, exposure to noise<sup>[13,14]</sup>, the level of social alarm about events or situations<sup>[15]</sup>, the possibility of urban mobility<sup>[16,17]</sup>, may have determinant effects on nutritional profiles and exercise implementation. Communication and perception of risks, as traditionally recognized, are flanked by communication and induction of apparently neutral behavior that can behave as true risk factors for disease. The strong pressure towards practices aimed at optimizing physical fitness and dietary methods aimed at healthy foods often involves forms of orthorexia<sup>[18]</sup>; such strategies are widely used to gain and maintain niches of food and fitness markets. All this would be irrelevant, except that, as in the case of prevention of obesity and fatty liver, and probably also in the field of atherosclerotic, neurodegenerative and cancer diseases, dietary caloric intake and a sedentary lifestyle are not the only factors exerting independent synergistic effects<sup>[6]</sup>. In fact, even the dietary profiles<sup>[19]</sup>, methods of exercise implementation<sup>[20,21]</sup>, and other related factors, such as sleep deprivation<sup>[4]</sup>, D vitamin deficiency and exposure to sunlight<sup>[22]</sup>, environmental noise<sup>[16]</sup>, and reasonably also others, seem to be part of an interrelated group of neglected risk factors, which only now are beginning to be studied more methodically.

Aim of our research is to investigate if some of the above mentioned neglected behavioural factors, concurrently with nutritional and physical exercise profile, may be associated or contribute independently as factors related to fatty liver in a group of non-alcoholic and otherwise healthy subjects with ultrasound (US)-detected fatty liver.

## MATERIALS AND METHODS

### Patients

Five hundred thirty-two non-alcoholic-fatty-liver-disease (NAFLD) and 667 non-NAFLD subjects (women 749, men 450, total 1199), age 21-60 years, without relevant acute or chronic disease, as below detailed in the exclusion criteria, were studied. These patients were consecutively referred to the same out-patients public medical unit (day-hospital) for lifestyle-nutritional prescription addressed to the management of minor digestive disease (mainly gastro-esophageal reflux syndrome or irritable bowel syndrome), overweight or obesity. The subjects were enrolled throughout January 2008-December 2015, were all patients first-time visitors, had not had previous referral or intervention in our unit, and were studied by a comprehensive US assessment (liver-abdomen, heart, thyroid and lung),

according to our current practice<sup>[3]</sup>. Exclusion criteria: (1) all patients with signs of moderate-severe congestive heart failure, previous myocardial infarction, idiopathic cardiomyopathy, pericarditis, malignancies; (2) severe chronic liver disease, apart from the lone finding of bright liver; abnormal aminotransferase levels at the beginning of this study, defined as alanine transaminase (ALT) > 30 IU/L in men and ALT > 19 IU/L in women; acute or chronic virus hepatitis, which were excluded by concurrent laboratory assays, as below detailed; (3) any history of diabetes mellitus (fasting glucose  $\geq$  126 mg/dL or HbA1c  $\geq$  6.5%) or drug intake of anti-diabetic drugs, particularly metformin; (4) extreme obesity [body mass index (BMI)  $\geq$  40] and underweight bad-nourished profile (BMI < 18.5 or serum albumin < 3 g/dL); (5) acute and/or chronic infectious, rheumatic or autoimmune disease; and (6) alcohol abuse (exceeding 20 g/d on a weekly base); renal insufficiency, *i.e.*, glomerular filtration rate < 90 mL/min per 1.73 m<sup>2</sup> and/or proteinuria > 0.10 g/d. According to these exclusion criteria 1508 further subjects, potentially but only partially eligible, are excluded by this study.

#### Laboratory/imaging methods

The severity of liver steatosis was assessed by US bright liver score (BLS), graded 1-3: grade 0 was the absence of bright liver, *i.e.*, a normal pattern<sup>[23]</sup>, BLS was and previously validated by US-guided fine needle aspirate biopsy by 20 Gauge Menghini's needles<sup>[3]</sup>; GE echo color Doppler machines (GE Logiq 5/Vivid7 Expert US manufactured by GE Medical Systems, Milwaukee, WI, United States), high resolution, equipped with real-time convex, phased array and linear scan transducers, were used throughout this study.

Routine laboratory tests included virus hepatitis (hepatitis A, B and C virus, *i.e.*, HAV, HBV and HCV) and cancer biomarkers (Alpha-fetoprotein, CEA, Ca125, Ca 19-9, Ca15-3), thyroid hormones FT3 FT4, thyroid-stimulating hormone, aspartate aminotransferase, ALT,  $\gamma$ -glutamyl transpeptidase, ferritin, total protein, and albumin. Mediterranean diet adherence profile was assessed by the adherence to mediterranean diet score (AMDS) on the basis of a 1-wk recall computerized questionnaire<sup>[3,5]</sup> using a pictogram-based method of visualizing dietary intake, descriptive also of the size of the single portion; pictograms includes also items for the quantification of physical activity, which is otherwise quantified by detailed physical activity reports (Baecke questionnaire)<sup>[5]</sup>. The Western Dietary Profile score, as a simplified paradigm of unhealthy diet, was assessed submitting a specific questionnaire, which is reported in Appendix; also the Baecke's physical activity questionnaire is briefly described in appendix, and subsequently the total score was studied by statistical analysis. The questionnaires submitted for quantifying sun exposure score, used mainly as an index of the open air activity and sleep habits questionnaires are routinely included within the context of a comprehensive lifestyle

assessment, and detailed in appendix. The study and the manuscript were approved by the institutional review board of the project office. No conflict of interest is to be declared for this invited manuscript. Written informed consent was obtained from each patient prior to the clinical data recording and before the US procedure, allowing the use of information for teaching and clinical research. Detail that might disclose the identity of the subjects under study is carefully omitted in any part of the study.

#### Statistical analysis

Comparison of data between the two groups of patients, NAFLD vs controls, is reported and differences assessed by Student's *t* test. Subsequently: (1) receiver operating characteristic (ROC) curve analysis of data of controls vs NAFLD subjects is used for defining the optimal cut-offs which may distinct the two group. The performance of each measure in prediction of NAFLD was evaluated by ROC curve. The area under the ROC curve and the 95%CI were used as indexes of accuracy. The optimal cut-off value was determined with maximum sum of sensitivity and specificity. For the purpose of identifying such thresholds, the measures used were BMI, HOMA, AMDS, western diet score (WDS), Physical activity Baecke's total score, sun exposure score, and sleep daily hours, calculated on a weekly base; (2) contingency tables and odds ratio of NAFLS vs non-NAFLD were calculated, according to each defined cut-off; and (3) MLR analysis, weighted by age, using BMI, HOMA, AMDS, WDS, physical activity baecke's total score, Sun exposure score, sleep hours vs BLS score of fatty liver was at last performed.

## RESULTS

The two groups of patients were comparable for age (Table 1), while other measures, such as BMI, HOMA and Triglycerides are greater in NAFLD. Comparison of data between the two groups of patients, NAFLD vs controls, is reported in detail (Table 1): A poorer adherence to a mediterranean diet profile, greater sedentary habits and greater use of "western diet" foods are the main differences. Moreover, liver size and, obviously, detection of fatty liver are the main US feature distinctive of the two groups. The ROC curve analysis graph of the data of controls vs NAFLD subjects for BMI, HOMA, HDL Cholesterol is displayed in Figure 1.

The most suitable thresholds distinctive of NAFLD vs controls are, in our population: BMI  $\geq$  26.40, HOMA  $\geq$  1.87, HDL < 54.50, TGL  $\geq$  94, AMDS < 34, WDS  $\geq$  15.5, physical activity Baecke's total score < 41.5, Sun exposure score SES < 34.5, and sleep daily hours, calculated on a weekly base sleep hours < 8.0. Contingency tables and Odds ratio were calculated for NAFLD vs controls, according to above defined thresholds. Greater prevalence of overweight-obesity, insulin resistance, increased triglycerides and low HDL cholesterol, poor adherence

**Table 1** Differences between non-alcoholic-fatty-liver-disease and control patients

	NAFLD (n = 532)	Controls (n = 667)	P value
Age, yr	48.11 ± 9.00	48.60 ± 8.70	0.343

Sleep hours	7.86 ± 1.31	7.90 ± 1.23	0.552

BMI: Body mass index; HOMA-IR: Homoeostasis model insulin resistance; HDL: High-density lipoprotein; LDL: Low-density lipoprotein; γ-GT: γ-glutamyl transpeptidase; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; AMDS: Adherence mediterranean diet score; NAFLD: Non-alcoholic-fatty-liver-disease; eGFR: Estimated glomerular filtration rate.

to mediterranean diet profile, greater use of Western diet food, greater sedentary life habits and minor sun exposure, open air time were observed (Table 2).

Multiple Linear regression analysis (Table 3), weighted by years of age for avoiding age as a potential confounding factor, using the same items as predictors of the severity of fatty liver, assessed by US as BLS, confirms the significance of the chosen model, displaying BMI, HOMA and AMDS as the most powerful predictors of fatty liver severity; also the physical activity score, the western diet habit and the sun exposure score are still inside the model, with significant independent effects. The number of sleep hours does not show any significant linear effect in the model. Nonetheless, in a separate analysis, sleep hours display a U shaped behaviour, showing a greater relationship with more severe fatty liver at the two extremes of the curve: Few and many hours of sleep are both associated with more severe fatty liver.

## DISCUSSION

Currently, overweight and obesity are the most established associated factors of NAFLD, and are considered, even with some limitation, actual risk factors and putative, indirect causative factors<sup>[2,3]</sup>. Nonetheless, other and quite neglected factors were and are studied: Most of

**Figure 1** Receiver operating characteristic curves of body mass index, homoeostasis model insulin resistance, Triglycerides and high-density lipoprotein - cholesterol. The performance of each measure in the prediction of NAFLD is evaluated by the receiver operating characteristic (ROC) curve. The area under the ROC curve (AUROC) and the 95%CI are used as indexes of accuracy. The optimal cutoff value is determined as the maximum sum of sensitivity and specificity. Accordingly, BMI displays the greater accuracy for predicting NAFLD in comparison of HOMA, Triglycerides and HDL-Cholesterol. The cutoffs are used as thresholds for the calculation of odds of NAFLD, as reported in Table 2. BMI: Body mass index; HOMA: Homoeostasis; HDL: High-density lipoprotein; NAFLD: Non-alcoholic-fatty-liver-disease.

them are related to behaviour, such as physical activity<sup>[5]</sup>, sleep habits<sup>[4]</sup> and Sun exposure, this last with a likely effects on vitamin D status<sup>[22]</sup>. Nutrition has a qualitative profile, and not only a quantitative one, *i.e.*, not only caloric intake, so that the association of unhealthy dietary habits, apart the abuse of alcohol, is associated with unhealthy liver and, notably, NAFLD. This is confirmed in our study in which we observe that, apart the greater BMI, also a poorer adherence to mediterranean diet profile<sup>[5]</sup>, widely and since several years used as a proxy of healthy diet, strongly predicts the occurrence of NAFLD, independently from overweight. Also the almost reciprocal western diet profile displays an unfavourable relationship for the occurrence of NAFLD. This is confirmed in our study by the significant difference of averages, with a greater WDS in NAFLD (Table 1), by the greater odds of NAFLD associated with greater BMI and western diet habits, and with lower adherence to mediterranean diet (Table 2). Moreover, by a model of multivariate analysis (Table 3) the effects of BMI, mediterranean diet and western diet are independently operating, addressing clearly to the opposite effects of mediterranean diet (favourable) and of western diet and overweight (detrimental). Concurrently with nutritional profiles and BMI, sedentary life, assessed quantitatively as physical activity score, displays the same effects: A better physical exercise profile is associated with a lower prevalence (Table 2) and severity of bright liver score (Table 3), as assessed in NAFLD by liver US. Physical activity score is overall poorer in NAFLD vs controls (Table 1). The same association is observed for the sun exposure score, which is greater in controls (Table 1) and which may indicate, apart a greater open air life, also a better D vitamin status, important because vitamin D deficiency is associated with NAFLD<sup>[22]</sup>. Differently from

**Table 2** Pearson's  $\chi^2$  and odds ratio

	NAFLD	Controls	$\chi^2$	P value	OR	95%CI

the observation reported in youngsters<sup>[4]</sup>, sleep hours do not show any significant relationship with NAFLD.

We must acknowledge several limitations of our study. First, the overall, comparison between NAFLD patients and controls (Table 1) does not display extreme differences, even if they are statistically significant, when considering sleep hours, sun exposure, AMDS and physical activity. There are very different features considering the greater score of Western Diet profile pattern in NAFLD. These even small differences between NAFLD and controls become more relevant within the model that takes into account all the co-variates, so that we must still consider them as relatively important features regarding NAFLD, even envisaging a size effect in the group studied.

Second limitation is that our eligibility criteria were rather strict, resulting in a population without significant co-morbidities, since all patients with diabetes and/or even minimally elevated ALT levels were excluded. It is possible that the analyzed lifestyle measures might work differently in a more comprehensive NAFLD cohort that includes other associated diseases. Scope of the study was to investigate NAFLD as an almost-isolated disease, and even with these restrictions association of recognized and neglected aspects of lifestyle are seemingly operating.

Modification over the time of healthier nutritional and behavioural profiles is a very articulated topic of investigation, which includes also the need of assessing the process of erosion of traditionally cohesive family and community relationships<sup>[24]</sup> with effects on health and mortality. Such studies have a counterpart in the current societal efforts aimed at the preservation of traditional habits, and even clinical conditions, such as high hemoglobin levels<sup>[25]</sup> which often are credited as healthier. Many animal models have been studied in which dietary variations produce liver injury, and by extrapolation, malnutrition, particularly deficiencies of protein and vitamins has long been considered an important factor in human cirrhosis when no evidence existed for another aetiology; by contrast, weight reduction through low-calorie diets or starvation reduces the steatosis resulting from obesity<sup>[1]</sup>. Malnutrition was in the last century, and now again, the key of many disease and, notably of liver disease, with its paradigm of fatty liver evolving toward fibrosis. Apart the pioneering studies on lifestyle changes<sup>[26]</sup> we are still on the starting blocks because each aspect of lifestyle is studied, and thereafter assessed and managed as

an individual factor. Despite the great attention which is devoted in Europe to healthier environment and to urban mobility, using the paradigm of smart city, few or no research are at the moment published and available, even if elsewhere there is already a move in this sense also by comprehensive approach focused to clinical risk assessment and management<sup>[2]</sup>. The important most recent reviews appropriately address benefits of healthy diet and exercise on NAFLD<sup>[27]</sup> both in adults<sup>[28]</sup> and in children<sup>[29]</sup>, even if other factors, genetic<sup>[30]</sup>, behavioural and environmental should not be neglected<sup>[31,32]</sup>. The opportunity for the medicine are relevant since articulated clinical intervention, which, according to our results, are justified, can be pursued with a focus on nutritional profile, physical exercise mainly open-air for enhancing sun exposure and improving sleep duration and rhythm<sup>[33]</sup>, cultural and traditional medicine issues and, comprehensively, the quality of life<sup>[34-39]</sup>. The pre-requisite is that both medical doctor and patient should not be mucking around in search of the magic bullet, and instead try to take seriously and with a strategy the road of lasting lifestyle change. Individual, professional and societal benefits are the outcomes that can be reached<sup>[2]</sup>.

## COMMENTS

### Background

In a very simplified manner today the authors tend to describe the lifestyles in medicine especially in terms of diet and physical inactivity or sedentary life, with a synergistic effect on body size - obesity - and on disease related with excessive food intake (atherosclerosis and liver disease).

### Research frontiers

Many animal models have been studied in which dietary variations produce liver injury, and by extrapolation, malnutrition; particularly deficiencies of protein and vitamins has long been considered an important factor in human cirrhosis when no evidence existed for another aetiology; by contrast, weight reduction through low-calorie diets or starvation reduces the steatosis resulting from obesity.

### Innovations and breakthroughs

This is confirmed in their study in which they observe that, apart the greater BMI, also a poorer adherence to mediterranean diet profile, widely and since several years used as a proxy of healthy diet, strongly predicts the occurrence of non-alcoholic-fatty-liver-disease (NAFLD), independently from overweight. Also the almost reciprocal western diet profile displays an unfavourable relationship for the occurrence of NAFLD. This is confirmed in our study by the significant difference of averages, with a greater western diet score in NAFLD, by the greater odds of NAFLD associated with greater body mass index and western diet habits, and with lower adherence to mediterranean diet.

### Applications

The opportunity for the medicine is relevant since articulated clinical intervention, which, according to their results, are justified, can be pursued with a focus on nutritional profile, physical exercise mainly open-air for enhancing sun exposure and improving sleep duration and rhythm, cultural and traditional medicine issues and, comprehensively, the quality of life. The pre-requisite is that both medical doctor and patient should not be mucking around in search of the magic bullet, and instead try to take seriously and with a strategy the road of lasting lifestyle change. Individual, professional and societal benefits are the outcomes that can be reached.

### Peer-review

The manuscript of "Neglected features of lifestyle: Their relevance in non-

alcoholic fatty liver disease" is very interesting.

### Abstract

#### AIM

To determine the laboratory and radiologic parameters, including the platelet count (PC)-to-spleen diameter (SD) ratio as a non-invasive marker that may predict the presence of esophageal varices (EV) in children with cirrhosis.

#### METHODS

Eighty-nine patients with cirrhosis, but without a history of variceal bleeding were prospectively included. The children were grouped into 6-12 and 12-18 years of age groups. These groups were also divided into 2 subgroups (presence and absence of EV). All of the patients underwent a complete biochemical and radiologic evaluation. The PC (n/mm<sup>3</sup>)-to-SD (mm) ratio was calculated for each patient.

#### RESULTS

Sixty-nine of 98 (70.4%) patients had EV. The presence of ascites in all age groups was significantly associated

with the presence of EV. There were no differences in serum albumin levels, PC, SD and the PC-to-SD ratio between the presence and absence of EV groups in both age groups ( $P > 0.05$ ).

## CONCLUSION

Laboratory and radiologic parameters, including the PC-to-SD ratio as a non-invasive marker (except for the presence of ascites), was inappropriate for detecting EV in children with cirrhosis.

**Key words:** Esophageal varices; Variceal bleeding; Platelet count-to-spleen diameter ratio; Children

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Laboratory and radiologic parameters, including the platelet count (PC)-to-spleen diameter (SD) ratio were investigated in children with cirrhosis as a non-invasive marker that may predict the presence of esophageal varices (EV). This study is the first study to assess the PC-to-SD ratio in children with cirrhosis for detecting EV according to age groups. This study demonstrated that the parameters, other than the presence of ascites, were inappropriate for detecting EV in children with cirrhosis.

Sezer OB, Çelik D, Tutar N, Özçay F. Can platelet count/spleen diameter ratio be used for cirrhotic children to predict esophageal varices? *World J Hepatol* 2016; 8(33): 1466-1470 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i33/1466.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i33.1466>

## INTRODUCTION

Esophageal variceal bleeding is among the most serious consequences of chronic liver disease<sup>[1]</sup>. Approximately two-thirds of children with cirrhosis have esophageal varices (EV), and the mortality associated with a variceal bleeding episode is 20%-35%<sup>[1-4]</sup>. Prevention of bleeding from a ruptured EV has become one of the main goals in the follow-up of these patients. Although a consensus has been reached for adults, there is no formal recommendation for endoscopic screening in children with cirrhosis<sup>[5]</sup>.

Esophagogastroduodenoscopy (EGD) is the present reference standard diagnostic test for EV. Nevertheless, only 50%-70% of cirrhotic patients have varices on the first EGD and < 30% have large varices and/or the red wale sign (high-risk EV for bleeding) in adults and children<sup>[6-8]</sup>. Because of the relatively low prevalence of varices that require primary prophylaxis, the cost, inconvenience, and morbidity associated with endoscopic surveillance may not be justified for all patients with cirrhosis. To reduce the increasing burden on endoscopy units and prevent unnecessary harm to patients, researchers have attempted to identify parameters for non-invasive

prediction of EV<sup>[9]</sup>. Several reports have identified non-invasive variables that may predict the presence of EV in childhood and have shown predictive factors for bleeding risk, such as hypoalbuminemia, the Child-Pugh score, an increased spleen diameter (SD), a low platelet count (PC), the PC-to-SD ratio, the clinical prediction rule, and the aspartate aminotransferase-to-platelet ratio index<sup>[6,7,10]</sup>. For this purpose, the PC-to-SD ratio was investigated to predict the presence of EV in adult patients with cirrhosis<sup>[11-14]</sup>. Chawla *et al*<sup>[15]</sup> concluded that the PC-to-SD ratio is elegant, simple and inexpensive, and it may become a helpful tool to limit the number of endoscopies for primary prophylaxis in adult patients with portal hypertension. Therefore, we conducted this study to investigate laboratory and radiologic parameters, including the PC-to-SD ratio, as predictors of EV in children with cirrhosis.

## MATERIALS AND METHODS

All children (6-18 years of age) who had been diagnosed with cirrhosis in the outpatient clinics of the Paediatric Gastroenterology Hepatology and Nutrition at Baskent University, Ankara, Turkey, were included in this prospective study. The diagnosis of cirrhosis was made based on laboratory, radiologic, and physical examination findings or by liver histology in the absence of clear clinical signs of liver cirrhosis. Demographic characteristics (age, gender and underlying disease), blood chemistry evaluations, international normalized ratio, and Child-Pugh scores were recorded for each patient.

Patients with a clinical history of upper digestive hemorrhage, band ligation, sclerosing therapy, transjugular intrahepatic portosystemic stent shunt, surgery for portal hypertension, hepatic encephalopathy, and use of beta-blockers or other vasoactive drugs were excluded from the study.

The children were further grouped into 6-12 and 12-18 year age groups. These groups were divided into two sub-groups (EV-present and -absent) based on the EGD. The EGD was performed by the same paediatric endoscopists in our endoscopy unit using a video endoscope (Olympus GIF-XP 240; Tokyo, Japan or Fujinon EG 590W videoendoscopy; Tokyo, Japan). EV were classified according to the Baveno IV criteria<sup>[16,17]</sup> and American Association for the Study of Liver Diseases practice guidelines<sup>[18]</sup> as no, small, and large varices. EV were also classified according to the bleeding risk as high risk and non-high risk using varices diameters and red sign parameters.

The spleen bipolar diameter and presence of ascites were evaluated by ultrasonography (Siemens Sonoline Antares 4.1 MHz or 9.4 MHz probe; Siemens Medical Solutions United States, Inc., Issaquah, WA, United States) by the same radiologist.

The study design was approved by the Ethics Committee of our hospital (Study No. KA11/11252). Before enrollment, written informed consent was obtained from the primary caretaker of each patient.

We used SPSS software (version 16.0; SPSS, Inc.,

INR: International normalized ratio; ALT: Alanine transaminase; AST: Aspartate transaminase.

Chicago, IL, United States) for statistical analysis. Data are expressed as the mean and standard deviation and proportions. For comparison of categorical variables, Fisher's exact test or a  $\chi^2$  test was used. Differences between numeric variables were tested with a Mann-Whitney *U*-test. Values of  $P < 0.05$  were considered to indicate statistically significant differences.

## RESULTS

Ninety-eight children with cirrhosis were included in this study. The ages of the children ranged from 6-18 years (median age, 12.16 ± 2.70 years). Forty-six children were females (46.9%) and 52 were males (53.1%).

The etiology of cirrhosis was cryptogenic cirrhosis ( $n = 40$ ), Wilson's disease ( $n = 35$ ), progressive familial intrahepatic cholestasis (2), sclerosing cholangitis ( $n = 4$ ), Budd-Chiari syndrome ( $n = 4$ ), tyrosinemia ( $n = 3$ ), glycogen storage disease ( $n = 3$ ), autoimmune hepatitis ( $n = 2$ ), hepatitis B infection ( $n = 2$ ), Allagille syndrome ( $n = 2$ ), and alfa1-antitrypsin deficiency ( $n = 1$ ). Sixty-one patients were Child-Pugh class A, 29 were class B, and 8 were class C.

In this study, 69 children (70.4%) were shown to have EV based on the first EGD and 29 children (29.6%) were shown not to have EV.

Fifty-five of the 69 patients had small EV (79.7%) and 14 patients (20.3%) had large EV. There were 11 children (15.9%) with red wale signs (seven children had large EV and four children had small EV). Therefore, 18 of the 69 patients with EV (26.1%) had high-risk EV for bleeding according to the presence of large varices and/or red sign (six patients in the 6-12 year age group, and 12 patients in the 12-18 year age group).

There were no differences in age and gender between the EV-present and -absent sub groups in both age groups ( $P > 0.05$ ). In the two age groups, a higher

percentage of ascites was observed among the EV-present group than the EV-absent group (Tables 1 and 2). We did not find a statistically significant difference in the PC-to-SD ratio between patients with large and small varices ( $636.9 \pm 256.5$  and  $894.1 \pm 844.4$ , respectively;  $P = 0.89$ ).

We did not find a significant difference for serum albumin, PC, SD and the PC-to-SD ratio between the EV-present and -absent varices sub-groups in both age groups ( $P > 0.05$ ; Tables 1 and 2).

## DISCUSSION

Despite advances in diagnosis and treatment, bleeding from EV is one of the major causes of morbidity and mortality among patients with cirrhosis. Hence, preventing the first episode of variceal bleeding may reduce mortality and morbidity.

In this prospective study involving children 6-18 years of age with cirrhosis, we found that only the presence of ascites is associated with the presence of EV. There have been several studies identifying non-invasive variables that may predict the presence of EV in children<sup>[6,7,10]</sup>. The first study, in which the predictive risk factors were evaluated by Fagundes *et al*<sup>[6]</sup> in a pediatric group [median age at the time of first EGD was 6 years (age range, 0.7-17.6 years)], showed that children with cirrhosis and splenomegaly were nearly 15-fold more likely to have EV compared with children with cirrhosis but without splenomegaly. Fagundes *et al*<sup>[6]</sup> concluded that hypoalbuminemia, splenomegaly, and a PC < 130000/mm<sup>3</sup> were predictors for the presence of EV, spleen size was not measured by ultrasonography. The second study, conducted by Gana *et al*<sup>[7]</sup>, derived a non-invasive clinical prediction rule capable of identifying children with EV. In this study, 17 of 51 children (< 18 years of age) with liver disease or portal vein thromboses were shown

to have EV, and hypoalbuminemia was shown to be an independent variable for the presence of EV. In the same study<sup>[7]</sup>, a higher percentage of ascites, increased spleen length, and lower PC (cut-off value = 115000/mm<sup>3</sup>) were reported among children with EV. Further, the PC-to-spleen length-for age Z score ratio was significantly lower among the EV-present group<sup>[7]</sup>.

Fagundes *et al.*<sup>[6]</sup> and Gana *et al.*<sup>[7]</sup> reported lower albumin levels among children with EV. Our results were not in agreement with the findings of these two studies. A possible explanation may be the difference in etiologic factors in our patients.

A recent study involving 103 patients with a diagnosis of chronic liver disease or extrahepatic portal vein obstruction (mean age, 8.9 ± 4.7 years) showed a significantly higher spleen length and lower PC (cut-off value = 115000/mm<sup>3</sup>) among children with EV than children without EV<sup>[10]</sup>. In the same study, it was reported that a PC-to-spleen size (cm) ratio < 1.0 discriminated between patients with and without EV, despite a lack of statistical significance based on logistic regression. The authors suggested that the lack of statistical significance was explained by the age and gender differences in spleen size.

Based on the findings of these three studies<sup>[6,7,10]</sup>, low PC and increased spleen length are logical parameters by which to determine EV in children with cirrhosis. In addition, Gana *et al.*<sup>[7]</sup> and Adami *et al.*<sup>[10]</sup> reported that PC (cut-off value = 115000/mm<sup>3</sup>) was the best predictor of EV.

In the current study, we did not find a significant difference for PC, SD and the PC-to-SD ratio between the EV-present and -absent sub-groups in both age groups. A possible explanation is the heterogeneity of patients studied. Another explanation is the lack of children with portal vein thromboses in the current study. The three studies investigating risk factors for EV included children with cirrhosis and portal vein thromboses<sup>[6,7,10]</sup>. It is well-known that portal vein thrombosis is a risk factor for splenomegaly and thrombocytopenia. The PC loses discriminatory power because of multi-causality (such as autoimmune events, myelotoxic effects of viruses, or reduced synthesis of thrombopoietin) as a consequence of progressive liver dysfunction; however, in children with portal vein thromboses, thrombocytopenia is directly related to portal hypertension, as well as the development of varices<sup>[19]</sup>.

One of the most important limitations of our study was the small number of patients; however, this study was the first study to assess the PC-to-SD ratio in children in two age groups with cirrhosis as a means to detect EV. We consider the PC, SD and PC-to-SD ratio to lack suitability as non-invasive markers for detecting EV in children with cirrhosis. Further studies on this subject with larger sample sizes are required to assess the importance of the PC, SD and PC-to-SD ratio in cirrhotic children with or without portal vein thrombosis.

## COMMENTS

### Background

Esophageal variceal (EV) bleeding is among the most serious consequences of chronic liver disease. Approximately two-thirds of children with cirrhosis have EV and the mortality associated with a variceal bleeding episode is 20%-35%. Identification of children with cirrhosis who are at high risk for EV using a non-invasive test is important to reduce the need for endoscopy. The authors' goal was to investigate laboratory and radiologic parameters, including the platelet count (PC)-to-spleen diameter (SD) ratio to predict the presence of EV in children with cirrhosis.

### Research frontiers

To reduce the increasing burden on endoscopy units and prevent unnecessary harm to patients with cirrhosis, researchers have attempted to identify parameters for the non-invasive prediction of EV.

### Innovations and breakthroughs

A few studies have shown that a low PC and PC-to-SD ratio may predict the presence of EV in patients with cirrhosis. In their study, the authors did not find a significant difference in the PC, SD and PC-to-SD ratio between the EV-present and -absent sub-groups in both age groups of children.

### Applications

The PC-to-SD ratio is not an appropriate index with which to predict EV in children with cirrhosis. This may indicate that endoscopy remains the ideal choice for detecting EV in children with cirrhosis.

### Terminology

Esophageal varices are abnormal, enlarged veins which generally occur in patients with serious liver diseases. The vessels can leak blood, or even rupture, thus causing life-threatening bleeding.

### Peer-review

It is helpful for clinical doctors to perform endoscopic examination promptly.

### Abstract

#### AIM

To investigate serum urokinase-type plasminogen activator receptor (uPAR) and liver stiffness in biliary atresia (BA) and examine the correlation of circulating uPAR, liver stiffness, and clinical outcomes in postoperative BA children.

#### METHODS

Eighty-five postKasai BA children and 24 control subjects were registered. Circulating uPAR was measured using enzyme-linked immunosorbent assay. Liver stiffness was analyzed using transient elastography.

#### RESULTS

BA children had significantly greater circulating uPAR and

liver stiffness scores than control subjects ( $P < 0.001$ ). Circulating uPAR and liver stiffness were substantially higher in jaundiced BA children than non-jaundiced BA children ( $P < 0.001$ ). In addition, circulating uPAR was positively associated with serum aspartate aminotransferase ( $r = 0.507$ ,  $P < 0.001$ ), alanine aminotransferase ( $r = 0.364$ ,  $P < 0.001$ ), total bilirubin ( $r = 0.559$ ,  $P < 0.001$ ), alkaline phosphatase ( $r = 0.325$ ,  $P < 0.001$ ), and liver stiffness scores ( $r = 0.508$ ,  $P < 0.001$ ).

### CONCLUSION

Circulating uPAR and liver stiffness values were greater in BA children than healthy controls. The increased circulating uPAR was associated with liver dysfunction in BA. As a consequence, serum uPAR and liver stiffness may be used as noninvasive biomarkers indicating the progression of liver fibrosis in postKasai BA.

**Key words:** Biliary atresia; Jaundice; Liver stiffness; Severity; Urokinase plasminogen activator receptor

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Urokinase plasminogen activator receptor (uPAR) is known to be a substantial factor in the etiopathogenesis of hepatic inflammation and liver fibrogenesis. This study is the first to show that circulating uPAR is more elevated in biliary atresia (BA) children than in control subjects, and that circulating uPAR is correlated with the degree of jaundice and liver fibrosis in biliary atresia. Elevated serum uPAR is positively correlated with the severity of liver stiffness in postKasai BA children. Hence, serum uPAR could be used as a biological parameter indicating the progression and prognosis of liver fibrosis in BA children.

## INTRODUCTION

Biliary atresia (BA) is a severe chronic cholestatic liver disease of unknown etiology in young infants. The estimated incidence of BA varies from 1 in 8000 to 1 in 20000 live births, with a high frequency in Asians<sup>[1]</sup>. Affected newborns exhibit evidence of biliary obstruction within the first few months of life. BA is manifested by impaired liver function and fibroinflammatory obliterative cholangiopathy of both intrahepatic and extrahepatic bile ducts<sup>[2,3]</sup>. Extrahepatic BA is the most common form of ductal cholestasis. BA patients initially develop neonatal jaundice due to hepatic cholestasis and progress to

hepatic fibrosis, which result in biliary cirrhosis<sup>[1-3]</sup>. Even though no medical therapies exist, sequential treatment strategy involving surgical Kasai portoenterostomy and liver transplantation is the only option for the most affected children. Nonetheless the precise pathogenesis of BA has yet to be determined, a number of theories regarding the etiology of BA include toxin exposure, virus-mediated inflammation, abnormal inflammatory response, defective morphogenesis, genetic mutation, and immunological dysregulation<sup>[4]</sup>.

Urokinase-type plasminogen activator receptor (uPAR, CD87) is a cellular membrane receptor that attaches to urokinase-type plasminogen activator (uPA) with high affinity, through promoting the pericellular activation of plasminogen<sup>[5]</sup>. The involvement of uPA, its receptor (uPAR), and plasminogen activator inhibitor-1 (PAI-1) in regulation of cell adhesion, migration, proliferation, differentiation, and cell survival has recently demonstrated<sup>[6]</sup>. uPAR is expressed by a wide range of immune cells and endothelial cells, which contribute to the etiopathogenesis of hepatic inflammation and liver fibrogenesis<sup>[7,8]</sup>. Once inflammation is activated, uPAR is released from the cell membrane by proteolytic enzymes to produce soluble uPAR<sup>[9]</sup>. In recent years, previous studies have investigated that elevated circulating uPAR levels have been observed in acute liver failure, chronic liver diseases, and nonalcoholic fatty liver diseases<sup>[10-12]</sup>.

It has been previously shown that certain cytokines and growth factors play possible parts in the etiopathology of biliary atresia<sup>[13-16]</sup>. The measurements on circulating uPAR and liver stiffness of BA have never been documented. We hypothesized that circulating uPAR and liver stiffness could be more elevated in BA patients than in control subjects and circulating uPAR would be associated with the disease severity and clinical outcomes in postKasai biliary atresia. Hence, the purpose of the current research is to determine circulating uPAR and liver stiffness measurements and to investigate the plausible correlation of circulating uPAR, liver stiffness, and clinical outcomes in postoperative biliary atresia children.

## MATERIALS AND METHODS

The present study was approved by the Institutional Review Board on Human Research of the Faculty of Medicine, Chulalongkorn University, and was conducted in compliance with the ethical guidelines of the Declaration of Helsinki. All parents of children were informed of the study's purpose and of any interventions involved in the current study. Written informed consent was derived from the parents prior to the subjects entering the study.

### Study population

Eighty-five BA children (39 girls and 46 boys with mean age of  $9.0 \pm 0.6$  years) and 24 normal control subjects (11 girls and 13 boys with mean age of  $8.5 \pm 0.5$  years) were enrolled in the study. None of them had undergone

liver transplantation. Healthy controls attending the Well Baby Clinic at our institution for vaccination had normal physical findings and no underlying disease. BA children were classified into two groups according to their serum total bilirubin (TB): Non-jaundiced BA children (TB < 2 mg/dL,  $n = 46$ ) and persistent jaundiced BA children (TB  $\geq 2$  mg/dL,  $n = 39$ ).

### Laboratory methods

Samples of peripheral venous blood were collected from every participant, and were kept at  $-80^{\circ}\text{C}$  for subsequent measurement. The quantitative assessment of serum uPAR was performed by using commercially available enzyme-linked immunosorbent assay (Quantikine, R and D Systems, Minneapolis, MN, United States). According to the manufacturer's protocol, recombinant human uPAR standards and serum samples were added into each well, which has been pre-coated with specific antibody to uPAR. After incubating for 2 h at room temperature, every well was washed thoroughly with wash buffer. Then, uPAR conjugate was pipetted into each well and incubated for 2 h at room temperature. After 4 washes, substrate solution was added into the wells and the microplate was incubated for 30 min at room temperature with protection from light. Lastly, the reaction was stopped by the stop solution and the optical density was determined using an automated microplate reader at 450 nm. A standard optical density-concentration curve was drawn for the determination of uPAR concentration. The liver function tests including serum albumin, TB, direct bilirubin, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and alkaline phosphatase (ALP) were measured using a Hitachi 912 (Roche Diagnostics, Basel, Switzerland) automated machine at the central laboratory of our hospital.

### Liver stiffness measurement

Transient elastography (Fibroscan, Echosens, Paris, France) measured the liver stiffness between 25 to 65 mm from the skin surface, which is approximately equivalent to the volume of a cylinder of 1 cm diameter and 4 cm length. The measurements were performed by placing a transducer probe of Fibroscan on the intercostal space at the area of the right lobe of the liver with patients lying in a dorsal decubitus position with maximum abduction of the right arm. The target location for measurement was a liver portion that was at least 6 cm thick, and devoid of major vascular structures. The measurements were performed until 10 validated results had been obtained with a success rate of at least 80%. The median value of 10 validated scores was considered the elastic modulus of the liver, and it was expressed in kilopascals (kPa).

### Statistical analysis

Statistical analysis was executed by using the SPSS version 22.0 statistical software package (SPSS Inc., Chicago, IL, United States). Comparisons of demographic

and clinical outcomes between groups were performed using  $\chi^2$  and Student's unpaired  $t$ -test when appropriate. Correlation between numerical data was obtained using Pearson's correlation coefficient ( $r$ ). Data were presented as mean  $\pm$  SEM of the mean. A two-tailed  $P$ -value of less than 0.05 was taken to indicate statistical significance.

## RESULTS

### Comparison between BA children and control subjects

Eighty-five postoperative biliary atresia children and 24 ethnically matched unaffected volunteers were prospectively recruited in the current work. The baseline features of BA children and control subjects are presented in Table 1. There was no significant difference of age and gender between case and control groups. However, circulating uPAR values were substantially greater in BA children than in control subjects ( $6085.9 \pm 400.7$  pg/mL vs  $4754.5 \pm 294.9$  pg/mL,  $P = 0.01$ ) (Figure 1). Moreover, BA group had notably greater liver stiffness values than control group ( $28.7 \pm 2.7$  kPa vs  $4.1 \pm 0.2$  kPa,  $P < 0.001$ ).

### Differences between jaundiced group and non-jaundiced group of BA children

BA children were subdivided into jaundiced group ( $n = 39$ ) and non-jaundiced group ( $n = 46$ ). The clinical characteristics and biochemical features of patients according to jaundice status are illustrated in Table 2. Jaundiced BA children exhibited remarkably greater serum uPAR levels than non-jaundiced BA children ( $7373.5 \pm 684.6$  pg/mL vs  $4994.2 \pm 400.9$  pg/mL,  $P = 0.003$ ) (Figure 2). Furthermore, mean liver stiffness measurement of jaundiced BA group was greatly increased compared with that of non-jaundiced BA group ( $46.2 \pm 3.7$  kPa vs  $13.9 \pm 2.0$  kPa,  $P < 0.001$ ).

Subsequent investigation revealed that circulating uPAR was directly associated with serum AST ( $r = 0.507$ ,  $P < 0.001$ ), ALT ( $r = 0.364$ ,  $P < 0.001$ ), TB ( $r = 0.559$ ,  $P < 0.001$ ), ALP ( $r = 0.325$ ,  $P < 0.001$ ), and liver stiffness values ( $r = 0.508$ ,  $P < 0.001$ ) in BA children (Figure 3). However, circulating uPAR concentration was negatively associated with serum albumin level ( $r = -0.666$ ,  $P < 0.001$ ) (Figure 3).

## DISCUSSION

Biliary atresia is a chronic progressive fibroinflammatory liver disorder with mysterious etiology. The etiopathology of BA currently remains elusive and it seems that multiple factors may contribute to the development of BA. Yet today, Kasai operation has been proved as the most effective option of surgical treatment. Without surgery, children with biliary atresia will finally die due to biliary cirrhosis and liver failure<sup>[1]</sup>. Recently, circulating uPAR levels have been shown to be involved in chronic liver disorders, including chronic hepatitis B and C, liver cirrhosis, and hepatocellular carcinoma<sup>[17-20]</sup>. Based on

**Table 1** Demographic data, biochemical characteristics, and liver stiffness scores of biliary atresia patients and healthy controls

Variables	BA (n = 85)	Controls (n = 24)	P value
Age (yr)	9.0 ± 0.6	8.5 ± 0.5	0.2
Gender (female:male)	39:46	11:13	0.4
Albumin (g/dL)	4.2 ± 0.1	-	NA
Total bilirubin (mg/dL)	2.7 ± 0.4	-	NA
Direct bilirubin (mg/dL)	2.3 ± 0.4	-	NA
AST (IU/L)	143.7 ± 11.9	-	NA
ALT (IU/L)	137.1 ± 12.5	-	NA
ALP (IU/L)	449.2 ± 34.0	-	NA
Liver stiffness (kPa)	28.7 ± 2.7	4.1 ± 0.2	< 0.001
uPAR (pg/mL)	6085.9 ± 400.7	4754.5 ± 294.9	0.01

The data was expressed as mean ± SEM. BA: Biliary atresia; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; uPAR: Urokinase-type plasminogen activator receptor; NA: Not applicable.

**Figure 1** Comparison of serum urokinase-type plasminogen activator receptor levels in biliary atresia patients and healthy controls. uPAR: Urokinase-type plasminogen activator receptor; BA: Biliary atresia.

our experience, there is no report about circulating uPAR and hepatic fibrosis in various degrees of postoperative biliary atresia.

The present study is the first to show that circulating uPAR and liver fibrosis values were significantly higher in children suffering from BA than in control subjects. Additionally, circulating uPAR in jaundiced BA children was markedly increased with respect to that in non-jaundiced BA children. Elevated circulating uPAR levels were directly associated with total bilirubin, AST, ALT, ALP in post Kasai BA children, suggesting that circulating uPAR is related to degree of jaundice BA children. Furthermore, the degree of jaundice is possibly linked to the severity of intrahepatic biliary obliteration. Both AST and ALT are extensively used as biochemical parameters of hepatic abnormality indicating liver cell injury. Hence, the findings imply that uPAR could have a plausible role in the mechanism of liver cell injury in postoperative biliary atresia, and it would be associated with the severity of bile duct obliteration.

The present investigation demonstrated that circulating uPAR was more pronounced in biliary atresia children than control subjects. In accordance with this

**Table 2** Comparison of biliary atresia patients without and with jaundice

Variables	BA patients with jaundice (n = 39)	BA patients without jaundice (n = 46)	P-value
Age (yr)	9.5 ± 0.9	8.6 ± 0.9	0.4
Gender (female:male)	18:21	21:25	0.5
Albumin (g/dL)	3.8 ± 0.1	4.5 ± 0.1	< 0.001
Total bilirubin (mg/dL)	5.1 ± 0.7	0.5 ± 0.1	< 0.001
Direct bilirubin (mg/dL)	4.5 ± 0.6	0.2 ± 0.1	< 0.001
AST (IU/L)	210.4 ± 17.2	84.7 ± 10.2	< 0.001
ALT (IU/L)	195.9 ± 19.9	85.1 ± 10.7	< 0.001
ALP (IU/L)	599.7 ± 52.8	313.0 ± 32.0	< 0.001
Liver stiffness (kPa)	46.2 ± 3.7	13.9 ± 2.0	< 0.001
uPAR (pg/mL)	7373.5 ± 684.6	4994.2 ± 400.9	0.003

The data are expressed as mean ± SEM. BA: Biliary atresia; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; uPAR: Urokinase-type plasminogen activator receptor; NA: Not applicable.

**Figure 2** Comparison of serum urokinase-type plasminogen activator receptor levels in biliary atresia patients without jaundice and with jaundice. uPAR: Urokinase-type plasminogen activator receptor.

observation, Sjöwall *et al*<sup>[10]</sup> reported that circulating uPAR was increased in subjects with non-alcoholic fatty liver disease and associated with the severity of fibrosis. Moreover, uPAR expressions in liver tissue samples have been documented in subjects with hepatocellular carcinoma as shown by Morita *et al*<sup>[21]</sup>. In addition, Zimmermann *et al*<sup>[12]</sup> reported that circulating uPAR was substantially elevated in subjects with chronic liver diseases compared with controls and were closely correlated with liver function and fibrosis.

In light of our findings, certain hypotheses could explain high circulating uPAR in jaundiced biliary atresia children. Firstly, the release of uPAR in the injured liver could be accountable for the increased circulating uPAR. Secondly, the elevation of circulating uPAR may be ascribed to the unbalance between uPAR synthesis and uPAR clearance. The reduction of uPAR destruction in BA children with liver fibrosis may lead to the elevated circulating uPAR. Decreased pre-systemic hepatic metabolism might explain the increased uPAR levels in serum BA children with hepatic dysfunction. Besides, other tissues outside the liver could synthesize and

**Figure 3** Scatter diagram and regression analysis in biliary atresia patients. uPAR levels are correlated with (A) serum aspartate aminotransferase (B) serum alanine aminotransferase (C) serum total bilirubin (D) serum alkaline phosphatase (E) serum albumin and (F) liver stiffness. uPAR: Urokinase-type plasminogen activator receptor.

release uPAR into the blood. The rising serum level of uPAR is likely attributable to the results of hepatocellular injury and further liver fibrosis. Whether increment of serum uPAR in BA children indicates low destruction, high production, or both remain obscure. Additional research will be needed to clarify the molecular basis leading to increased circulating uPAR.

Several caveats need to be acknowledged in this study. First, relatively small sample size of enrolled subjects limits the statistical power of our findings. Second, the cross-sectional study precludes definite information regarding causal relationships. In addition, inadequate assessment of various confounders such as comorbidity must be considered. To address these challenges, future studies should collect prospective measurements of these data

to preclude bias and reverse causation. Moreover, the present investigation was restricted to the subjects under follow-up at our institution. Accordingly, our results may not be generalized across different populations. Finally, hepatic expression of uPAR has not been investigated. Further studies on immunohistochemistry of uPAR from liver tissues might provide better knowledge on molecular mechanisms of uPAR in biliary atresia.

To sum up, our study illustrated that circulating uPAR and liver stiffness measurement were markedly higher in biliary atresia children than in control subjects. Circulating uPAR was more elevated in jaundiced BA children compared to non-jaundiced BA children. Furthermore, elevated serum uPAR was correlated with hepatic dysfunction and outcome parameters. Circulating uPAR

and liver stiffness values might be used as noninvasive biological markers indicating the progression and prognosis of hepatic fibrosis in postoperative biliary atresia children. Although underlying mechanisms of the cause and effect relationships remain elusive, there is abundant room for the definite role of uPAR in the etiopathogenesis of hepatic fibrosis in BA.

## COMMENTS

### Background

Biliary atresia (BA) is a severe chronic cholestatic liver disease of unknown etiology in young infants. The exact pathogenesis of BA remains a matter of debate. Circulating urokinase plasminogen activator receptor (uPAR) has arisen as a promising biochemical marker of certain disorders, such as liver injury and fibrosis. Although recent reports suggest a potential applicability for the measurement of circulating uPAR in liver fibrosis, the assessments on circulating uPAR and liver stiffness of BA have never been documented.

### Research frontiers

Recent evidences demonstrate the significance of urokinase plasminogen activator receptor in hepatitis, liver fibrosis, and liver failure. The current study shows that circulating uPAR levels are more elevated in BA children than in control subjects. Moreover, uPAR level is correlated with liver stiffness, and clinical outcomes in postoperative BA.

### Innovations and breakthroughs

BA children exhibited significantly higher circulating uPAR and liver stiffness values than control subjects. Circulating uPAR and liver stiffness values were more pronounced in jaundiced BA children than in non-jaundiced BA children. Additionally, elevated circulating uPAR levels were associated with hepatic dysfunction and clinical outcomes.

### Applications

Increased circulating uPAR and liver stiffness values were associated with hepatocellular dysfunction in postKasai children affected with BA. As a consequence, circulating uPAR and liver stiffness measurements could be used as noninvasive biological markers indicating the progression and prognosis of liver fibrogenesis in BA children.

### Terminology

uPAR also known as CD87, is a multidomain membrane protein that has a role in the regulation of cell migration, proliferation, and survival and is expressed by diverse immune cells and endothelial cells, which contribute to the etiopathogenesis of hepatic inflammation and liver fibrogenesis.

### Peer-review

Great paper that needs to be published. uPAR is known to be a substantial factor in the etiopathogenesis of hepatic inflammation and liver fibrogenesis.

### Abstract

#### AIM

To identify and assess the research situation of top 100 cited articles in nonalcoholic fatty liver disease (NAFLD).

#### METHODS

The global scientific research articles in the Science Citation Index-Expanded relevant to NAFLD were retrieved and listed according to their citation times from the most to the least. The 100 most frequently cited original articles were selected to systematically evaluate their bibliometric parameters including times cited, publication year, journals, subject categories, and the highly related concepts of NAFLD, which reflected the history and current situation, publication distribution of leading countries and institutes as well as the research hotspots of NAFLD.

#### RESULTS

Top 100 cited articles in NAFLD were published from 1965 to 2015 with a citation ranging of 227 to 2151 times since publication, in which the United States was the most predominant country and Mayo Clin was the most productive institution. The majority of the top 100 cited articles were concentrated in SCI subject category of Gastroenterology and Hepatology. Hepatology and Gastroenterology is the top journal that published over half 100 top-cited articles. The significant peak of top cited articles present in the first half of the 2000s while the highest mean number of citation presents in first half of the 1980s. In addition, concepts related to pathology characteristics, epidemiology and medicalization, metabolic syndrome and its combination of symptoms including insulin resistance, biomarkers

of lipid metabolism and obesity are listed as the highly related concepts.

### CONCLUSION

The 100 top-cited articles marked with the leading countries, institutions, journals, hotspots and development trend in NAFLD field that could provide the foundation for further investigations.

**Key words:** Bibliometrics; Top-cited articles; Metabolic syndrome; Prevalence; Medicalization; Nonalcoholic fatty liver disease

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Bibliometrics was used to quantitatively analyze top 100 cited articles from the database of the Science Citation Index Expanded to reveal the global publication trends about nonalcoholic fatty liver disease (NAFLD). This study is the first global look at the history and current situation of NAFLD research to assess the performances of leading countries/territories and institutes and research hotspots of this disease. The performances and research hotspots are related to the potential pathogenesis of NAFLD. Incidence and prevalence as well as treatment progress for NAFLD were systematically reviewed, and their relationships with global performances results were also discussed.

Bibliometric analysis of top 100 cited articles in nonalcoholic fatty liver disease research. *World J Hepatol* 2016; 8(33): 1478-1488 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i33/1478.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i33.1478>

### INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is defined by liver fat deposition with a concentration of hepatic triglycerides exceeding 5% of liver weight in the absence of excessive alcohol intake. NAFLD is an umbrella term used to describe a histological spectrum ranging from simple steatosis to nonalcoholic steatohepatitis (NASH). NASH is virtually indistinguishable histologically from alcoholic steatohepatitis, which is designated the disease with inflammation and liver cell injury in some NAFLD patients<sup>[1]</sup>. It was thought that hepatic fatty change was a kind of benign lesions previously. However, the recent research showed that about 10%-30% of NAFLD could evolve into NASH, accompanying by fibrosis, cirrhosis, liver failure and even hepatocellular carcinoma<sup>[2]</sup>. NAFLD patients are more likely to be accompanied with obesity, diabetes, cardiovascular and cerebrovascular diseases to increase death and disability rate. Owing to the high morbidity rate of obesity and metabolic syndrome worldwide, NAFLD has become the leading cause of chronic liver disease<sup>[1]</sup>. It is time to identify and evaluate

the high citation articles to get insight into history and current situation of NAFLD research.

Citation rank list has been often used in medicine to characterize works with the remarkable intellectual influence<sup>[3]</sup>. Many highly cited articles have stimulated further standard-breaking investigations and discussions<sup>[4]</sup>. However, the bibliometric analysis of the most influential articles in NAFLD field remains unexploited. As the most frequently used source database for a broad review of scientific value in a specific research field, Science Citation Index-Expanded (SCI-Expanded) from Thomson Reuters is a highly effective research tool for evaluating scientific performance and tracking evolution trends. In this study, bibliometric method was applied to analyze the citation times, publication year, countries and institutes, journals, subspecialty, and key words of the 100 most cited articles in NAFLD field in SCI-Expanded from 1965 to 2015.

### MATERIALS AND METHODS

The data were obtained from the SCI-Expanded from the Institute for Scientific Information, which indexed 8618 major journals with citation references across 176 categories in science edition in 2015. The keywords for bibliography retrieval in database consisted of "nonalcoholic steatohepatitis", "nonalcoholic fatty liver disease", and their heteromorphic form and abbreviation limited in liver or hepatology fields. Papers were listed according to their citation times from the most to the least. Only the top 100 original articles from the most citation list were included for further analysis. The retrieve process of the top 100 cited articles was shown in Figure 1. In detail, the retrieved data for statistical process were imported to Excel 2010. According to JCR in 2014 (available in June 2015), the reported impact factor (IF) of each journal was referred. The 100 top cited articles were assessed by decreasing orders of articles and citation. Bibliometric parameters including publication productions of countries and institutes with five indexes including total, independent, collaborative, first author, and corresponding author articles; distribution of journals and subspecialties; top 10 of most cited articles were assessed.

Furthermore, the most frequent key words and concepts were also discussed. Part of concepts such as "NAFLD" and "NASH" were abandoned since they completely overlap with the study content. Highly related concepts including all concepts from the Gene Ontology (GO) and the Medical Subject Headings (MeSH) were categorized by semantic search technology using GoPubMed® search engine (<http://www.gopubmed.org/web/gopubmed/>).

### RESULTS

#### Publication year

After screening, 8828 meaningful articles related to NAFLD were retrieved in the period of 1965 to 2015. It

**Figure 1** Flow chart of the selection process for the top 100 cited in nonalcoholic fatty liver disease. NAFLD: Nonalcoholic fatty liver disease.

can be seen that the number of total articles increased at an exponential rate, which entered an exponential growth phase since 2004 (Figure 2). A power exponential function can describe the growth curve:  $Y = 1 \times 10^{-233} e^{0.2701x}$ ,  $R^2 = 0.9668$ .

The publication years of the top 100 cited articles in NAFLD field spanned from 1980 to 2012 with a citation ranging from 227 to 2151 times since publication. The majority of top 100 cited articles (74%) were concentrated in the 2000s (Figure 3). The most cited article published by Kleiner DE (National Cancer Institute, United States) in 2005 was cited 2151 times according to the SCI-Expanded database (Table 1).

### Publication distribution of countries and institutes

The top 100 cited articles were originated from 19 countries. The most productive country was the United States (55), followed sequentially by Italy (20), Australia (14), France (9), United Kingdom (7). The rest of the countries had less than four publications (Table 2). The numbers in the brackets refer to the publication number (similarly hereinafter).

Twelve institutions published more than 4 top cited articles. Mayo Clin (12) ranked the first place in NAFLD research, followed by University of Bologna (9), University of Turin (9), The University of Sydney (7) and University of California, San Diego (6). And the rest of the Institutes such as University of Texas, Saint Louis University and Virginia Commonwealth University contributed five each to the top 100 cited articles (Table 3).

### Subspecialties and journals

According to the JCR in 2014, the top 100 articles of NAFLD were scattered in 13 SCI subject categories (Table 4).

These main subspecialties were Gastroenterology and Hepatology (71), Endocrinology and Metabolism (7), General and Internal Medicine (6), Research and Experimental Medicine (4) and Science and Technology (4).

The top 100 articles were distributed in 25 journals including professional journals and other disciplines journals. Eleven (44%) journals published 2 or more articles (Table 5), among which the most productive journal was *Hepatology* (42), followed by *Gastroenterology* (16), *Am J Gastroenterol* (5), *J Hepatol* (5), *J Clin Invest* (4), *Proc Natl Acad Sci USA* (3) and *J Clin Endocrinol Metab* (3).

### The most frequently cited articles

As elaboration of all the top 100 cited articles is difficult, the top 10 citation articles were further discussed instead. United States (7), Italy (2) and Australia (1) respectively published the top 10 most frequently cited articles (Table 1). Three in ten focused on epidemiological subjects to investigate the regional and ethnic differences and explore the genetic mechanism implied in NAFLD, which were published respectively in the year of 1990 (864 citations), 2004 (1320 citations) and 2005 (974 citations) (Table 1). Other three articles discussed the pathogenic role of metabolic syndrome where insulin resistance and obesity were repeatedly mentioned. The rest of articles analyzed NAFLD from the clinical and histological aspect, among which two were about the histological grading and staging of NAFLD.

### Highly related concepts

Highly related concepts of the top 100 cited papers from GO and MeSH with frequency more than 10 times were listed in Table 6. The analysis indicated that multi-system metabolic syndrome and its related key words (obesity, insulin resistance, etc.) occupied a majority of proportion. Some key words discussed histological and pathology characteristics of NAFLD including hepatic steatosis, fibrosis, biopsies, etc. Noteworthy, the topic of epidemiology covering prevalence, male/men, female/women, middle aged and adolescent was also involved in frequent concepts (Table 7).

## DISCUSSION

This paper used bibliometrics method to evaluate top 100 cited articles to reveal the global publication performance of NAFLD. The high citation articles can reflect the development evolution direction and scientific level in the NAFLD research field to a certain extent.

### Publication trends and distribution of NAFLD-related literature

In recent five decades, exponential increase of published articles reflects the globally development trend of NAFLD. In line with the increased prevalence of obesity, diabetes, and hyperlipemia, NAFLD has been increasing worldwide over recent half century<sup>[5]</sup>. As a result of modern

**Figure 2** Number of global SCI Journal articles varies with time. Remarks: Fitting equation during 1985-2015 is:  $Y = 1 \times 10^{-233} e^{0.2701x}$ ,  $R^2 = 0.9668$ . In the equation, Y is the number of accumulation articles and X is the sequence number of year. It indicated that research on NAFLD entered an exponential growth phase since 2004. NAFLD: Nonalcoholic fatty liver disease.

**Figure 3** Number of the top 100 cited papers in nonalcoholic fatty liver disease per five year and the mean of the citation of the top cited paper with five years bin.

sedentary and over-nutrition lifestyle which makes a very large population fall risk of NAFLD, research on NAFLD would develop more rapidly in the near future<sup>[6]</sup>.

East Asian countries/territories such as Japan, China (mainland), South Korea and Taiwan occupied an important place in NAFLD research and their importance tended to be more and more obvious. This might owe to the rising prevalence of NAFLD in Asia recently as well as the growth of economic power and the advance of scientific research which prompted these countries/territories to invest more in research to prevent and control NAFLD<sup>[6]</sup>. A global scientific review covered total articles relevant to NAFLD from 1986 to 2013 were performed to analyze distribution of publication number and found that Japan, China (mainland) and South Korea ranked second, fourth and ninth respectively among the most productive country/territories<sup>[7]</sup>. However, only six of top 100 cited papers originate these countries/territories. It shows that the quality and influence of research in NAFLD need to improve for East Asian countries.

It was found that most of the 100 most cited papers

were published in 2000s (74 articles), while the most of high citation times per articles distributed in 1990s. These distributions suggested that the older paper had the more citation times<sup>[8]</sup>. The opinions in 1990s and 2000s were neither too old to be outdated nor too nearly to be cited. Actually, academic community has recognized that the real importance and influence of a work often can't be precisely assessed for at least 2 decades after it is published<sup>[9]</sup>.

### The research hotspots of NAFLD

Highly related concepts and top keywords could partly reflect the profile of hotspots in NAFLD research. GoPubMed® search engine connect text (abstracts from the MEDLINE database) to background knowledge in the form of semantic networks of concept categories, which is done by meaning and not by keywords only. These results are approximately consistent with our contemporaneous bibliometric analysis in high frequency keywords that covered total articles relevant to NAFLD<sup>[7]</sup>.

**Potential pathogenesis:** According to highly related concepts list, a cluster of pathogenesis related keywords occupied a majority of high frequency words mentioned by NAFLD researches. The research hotspots extracted using bibliometrics analysis informs the underlying pathogenesis of NAFLD. The results indicated that multisystem metabolic syndrome and its combination of symptoms including insulin resistance, obesity as well as oxidative stress and dyslipoproteinemia played a vital role in the pathogenesis of NAFLD. In fact, although pathogenesis of NAFLD remains elusive, the severity of NAFLD seems to increase in parallel with the features of metabolic syndrome<sup>[10-12]</sup>. NAFLD/NASH is increasingly regarded as a hepatic manifestation of metabolic syndrome. However, considering that not all patients with NAFLD/NASH suffer from one of these conditions<sup>[1]</sup>, still uncertain pathogenesis of NAFLD might hinder the people and needs to be explored<sup>[13]</sup>.

**Table 1** The information of top 100 cited articles in nonalcoholic fatty liver disease

Rank	Title of article	Journal	First author/institute	Year	Times cited
1	Design and validation of a histological scoring system for nonalcoholic fatty liver disease	<i>Hepatology</i>	Kleiner DE/NCI, United States	2005	2151
2	Nonalcoholic steatohepatitis: A proposal for grading and staging the histological lesions	<i>Am J Gastroenterol</i>	Brunt EM/Saint Louis University, United States	1999	1609
3	Nonalcoholic fatty liver disease: A spectrum of clinical and pathological severity	<i>Gastroenterology</i>	Matteoni CA/Cleveland Clin Fdn, United States	1999	1506
4	Prevalence of hepatic steatosis in an urban population in the United States: Impact of ethnicity	<i>Hepatology</i>	Browning JD/Univ Texas, United States	2004	1320
5	Non-alcoholic steatohepatitis - Mayo-Clinic experiences with A hitherto unnamed disease	<i>Mayo Clin Proc</i>	Ludwig J/Mayo Clin, United States	1980	1206
6	Nonalcoholic fatty liver, steatohepatitis, and the metabolic syndrome	<i>Hepatology</i>	Marchesini G/Università di Bologna, Bologna, Italy	2003	1134
7	Nonalcoholic fatty liver disease - a feature of the metabolic syndrome	<i>Diabetes</i>	Marchesini G/Univ Bologna, Italy	2001	1072
8	The natural history of nonalcoholic fatty liver disease: A population-based cohort study	<i>Gastroenterology</i>	Adams LA/Mayo Clin, United States	2005	974
9	Nonalcoholic steatohepatitis: Association of insulin resistance and mitochondrial abnormalities	<i>Gastroenterology</i>	Sanyal AJ/Virginia Commonwealth Univ, United States	2001	935
10	The natural-history of nonalcoholic steatohepatitis - a follow-up-study of 42 patients for up to 21 yr	<i>Hepatology</i>	Powell EE/University of Queensland, Australia	1990	864
11	Independent predictors of liver fibrosis in patients with nonalcoholic steatohepatitis	<i>Hepatology</i>	Angulo P/Mayo Clin, United States	1999	802
12	Sources of fatty acids stored in liver and secreted <i>via</i> lipoproteins in patients with nonalcoholic fatty liver disease	<i>J Clin Invest</i>	Donnelly KL/Univ Minnesota, United States	2005	801
13	Nonalcoholic steatohepatitis - an expanded clinical entity	<i>Gastroenterology</i>	Bacon BR/St. Louis UNIV, United States	1994	756
14	Association of nonalcoholic fatty liver disease with insulin resistance	<i>Am J Med</i>	Marchesini G/Univ Bologna, United States	1999	736
15	Long-term follow-up of patients with NAFLD and elevated liver enzymes	<i>Hepatology</i>	Ekstedt M/Linköping Univ Hosp, Sweden	2006	719
16	Expanding the natural history from cryptogenic cirrhosis to of nonalcoholic steatohepatitis: Hepatocellular carcinoma	<i>Gastroenterology</i>	Bugianesi E/Univ Turin, Italy	2002	712
17	The utility of radiological imaging in nonalcoholic fatty liver disease	<i>Gastroenterology</i>	Saadeh S/Inova Fairfax Hosp, United States	2002	708
18	The fat-derived hormone adiponectin alleviates alcoholic and nonalcoholic fatty liver diseases in mice	<i>J Clin Invest</i>	Xu AM/Univ Auckland, China	2003	696
19	Nonalcoholic fatty liver disease: Predictors of nonalcoholic steatohepatitis and liver fibrosis in the severely obese	<i>Gastroenterology</i>	Dixon JB/Monash Univ, Australia	2001	666
20	A placebo-controlled trial of pioglitazone in subjects with nonalcoholic steatohepatitis	<i>N Engl J Med</i>	Belfort R/Univ Texas, Italy	2006	662
21	Genetic variation in PNPLA3 confers susceptibility to nonalcoholic fatty liver disease	<i>Nature Genet</i>	Romeo S/Univ Texas, United States	2008	614
22	NASH and insulin resistance: Insulin hypersecretion and specific association with the insulin resistance syndrome	<i>Hepatology</i>	Chitturi S/Univ Sydney, Australia	2002	610
23	Sampling variability of liver biopsy in nonalcoholic fatty liver disease	<i>Gastroenterology</i>	Ratziu V/Grp Hosp Pitie Salpetriere, France	2005	572
24	Fat accumulation in the liver is associated with defects in insulin suppression of glucose production and serum free fatty acids independent of obesity in normal men	<i>J Clin Endocrinol Metab</i>	Seppala-Lindroos A/Univ Helsinki, Finland	2002	563
25	Beyond insulin resistance in NASH: TNF-alpha or adiponectin?	<i>Hepatology</i>	Hui JM/Westmead Hosp, Australia	2004	552

92	Hepatic-Effects Of Dietary Weight-Loss In Morbidly Obese Subjects	<i>J Hepatol</i>	Andersen T/Univ Copenhagen, Denmark	1991	236
93	Rosiglitazone for nonalcoholic steatohepatitis: One-year results of the randomized placebo-controlled fatty liver improvement with rosiglitazone therapy trial	<i>Gastroenterology</i>	Ratzl V/Univ Paris, France	2008	234
94	Diagnosis of Fibrosis and Cirrhosis Using Liver Stiffness Measurement in Nonalcoholic Fatty Liver Disease	<i>Hepatology</i>	Wong VWS/Hop Haut Leveque, China	2010	232
95	Increased hepatocyte CYP2E1 expression in a rat nutritional model of hepatic steatosis with inflammation	<i>Gastroenterology</i>	Weltman MD/Univ Sydney, Australia	1996	230
96	Effect of steatohepatitis associated with irinotecan or oxaliplatin pretreatment on resectability of hepatic colorectal metastases	<i>J Am Coll Surg</i>	Fernandez FG/Washington Univ, United States	2005	229
97	Adiponectin and its receptors in non-alcoholic steatohepatitis	<i>Gut</i>	Kaser S/Univ Innsbruck Hosp, Spain	2005	229
98	Long-term outcomes of cirrhosis in nonalcoholic steatohepatitis compared with hepatitis C	<i>Hepatology</i>	Hui JM/Univ Sydney, Australia	2003	229

99	Noninvasive markers of fibrosis in nonalcoholic fatty liver disease: Validating the European liver fibrosis panel and exploring simple markers	<i>Hepatology</i>	Guha IN/Guha, United Kingdom	2008	228
100	Plasma adiponectin in nonalcoholic fatty liver is related to hepatic insulin resistance and hepatic fat content, not to liver disease severity	<i>J Clin Endocrinol Metab</i>	Bugianesi E/Univ Turin, Italy	2005	227

NAFLD: Nonalcoholic fatty liver disease; NASH: Non-alcoholic steatohepatitis; TNF: Tumor necrosis factor; ALT: Alanine aminotransferase; PPAR: Peroxisome proliferator activated receptor; HCV: Hepatitis C virus.

**Table 2 Countries of origin of the top 100 articles in nonalcoholic fatty liver disease**

Rank	Nation	TP	FP	SP	CP	RP	TC
1	United States	55	48	45	10	49	26975
2	Italy	20	13	11	9	15	5567
3	Australia	14	10	8	6	9	4767
4	France	9	6	6	3	7	1861
5	United Kingdom	7	5	2	5	2	1826
6	Japan	4	4	4	0	4	1191
7	Spain	3	3	2	1	2	810
8	Sweden	2	2	1	1	1	1074
9	China	2	2	0	2	0	928
10	Canada	2	2	0	2	0	694
11	Germany	2	1	1	1	1	264
12	Finland	1	1	1	0	1	563
13	Greece	1	1	0	1	0	323
14	Belgium	1	1	0	1	0	285
15	Denmark	1	1	1	0	1	236
16	New Zealand	1	0	0	1	1	0
17	Austria	1	0	0	1	1	0
18	South Africa	1	0	0	1	0	0

TP: The number of total 100 top-cited articles; FP: The number of first author articles; SP: The number of single-country articles; CP: The number of internationally collaborative articles; RP: The number of corresponding author articles in total 100 top-cited articles; TC: Total citation of first author articles; Rank: According to the order of TP firstly and TC secondly. As for New Zealand Austria and South Africa, the country with more citation of corresponding author articles took precedence.

**Epidemic studies:** Concepts related to epidemiology such as humans, male/men, female/women, middle aged and adolescent make up another high frequency concepts cluster, which might be closely involved in the accelerating incidence of this disease. The morbidity rate of NAFLD has doubled during last 20 years, whereas the morbidity rate of other chronic liver diseases has remained stable or even decreased. Epidemic investigations of NAFLD primarily focus on human genetic and metabolic studies<sup>[14]</sup>. Several epidemiological investigations such as case series, familial and twin studies have widely revealed the function of heritability<sup>[15]</sup>. Noteworthy, in comparison to high-risk population of NAFLD clustering around middle-aged and elderly adults before, younger age trend has gradually shown especially in Asian countries during the last two decades. Following the epidemics of childhood obesity, NAFLD as the most common form of chronic liver disease in adolescents has become a reality<sup>[16]</sup>.

**Medicalization progress:** Medicalization is also a high frequency concepts cluster. Lack of uniformed

**Table 3 Top productive institutions list with top 100 cited articles in nonalcoholic fatty liver disease**

Rank	Institution	TP	FP	SP	CP	RP	TC
1	Mayo Clinic	12	12	8	4	11	5950
2	University of Bologna	9	5	1	8	5	3627
2	University of Turin	9	4	1	8	4	1591
4	The University of Sydney	7	4	1	6	2	1504
5	University of California, San Diego	6	3	0	6	3	1028
6	University of Texas	5	5	1	4	4	3428
7	Saint Louis University	5	3	3	2	3	2771
8	Virginia Commonwealth University	5	4	2	3	2	2181
9	Westmead Hospital	4	2	0	4	3	907
10	Washington University	4	2	0	4	1	552
11	University of Paris	4	1	0	4	1	234
12	University of California, San Francisco	4	1	1	3	0	237
13	National Cancer Institute	4	1	0	4	1	2151
14	MetroHealth Medical Center	4	0	0	4	0	0

TP: The number of total 100 top-cited articles; FP: The number of first author articles; SP: The number of single-country articles; CP: The number of internationally collaborative articles; RP: The number of corresponding author articles in total 100 top-cited articles; TC: Total citation of first author articles; Rank: According to the order of TP firstly and TC secondly. As for National Cancer Institute and MetroHealth Med Ctr, the institute with more corresponding author articles took precedence.

diagnosis regulation and no established therapy remains a hindrance to be broken through in this field. NASH is characterized by hepatocellular damage, lobular necro-inflammation and fibrogenesis. The early diagnosis of advanced fibrosis in NAFLD is therefore crucial<sup>[17,18]</sup>. The liver biopsy remains the most reliable diagnostic method to appropriately evaluate the severity of liver fibrosis. Facing to limitations of this invasive technique in current use, a number of experimental biomarkers have been developed in order to predict the degree of liver fibrosis<sup>[19]</sup>. Moreover, as a promising method for evaluation of patients with NAFLD, nuclear medicine through liver scintigraphy has recently been proposed<sup>[20]</sup>.

Preventing existing comorbidities such as metabolic disorders, cardiovascular or cerebrovascular events are the primary target for NAFLD treatment, while the secondary goal of NAFLD therapy is reversal of hepatic steatosis<sup>[21-23]</sup>. Lifestyle modification such as weight loss and balanced diet remains the main way of management in NAFLD/NASH. In addition, the benefit of nutritional supplementation on disease progression has attracted growing interest<sup>[24]</sup>. Most recent data has evidenced the effects of nutrients and dietary bioactive compounds intake (*i.e.*, long-chain PUFA, Vitamin E,

**Table 4** Most frequent subspecialties with the top 100 cited articles in nonalcoholic fatty liver disease

Rank	Subject categories	No. of articles	Total citation
1	Gastroenterology and Hepatology	71	33290
2	Endocrinology and Metabolism	7	3341
3	General and Internal Medicine	6	3917
4	Research and Experimental Medicine	4	2172
5	Science and Technology	4	1587
6	Biochemistry and Molecular Biology	2	817
7	Physiology	2	809
8	Pediatrics	2	766
9	Genetics and Heredity	1	614
10	Pathology	1	346
11	Cell Biology	1	285
12	Oncology	1	285
13	Surgery	1	229

Remarks: In the situation of equal numbers of articles, the subspecialties with more total citation took precedence.

**Table 5** Journal distribution of top 100 cited articles in nonalcoholic fatty liver disease

Rank	Journal	No. of articles	Total citation	Impact factor (2014)
1	<i>Hepatology</i>	42	18867	11.055
2	<i>Gastroenterology</i>	16	9490	16.716
3	<i>Am J Gastroenterol</i>	5	2685	10.755
3	<i>J Hepatol</i>	5	1437	11.336
5	<i>J Clin Invest</i>	4	2172	13.215
6	<i>Proc Natl Acad Sci USA</i>	3	1188	9.674
7	<i>J Clin Endocrinol Metab</i>	3	1179	3.457
8	<i>Diabetes</i>	2	1343	8.095
9	<i>New Engl J Med</i>	2	1212	55.873
10	<i>J Biol Chem</i>	2	817	4.573
11	<i>Gut</i>	2	553	14.66

Remarks: In the situation of equal numbers of articles, the journals with more total citation took precedence.

Vitamin D, minerals and polyphenols) on the modulation of molecular mechanisms leading to fat accumulation, oxidative stress, inflammation and liver fibrosis in NAFLD patients<sup>[25]</sup>. In the field of pharmaceutical therapies, a wide range of drugs have been applied in clinical trials, including antioxidants, lipid lowering agents, and rennin-angiotensin system blockers<sup>[26-28]</sup>. Up to the present, lifestyle modification is the main clinical recommendation as an initial step. Although promising results have shown that long-term insulin sensitizers such as metformin, rosiglitazone, and thiazolidinediones are effective in NAFLD therapy, there are no approved drugs<sup>[29-31]</sup>.

In conclusion, it is important to acknowledge the top 100 cited articles because they marked with the leading countries, institutions, journals, hotspots, past and current trends in NAFLD field that could provide the foundation for further investigations. Highly related concepts of the top 100 cited papers in NAFLD suggest that pathogenesis mainly related to metabolic syndrome, epidemiology, and medicalization including diagnosis and

**Table 6** High frequency key words in the top 100 cited articles in nonalcoholic fatty liver disease (frequency > 2)

Rank	Key word	Frequency
1	Hepatic steatosis	4
1	Obesity	4
3	Fibrosis	3
4	Metabolic syndrome	2
4	Insulin resistance	2
4	Biopsies	2
4	Intestinal bacteria	2
4	Endotoxin	2

treatment are attracting ever-growing attention.

## ACKNOWLEDGMENTS

We would like to thank Professor Yuh-Shan Ho from Asia University and Hui-Min Guo, PhD, from Logistics University of People's Armed Police Force for their comments on drafting and polishing the manuscript.

## COMMENTS

### Background

Due to the increasing prevalence of obesity and metabolic syndrome worldwide,

nonalcoholic fatty liver disease (NAFLD) becomes the leading cause of chronic liver disease. The rapid growth of NAFLD research recently drives top cited articles in the field to be identified and bibliometric analysis to assess the history and current situation, publication distribution of leading countries and institutes as well as the research hotspots of NAFLD.

### Research frontiers

A systematic review in 2015 covered total articles relevant to NAFLD from Science Citation Index-Expanded (SCI-Expanded) showed article amount has appeared to geometric growth in recent decades. However, bibliometric result from total articles is not sufficient to indicate the evolution and direction in NAFLD research. The citation times by other authors has been used as a measurable comparison to evaluate the academic impact of an article in its subject field. To date, there have no top cited articles analysis were carried out in NAFLD field.

### Innovations and breakthroughs

This paper summarized the current findings from the analysis of the top 100 cited articles in NAFLD field. It is the first global look at the history and current situation of NAFLD research to assess the performances of leading countries/territories and institutes and research hotspots of this disease. In terms of the number of published 100 top-cited articles in NAFLD, United States was the most predominant country and Mayo Clin was the most productive institution. Highly related concepts of the top 100 cited papers in NAFLD suggest that pathogenesis (mainly related to metabolic syndrome), epidemiology, and medicalization (including diagnosis and treatment) are attracting ever-growing attention.

### Applications

Top 100 cited articles marked with the leading countries, institutions, journals, hotspots, past and current trends in NAFLD field that could provide the foundation for further investigations. Medical bibliometric analysis on top 100 cited articles is expected to provide a reference for the researchers to get involved in NAFLD area.

### Terminology

The articles involved in bibliometric analysis were collected based on online version of SCI-Expanded from Thomson Reuters. Keywords for bibliography retrieval in database consisted of "nonalcoholic steatohepatitis" and "nonalcoholic fatty liver disease".

### Peer-review

This study retrieved the top 100 cited articles in the field of NAFLD and determined the country of origin, peak of highly-cited articles and international collaborations. The present study is very interesting on a high prevalent chronic liver disease.

# World Journal of *Hepatology*

*World J Hepatol* 2016 December 8; 8(34): 1489-1540

## Editorial Board

2014-2017

The *World Journal of Hepatology* Editorial Board consists of 474 members, representing a team of worldwide experts in hepatology. They are from 52 countries, including Algeria (1), Argentina (6), Armenia (1), Australia (2), Austria (4), Bangladesh (2), Belgium (3), Botswana (2), Brazil (13), Bulgaria (2), Canada (3), Chile (1), China (97), Czech Republic (1), Denmark (2), Egypt (12), France (6), Germany (20), Greece (11), Hungary (5), India (15), Indonesia (3), Iran (4), Israel (1), Italy (54), Japan (35), Jordan (1), Malaysia (2), Mexico (3), Moldova (1), Netherlands (3), Nigeria (1), Pakistan (1), Philippines (2), Poland (1), Portugal (2), Qatar (1), Romania (6), Russia (2), Saudi Arabia (4), Singapore (1), South Korea (12), Spain (20), Sri Lanka (1), Sudan (1), Sweden (1), Switzerland (1), Thailand (4), Turkey (21), Ukraine (3), United Kingdom (18), and United States (55).

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Dr. Andrea Mancuso, MD, Medicina Interna 1, ARNAS Civico, 90100 Palermo, Italy

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Ischemia-reperfusion injury (IRI) continues to be a major contributor to graft dysfunction, thus supporting the

need for therapeutic strategies focused on minimizing organ damage especially with growing numbers of extended criteria grafts being utilized which are more vulnerable to cold and warm ischemia. Nitric oxide (NO $\cdot$ ) is highly reactive gaseous molecule found in air and regarded as a pollutant. Not surprising, it is extremely bioactive, and has been demonstrated to play major roles in vascular homeostasis, neurotransmission, and host defense inflammatory reactions. Under conditions of ischemia, NO $\cdot$  has consistently been demonstrated to enhance microcirculatory vasorelaxation and mitigate pro-inflammatory responses, making it an excellent strategy for patients undergoing organ transplantation. Clinical studies designed to test this hypothesis have yielded very promising results that includes reduced hepatocellular injury and enhanced graft recovery without any identifiable complications. By what means NO $\cdot$  facilitates extra-pulmonary actions is up for debate and speculation. The general premise is that they are NO $\cdot$  containing intermediates in the circulation, that ultimately mediate either direct or indirect effects. A plethora of data exists explaining how NO $\cdot$ -containing intermediate molecules form in the plasma as S-nitrosothiols (*e.g.*, S-nitrosoalbumin), whereas other compelling data suggest nitrite to be a protective mediator. In this article, we discuss the use of inhaled NO $\cdot$  as a way to protect the donor liver graft against IRI in patients undergoing liver transplantation.

**Key words:** Liver; Nitric oxide; Ischemia-reperfusion; Nitrite; Transplantation

**Core tip:** Our manuscript assesses the basic and clinical literature of nitric oxide and liver transplantation and creates a scientific/clinical justification for its routine use.

Fukazawa K, Lang JD. Role of nitric oxide in liver trans-

plantation: Should it be routinely used? *World J Hepatol* 2016; 8(34): 1489-1496 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i34/1489.htm> DOI: <http://dx.doi.org/10.4254/wjgh.v8.i34.1489>

## INTRODUCTION

Liver transplantation has become a viable treatment option for recipients suffering from irreversible liver failure for more than three decades. However, the number of recipients on the waiting list continues to grow due to the major mismatch between organ supply and demand, creating tremendous pressure on for the development of techniques to expand the donor pool. There is about 7000 liver transplants performed annually with a trend that is increasing due to demand. As a result, according to national transplant registry database from the Organ Procurement and Transplant Network, about 1000 potential recipients on the waiting list die annually (Figure 1). Therefore, strategies are actively being sought to increase in donor pool. The transplant community has evaluated an option to relax the standard for donors to include donors with suboptimal quality [more damage from anoxic preservation and ischemia-reperfusion injury (IRI)], including the advanced age donor, prolonged cold and warm ischemia time, and hepatic steatosis. Currently, extended criteria donors make up 5%-10% of all donors and this number is increasing. IRI to the liver remains a significant contributor to graft dysfunction, or primary non-function, resulting in increased intensive care unit and hospital stay, increase financial burden, re-transplantation and, in a worst case scenario, death<sup>[1]</sup>.

Nitric oxide (NO $\cdot$ ) is an important endogenously produced biological mediator affecting vascular function, metabolic function and host defense mechanisms<sup>[2]</sup>. It is produced by macrophages, dendritic cells and plays a critical role in host innate and adaptive immunological processes<sup>[3,4]</sup>. Inhaled NO $\cdot$  has been clinically used to treat pulmonary hypertension due to its vasodilating effect in pulmonary microcirculation without causing any unfavorable systemic hemodynamic changes. More recent evidence has suggested a relative NO $\cdot$  deficiency due to IRI and that the use of preemptive inhaled NO $\cdot$  can attenuate liver IRI during liver transplantation.

## ENDOGENOUS NO $\cdot$ AND THE LIVER DURING ISCHEMIA-REPERFUSION

Liver graft injury from ischemia-reperfusion is the principal mechanism of liver injury related to procedures involving clamping of hepatic inflow such as hepatectomy and liver transplantation. Cessation of oxygen delivery to sinusoidal microcirculation causes severe ATP depletion which leads to retraction of sinusoidal endothelial cells and Kupffer cells, bleb formation in the microcirculation<sup>[5]</sup>. There is obstruction of sinusoid and

microcirculatory disturbance due to bleb formation as well as accumulation of leukocytes and platelets leads to prolonged ischemia of hepatocytes, so-called, "no-flow phenomenon". In addition, due to the upregulation and generation of inflammatory mediators such as oxygen free radicals, cytokines and chemokines from the Kupffer cells occupying sinusoid there is both a local and systemic inflammatory response after reperfusion<sup>[6]</sup>. Therefore, IRI of the liver is generally believed to cause severe hepatocellular injury as well as extrahepatic organ inflammation and injury that contributes to perioperative morbidity and mortality.

Reductions of NO $\cdot$  during ischemia-reperfusion of liver aggregates liver injury in both animals and humans<sup>[7,8]</sup>. In fact, decreased hepatic production of NO $\cdot$  from endothelial nitric oxide synthase or endothelial nitric oxide synthase (eNOS) (responsible for the constitutive production of NO $\cdot$ ) within 60 min after reperfusion in human liver transplantation contributes to the ischemia-reperfusion graft injury<sup>[8]</sup>. In addition to reduced production, NO $\cdot$  is inactivated from the reactions with reactive oxygen species, such as superoxide radical leading to reduced bioavailability<sup>[9,10]</sup>. As a consequence, reduced NO $\cdot$  bioavailability leads to apoptosis, leukocyte adhesion, increase microcirculatory resistance, and mitochondrial dysfunction<sup>[10]</sup>. Not surprisingly, the restoration of NO $\cdot$  concentrations lessens liver ischemia injury *via* reversing the most of the previously mentioned adverse actions. Additional studies support the finding that eNOS is essential for reduction liver graft injury during liver ischemia-reperfusion. Injury to the liver was decreased in the wild type when compared to mice where eNOS was knocked out. When eNOS expression was exogenously increased or NO $\cdot$  donors enhanced protection was realized<sup>[11,12]</sup>. In addition, established NO $\cdot$  concentrations resulting from inflammation are generally greater due to more robust inducible nitric oxide synthase (iNOS) expression. At the present time the role of iNOS in liver protection is not well known. In a rat liver ischemia-reperfusion model, iNOS enzyme activity was significantly increased in parallel with increased iNOS mRNA expression after reperfusion, which suggests that induction of iNOS has an important role in liver ischemia-reperfusion<sup>[13]</sup>. Counter to this observation, in a porcine ischemia-reperfusion model, is that portal injection of aminoguanidine, a selective iNOS inhibitor, decreased IRI<sup>[14]</sup>. Additionally, when iNOS was knocked out in mice and then exposed to warm liver ischemia-reperfusion, they incurred more injury when compared to wild types. While the injury was greater in the iNOS deficient animals, iNOS mRNA was also undetectable in the wild types. While iNOS is crucial in increasing net NO $\cdot$  concentrations and contributing to liver injury resulting from ischemia-reperfusion, further work is needed.

Additional hepatoprotective studies thought to due to endogenous NO $\cdot$  production have been published. Nitric oxide-mediated protection has been shown to inhibit apoptosis depending on concentration *via* inhibition

**Figure 1** Number of transplants, waiting list additions and waiting list deaths in the United States between 1995 and 2015. Number of waiting list additions and deaths are based on the candidates and candidate who is listed more than one place is counted as one candidate. Data are available from: URL: <https://optn.transplant.hrsa.gov/data/>.

of caspase proteases *via* S-nitrosylation<sup>[15]</sup> (Figure 2). Reduced compartmental concentrations of NO $\cdot$  inhibits apoptosis while increasing concentrations yields toxic reactive nitrogen species such as peroxynitrite or oxygen radicals that have shown to cause apoptosis and necrosis<sup>[16]</sup>. Other proposed mechanisms of how NO $\cdot$  protects include down-regulation of nuclear factor kappa B<sup>[17]</sup>, mitochondrial complex I inhibition that is reversible, and reductions in mitochondrial calcium accumulation<sup>[18]</sup>. Controversy continues in regards to how NO $\cdot$  may mitigate inflammation and injury. In fact, Jaeschke *et al.*<sup>[19]</sup> demonstrated that NOS inhibition did not contribute to hepatic injury at the time of reperfusion. Additionally, the inhibition of NO $\cdot$  did not influence neutrophil function as related to migration or adhesion<sup>[20]</sup>. Nonetheless, most evidence whether lab-based or clinical, demonstrates favorable effects of NO $\cdot$  during liver ischemia-reperfusion. It is difficult to reconcile the results, but no doubt diversity exists in the role of NO $\cdot$  in different cell types, as well as differing cellular compartmental NO $\cdot$  concentrations, timing of administration, and duration of NO $\cdot$  exposure. Also laboratory methods applied may have some role on this conflicting results.

## IMPACT OF EXOGENOUS NO $\cdot$ DELIVERY IN ATTENUATING LIVER IRI

Administration of inhaled NO $\cdot$  has demonstrated efficacy both in animal and human studies<sup>[21-25]</sup>. NO $\cdot$  inhalation decreases pulmonary and systemic vascular resistance with resultant improvements in tissue oxygenation increases in renal blood flow, and glomerular filtration rate<sup>[26-28]</sup>. Moreover, inhaled NO $\cdot$  has been demonstrated to exert extra-pulmonary or peripheral effects to the microvasculature as measured by enhanced perfusion and anti-inflammatory properties during post-reperfusion period<sup>[21,22,29,30]</sup>. Due to this seminal work, administration

of inhaled NO $\cdot$  has undergone more extensive assessment as an anti-inflammatory therapy in humans subjected to predictable ischemia-reperfusion<sup>[23,30-32]</sup>. How extra-pulmonary effects of inhaled NO $\cdot$  remains unclear but generally it is believed in transformation of unstable NO $\cdot$  to relatively stable, NO $\cdot$ -containing intermediate upon entering in the circulation, and then recycled back to NO $\cdot$  at targeted remote location<sup>[31]</sup>. Study with a feline ischemia-reperfusion model suggested the intermediate molecule may be plasma S-nitrosothiols (e.g., S-nitrosoalbumin), while studies in both mice and humans points to nitrite as a possible intermediate<sup>[31,33,34]</sup>. A protective role for nitrite in ischemia-reperfusion is also demonstrated by direct administration of nitrite in murine hepatic ischemia-reperfusion models and together with the demonstration of nitrite conversion to NO $\cdot$  under ischemic location<sup>[33,35]</sup>. NO $\cdot$ -containing molecules in the blood that are labile under biological conditions and can also be formed with the inhalation of NO $\cdot$  (*via* nitrosylation or S-nitrosation reactions). These also includes S-nitrosothiols in the red blood cell, ferrous-nitrosylhemoglobin and C- or N-nitrosamines<sup>[31,36-38]</sup>.

Specifically, inhaled NO $\cdot$  (80 ppm, co-administered with 50% oxygen and 50% nitrous oxide, approximately 5 h) was administered preemptively to healthy patients undergoing lower extremity surgery requiring approximately two hours of tourniquet-induced ischemia and continued until the completion of the surgery<sup>[32]</sup>. Administration of inhaled nitric oxide (80 ppm) reduces the expression of CD11b/CD18, P-selectin, and NF- $\kappa$ B. Also there are associated increase in plasma levels of nitrate/nitrite, and reduced oxidative stress. In this health cohort inhaled NO $\cdot$  administered at 80 ppm significantly reduced inflammation from ischemia-reperfusion of lower extremity. Therefore, under conditions of impaired NO $\cdot$  metabolism, inhaled NO $\cdot$  may be an effective therapy to replenish systemic NO $\cdot$ , thus mitigates injury. A subsequent randomized controlled clinical trial evaluated the effects of preemptive inhaled NO $\cdot$  in recipients ( $n = 20$ ) undergoing liver transplantation<sup>[39]</sup>. Again, inhaled NO $\cdot$  (80 ppm, approximately 4 h) vs placebo was randomly administered to the recipients after patients were anesthetized and stopped upon case completion. Patients who received inhaled NO $\cdot$  significantly demonstrated shorter hospital stay and enhanced recovery of graft function (alanine transaminase and aspartate aminotransferase, prothrombin time and activated partial thromboplastin time) by approximately 2-3 d when compared to the placebo group. The intraoperative transfusion of platelets was reduced by 50% in recipients who received inhaled NO $\cdot$ . As would be expected plasma nitrite levels were significantly increased in inhaled NO $\cdot$  group compare when compared to placebo. Commonly cited untoward side effects such as the formation of critical levels of met hemoglobin, nitrogen dioxide or bleeding complications were not observed. Lang *et al.*<sup>[39]</sup> then compared a placebo group of patients who received 80 ppm of inhaled NO $\cdot$  during the operative phase of liver transplantation. Patients receiving NO $\cdot$  had better allograft function and

**Figure 2 Delivery of nitric oxide to donor liver graft in liver transplantation.** Preemptive treatment with inhaled nitric oxide can attenuate ischemia-reperfusion injury via modulation of a myriad of inflammatory, cellular and vascular mechanisms. IV: Intravenous; NO: Nitric oxide; NO<sub>2</sub><sup>-</sup>: Nitrite; NO<sub>3</sub><sup>-</sup>: Nitrate; eNOS: Endothelial nitric oxide synthase; PO: Per oral.

reduced hepatobiliary complications 9 mo following the initial operation. Also, inhaled NO<sup>•</sup> significantly increased concentrations of serum nitrate, nitrite, and nitrosylhemoglobin. Consistent with previous data, nitrite was hypothesized to be critical to the findings of allograft protection. No adverse metabolic or hematologic effects were observed between groups. Mean costs of inhaled NO<sup>•</sup> was \$1020 per transplantation. Use of inhaled NO<sup>•</sup> has also been tested in models of a non-heart beating donor model and steatotic liver, and demonstrated the injury attenuation and enhanced microcirculatory perfusion<sup>[40,41]</sup>. These studies are in line with other studies demonstrating inhaled NO<sup>•</sup> mitigates injury when utilized prior to predictable IRI. Replenishing NO<sup>•</sup> maybe more important in extended criteria donors which appear even susceptible to ischemia (cold and warm)-reperfusion.

Methemoglobinemia is a well-documented side effect of high dose supplemental inhaled NO<sup>•</sup>. Methemoglobin (MetHb) is rapidly formed by the oxidation of nitrosylhemoglobin, which is a byproduct from the binding of NO<sup>•</sup> to hemoglobin. This has been shown to occur in a dose and time-dependent fashion. MetHb has a fewer hemes to bind oxygen despite that methemoglobin has a higher affinity to oxygen compared to hemoglobin (1500 times higher affinity compared to carbon monoxide)<sup>[42]</sup>, thus diminishing the oxygen carrying capacity of the blood. MetHb level of 10% of total hemoglobin cause clinically apparent cyanosis, and MetHb level of 35% cause headache, weakness, and dyspnea, and MetHb level of more than 70% are fatal. As aforementioned, clinically significant methemoglobinemia

has not been reported when low-dose inhaled NO<sup>•</sup> is used. Only few case reports of methemoglobinemia has been reported when inhaled NO<sup>•</sup> was used in high dose (> 80 ppm)<sup>[43-45]</sup>. However it is worth mentioning that two cases of methemoglobinemia associated with low dose inhaled NO<sup>•</sup> due to delivery failure have been reported<sup>[46]</sup>. In both cases, methemoglobin reductase levels were confirmed to be normal, excluding of heredity methemoglobin reductase deficiency. Authors have speculated that variable (phasic) main flow provided from mechanical ventilator caused periodical accumulation of NO<sup>•</sup> in the inspiratory limb of airway circuit, leading to variable inhaled NO<sup>•</sup> concentration. Incorporated slow-response chemiluminescent analyzer was unable to detect this fluctuation of inhaled NO<sup>•</sup>. This fluctuation of NO<sup>•</sup> was also shown in lung model. Yamaguchi *et al.*<sup>[47]</sup> showed that inhaled NO<sup>•</sup> was more concentrated when it was administered more distally in the inspiratory limb of the circuit as well as administered with lower flow rates. They speculated that delivered NO<sup>•</sup> was diluted by backflow in the NO<sup>•</sup> tubing from the higher pressure in the circuit in the early inspiratory phase of ventilation. This concentrated NO<sup>•</sup> in NO<sup>•</sup> tubing was delivered in the early expiratory phase, leading to fluctuation in NO<sup>•</sup> concentration. Therefore, inhaled NO<sup>•</sup> treatment requires caution during administration and other form of supplementation of NO<sup>•</sup> may be favored in terms of avoiding life-threatening methemoglobinemia.

Other possible complication is the generation of cytotoxic oxidant, "peroxynitrite" by rapidly reacting with superoxide anion<sup>[48]</sup>. Peroxynitrite can induce lipid

peroxidation and inhibit mitochondrial respiration<sup>[49,50]</sup>. Indeed lung damage has been reported after inhaled NO $\cdot$  administration<sup>[51]</sup>. Hydrogen gas discover to have an anti-oxidative effect by scavenging peroxynitrite and other hydroxyl radicals<sup>[52]</sup>. Hydrogen gas has been shown to ameliorate lipopolysaccharide-induced<sup>[53]</sup>, ventilator-associated<sup>[54]</sup>, and hyperoxia-induced acute lung injury<sup>[55]</sup>. Therefore co-administration of hydrogen gas has been investigated to enhance lung protection by NO $\cdot$ .

Underlying mechanisms of how inhaled NO $\cdot$  decreases injury remains speculative. Nitrite, an oxidative product of NO $\cdot$  metabolism, seems to play a protectant role, however<sup>[33,34,56-58]</sup>. Thus, consistent with this line of thinking, sodium nitrite has been shown to alleviate acute injury from ischemia-reperfusion in both murine heart (decreased myocardial infarct size) and liver (decrease apoptosis in hepatocytes)<sup>[33]</sup>. Nitrite-mediated protection seems to involve biochemical pathways that connect ischemia to nitrite reduction to NO $\cdot$  production, therefore exerting cytoprotection by multiple possible mechanisms. In a model of murine liver transplantation, harvested syngeneic liver grafts were perfused with Lactated Ringers, and University of Wisconsin solution, and sodium nitrite supplemented solution during cold preservation period. Several recipients were treated with or without nitrite *via* an intraperitoneal injection. Liver injury demonstrated by enzyme release was significantly mitigated with both nitrite-supplemented solutions. The protective role of nitrite against cold ischemic-induced injury was more robust with longer preservation periods. Cell morphology and architecture was better preserved with grafts treated with nitrite. Hepatocyte cell death/necrosis was significantly reduced in the nitrite supplemented liver grafts. Liver grafts with extended cold preservation times demonstrated both improved tissue histology and liver function after reperfusion when treated with either the nitrite-supplemented preservation solution or in just the nitrite-treated recipients. Surprisingly, combination treatment of both liver graft and recipient did not demonstrate protection. Further clinical studies in the use of inhalation of NO $\cdot$  or injection of NO $\cdot$  donors for extended criteria donor may have a large clinical impact given that there is a surge in use of extended criteria donors to expand donor pool and warrants further investigation.

Other potential route of NO $\cdot$  donor administration is per gastrointestinal tract. In fact, dietary intake of nitrate is major source of NO $\cdot$  donor in mammals<sup>[59]</sup>. Dietary nitrate is abundant in many vegetables and water. Ingested nitrate is absorbed from intestine. One quarter of absorbed nitrate is concentrated in saliva and metabolized to nitrite by commensal bacteria<sup>[60]</sup>. Inorganic nitrite is metabolized to NO $\cdot$  in the presence of gastric acid<sup>[61-63]</sup>. This production pathway of nitric oxide is independent of eNOS (eNOS - independent NO $\cdot$  production) and accounts for majority of nitrite and nitrate in mammalian body<sup>[62,63]</sup>. Absorbed nitrite,

nitrate, or NO $\cdot$  from small intestine is directly delivered to liver through portal vein (Figure 2). Therefore, per oral administration of NO $\cdot$  donor can be a potential route of administration, especially post-transplant period.

Additional drugs that donate NO $\cdot$  have been thoroughly assessed<sup>[64-67]</sup>. Only two types of these drugs feasible to use clinically: Nitrates, and sodium nitroprusside. Nitrates, such as nitroglycerin are widely used to treat patients suffering from coronary ischemia and/or myocardial infarction due to the pronounced venodilatory effect that assists in reducing venous return and myocardial oxygen demand. Several formulations are available commercially including a slow release oral form, an ointment, a transdermal patch, a nebulizer, and lastly intravenous formulations. A major limitation of organic nitrates is tachyphylaxis due to sustained usage. Nitroglycerin releases NO $\cdot$  *via* the enzyme mitochondrial aldehyde dehydrogenase<sup>[68]</sup>. Sodium nitroprusside is another commercially available drug that is an NO $\cdot$  donor. Sodium nitroprusside's release of NO $\cdot$  is complex and but its net effect is to significantly diminish mRNA expression of a few pro-inflammatory mediators that promote hepatic injury<sup>[12]</sup>. Lastly, enhanced eNOS up-regulation confers hepatoprotection during IRI and may allow for another therapeutic option. When agents that increase eNOS expression such as trimetazidine, 5-amino-4-imidazole carboxamide riboside or activated protein C, are added to liver preservation solutions, hepatic allograft protection is afforded<sup>[12]</sup>.

## CONCLUSION

IRI has been well characterized the liver especially as it relates to liver resections and liver transplantation. The contribution of NO $\cdot$  deficiency is a newer finding and may have a central role in the pathogenesis of this injury. Replenishing the liver with NO $\cdot$  *via* either by inhalation, inhaled or intravenous nitrate or *via* other donor drugs represents a pragmatic means of mitigating injury. Clinical studies incorporating inhaled NO $\cdot$  provide solid evidence in mitigating injury from IRI. Inhaled NO $\cdot$  has demonstrated repeated efficacy without any demonstrable metabolic or hematological toxicities. Costs of routine NO $\cdot$  administration during liver transplantation is negligible when the entire spectrum of care is considered. Therefore, NO $\cdot$  has a potential to be a good therapeutic option for organ resuscitation in liver transplantation, especially for the extended criteria (marginal quality) donors, but further investigation is still warranted for routine clinical use.

### Abstract

#### AIM

To determine the accuracy of fractional excretion of sodium (FeNa) in the diagnosis of hepatorenal syndrome (HRS).

#### METHODS

Eighty-eight liver transplantation candidates with renal dysfunction and/or proteinuria were included in the study sample. The baseline characteristics of the patients were obtained. All the 88 patients underwent iothalamate glomerular filtration rate testing, 24-h urine collection for urinary sodium and protein excretions, random urine for sodium and creatinine testing, and percutaneous kidney biopsy. FeNa was calculated using the equation  $[(\text{urine sodium} \times \text{serum creatinine}) / (\text{serum sodium} \times \text{urine creatinine})] \times 100\%$ . Diuretic use was recorded among the participants. Patients on renal replacement therapy were not included in the original sample.

#### RESULTS

Seventy-seven (87%) of the 88 patients had FeNa < 1%. FeNa < 1% was present in 10/10, 10/12, 11/13, 12/15 and 34/38 in patients with HRS, acute tubular necrosis, membranoproliferative glomerulonephritis, minimal histological findings ( $\leq 30\%$ ) and advanced ( $\geq 30\%$ -40%) interstitial fibrosis and/or glomerulosclerosis, respectively ( $P = 0.4$ ). FeNa < 1% was 100% sensitive and 14% specific in diagnosing HRS. Receiver operating characteristic curve confirmed the poor accuracy of FeNa < 1% in diagnosing HRS (area under the curve = 0.58,  $P = 0.47$ ). Calculated positive predictive value

and negative predictive value for FeNa < 1% in HRS diagnosis were 46% and 100%, respectively. When used as a continuous variable, FeNa did not correlate with kidney biopsy findings ( $P = 0.41$ ).

## CONCLUSION

FeNa < 1% was common in cirrhotic patients with renal dysfunction and it did not differentiate between HRS and other causes of renal pathologies. HRS diagnosis should be avoided in patients with FeNa > 1%.

**Key words:** Fractional excretion of sodium; Hepatorenal syndrome; Renal dysfunction; Liver transplantation; Urinary sodium excretion; Accuracy

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** In this retrospective analysis of patients with advanced end-stage liver disease, we describe three main concepts. First, our data indicates that fractional excretion of sodium (FeNa) < 1% is a common finding in this group of patients irrespective of the etiology of their renal dysfunction. Second, our study suggests that FeNa < 1% cannot differentiate hepatorenal syndrome (HRS) from other causes of renal pathology. And third, we statistically measured the performance of FeNa < 1% in patients with HRS using kidney biopsy findings as golden diagnostic standard.

## INTRODUCTION

Kidney dysfunction is common in patients with end-stage liver disease (ESLD). It is estimated that nearly 20% to 25% of patients with ESLD will have some type of kidney dysfunction during their course of disease<sup>[1]</sup>. The spectrum of kidney disease can range from reversible kidney injury like acute kidney injury [whether prerenal azotemia or acute tubular necrosis (ATN)] to permanent and chronic kidney damage (CKD) and fibrosis. CKD could be either from causes unrelated to the liver disease such as diabetes, or related to the liver disease such as hepatitis C virus infection.

Hepatorenal syndrome (HRS) is a form of prerenal azotemia that is unique to patients with liver cirrhosis and ascites that is diagnosed after excluding other causes of renal impairment<sup>[2,3]</sup>. HRS occurs in nearly 8% of patients with ascites and 75% of patients with HRS will require dialysis<sup>[2]</sup>.

Early studies have demonstrated that kidneys procured from HRS patients had normal renal histology and exhibited immediate allograft function after transplantation<sup>[4]</sup>. Patho-

physiologically, patients with HRS experience severe vasoconstriction that involves various vascular beds including the kidneys with subsequent reduction in renal blood flow, glomerular filtration rate, and reciprocal increase in proximal tubular sodium re-absorption<sup>[5]</sup>. Indeed, urinary sodium excretion is low in patients with HRS<sup>[6,7]</sup>. Classic teaching has utilized FeNa cut-off of < 1% or > 1% to differentiate between prerenal (including HRS) and intrinsic renal dysfunctions especially those caused by ATN. While this FeNa cut-off has been used as discriminatory tool in cirrhotic patients presenting with elevated serum creatinine, its accuracy has not been tested in diagnosing HRS against a gold standard such as kidney biopsy. Our program utilizes kidney biopsy in evaluating selected liver transplant candidates with renal dysfunction.

In this study, we sought to determine the accuracy of FeNa < 1% in HRS diagnosis using histological data as a gold standard for comparison.

## MATERIALS AND METHODS

### Settings and participants

After obtaining Mayo Clinic Institutional Review Board approval, we retrospectively reviewed the electronic medical record of 88 patients with ESLD who were undergoing LT evaluation at Mayo Clinic in Jacksonville, Florida. All 88 patients had renal dysfunction defined as an iothalamate glomerular filtration rate (GFR) of less than 40 mL/min per 1.73 m<sup>2</sup> or the presence of proteinuria or hematuria. Patients with fulminant hepatic failure were not included.

All study patients had undergone renal biopsy after a stabilization of platelets count of less than 50000 × 10<sup>6</sup>/L with platelets transfusion, and an international normalized ratio of less than 1.5 by fresh frozen plasma transfusion.

Data for GFR and 24-h urine collection for urinary sodium excretion, protein excretion, random urine sodium, and random creatinine were collected. Patients who underwent renal replacement therapy within the last 6 wk prior to evaluation were not included in the original sample, as their serum and urine electrolyte values will be modulated by dialysis. Diuretic use was recorded.

Kidney biopsy specimens were assessed using light microscopy, immunofluorescence and electron microscopy and were interpreted by an experienced nephropathologist as previously described<sup>[8]</sup>. Patients were grouped according to the primary kidney biopsy diagnosis into five main groups: HRS (normal kidney pathology), ATN, membranoproliferative glomerulonephritis (MPGN), minimal histological changes [defined as 10%-30% interstitial fibrosis (IF) and/or glomerulosclerosis (GS)] and advanced (> 30%) IF and/or GS.

FeNa was calculated using the equation: [(urine sodium × serum creatinine)/(serum sodium × urine creatinine)] × 100.

Patients with fulminant hepatic failure were not included in this analysis.

**Table 1** Baseline characteristics of the 88 liver transplant candidates with renal dysfunction

Variable	
Age	60 ± 7
Male gender	57 (65)
Cause of ESLD	
HCV infection	40 (45)
NASH	13 (15)
Alcoholic cirrhosis	12 (14)
Cryptogenic cirrhosis	10 (11)
Other	13 (15)
MELD score	17.5 ± 5.8
History of diabetes	35 (40)
History of hypertension	40 (45)
Iothalamate GFR mL/min per 1.73 m <sup>2</sup>	28 ± 14
Serum creatinine (mg/dL)	1.9 ± 0.9
Serum Na (mEq/dL)	137 ± 5
24-h urinary protein excretion (mg/d)	87 (0-13625)
24-h urinary Na excretion (mEq/d)	56 (0-238)
24-urine protein > 150 mg/d	35 (40)
Hematuria	40 (45)
Diuretic use	64 (72)
FeNa < 1	77 (87)
Kidney Biopsy	
HRS	10 (11)
ATN	12 (14)
MPGN	13 (15)
Minimal histology	15 (17)
≥ 30%-40% IF/GS	38 (43)

Data presented as number (percent), mean ± SD or median (range). ESLD: End-stage liver disease; HCV: Hepatitis C virus; NASH: Non-alcoholic steatohepatitis; MELD: Model of end stage liver disease; GFR: Glomerular filtration rate; Na: Sodium; FeNa: Fractional excretion of sodium; HRS: Hepatorenal syndrome; ATN: Acute tubular necrosis; MPGN: Membranoproliferative glomerulonephritis; IF: Interstitial fibrosis; GS: Glomerulosclerosis.

### Outcome measures

The primary outcome was to calculate the sensitivity, specificity, positive predictive value (PPV) and (NPV) of FeNa < 1% in diagnosing HRS. Secondary outcome was to measure the correlation between FeNa as a continuous variable and the kidney biopsy diagnosis.

### Statistical analysis

Using SPSS software version 22, (Cary, NC), we analyzed the data of the 88 LT patients. Continuous variables were presented as mean ± SD; categorical variables were presented as number (%). The sensitivity, specificity, PPV and NPV in HRS diagnosis were calculated. A receiver operating characteristic (ROC) curve was constructed to assess the diagnostic accuracy of FeNa < 1% in diagnosing HRS.

## RESULTS

Table 1 summarizes the baseline characteristics of the 88 liver transplantation patients. The mean ± SD age of the cohort was 60 ± 7 years and the majority were of male gender (65%). Seventy two percent of the patients were using at least one diuretic at time of FeNa calculation. Out of the 88 LT candidates, 77 (87%) had

FeNa < 1%. As demonstrated in Table 1, FeNa < 1% was present in 10/10, 10/12, 11/13, 12/15 and 34/38 in patients with HRS, ATN, MPGN, minimal histological changes (10%-30% fibrosis) and advanced (≥ 30%) IF and/or glomerulosclerosis (GS), respectively ( $P = 0.4$ ).

### Primary outcome measure

FeNa < 1% was 100% sensitive and 14% specific in diagnosing HRS. Calculated PPV and NPV for FeNa < 1% in the setting of HRS were 46% and 100%, respectively. Figure 1 represents the result of the ROC curve assessing the performance of FeNa < 1% in HRS diagnosis. As demonstrated in Figure 1, FeNa < 1% showed poor accuracy in diagnosing HRS with an area under the curve (AUC) of 0.58,  $P = 0.47$ . To assess the effect of diuretic use on the performance of FeNa < 1% in HRS diagnosis, we compared urinary sodium indices between patients on diuretics ( $n = 64$ ) and those not on diuretic ( $n = 24$ ) treatment. There was no observed difference in the 24-h urinary sodium excretion, FeNa (as a continuous variable) and number of patients with FeNa < 1% between those using and not using diuretics at time of FeNa calculation ( $P > 0.3$  for all). Also, the sensitivity (100%), specificity (12.5%), PPV (14%) and NPV (100%) of FeNa < 1% in diagnosing HRS did not differ when patients not using diuretics were excluded from the analysis.

### Secondary outcome measure

We then correlated FeNa as continuous variable with the kidney biopsy finding. Although FeNa was lowest in HRS patients it did not differentiate between HRS and other renal pathologies (Figure 2).

There was also no correlation between the degrees of the IF ( $r = 0.07$ ,  $P = 0.54$ ) or GS ( $r = 0.2$ ,  $P = 0.07$ ) and the 24-h urinary sodium excretion (Figures 3 and 4, respectively). This lack of correlation was not affected by diuretic use (data not shown).

## DISCUSSION

Our study indicates that the majority of ESLD patients with renal dysfunction of unknown etiology or duration have a low 24-h urinary sodium excretion and a FeNa < 1% irrespective of renal pathology on kidney biopsy. Using kidney biopsy findings as a gold standard, we were able to determine the accuracy of FeNa < 1% in diagnosing HRS. Our results defined the sensitivity, specificity, PPV and NPV of FeNa < 1% in HRS as 100%, 14%, 46% and 100%, respectively. These results suggest that a FeNa > 1% excludes HRS diagnosis but a FeNa < 1% is not useful in diagnosing HRS.

Previous studies confirm that cirrhotic patients without renal dysfunction have low urinary sodium excretion rates and increased renal tubular reabsorption due to the activation of various neuro-hormonal mechanism and subsequent increase in renal tubular sodium reabsorption<sup>[5,9]</sup>. In patient with renal dysfunction however, low urinary sodium excretion implies maintained tubular integrity and favors either prerenal azotemia or HRS

**Figure 1** Receiver operator characteristics curve showing the poor accuracy of fractional excretion of sodium < 1% in diagnosing hepatorenal syndrome with area under the curve of 0.58,  $P = 0.47-0.58$ . AUC: Area under the curve.

**Figure 2** Correlation between fractional excretion of sodium as a continuous variable and kidney biopsy diagnosis. Although FeNa was lowest in HRS patients, it did not differentiate between HRS and other renal pathologies ( $P = 0.41$ ). FeNa: Fractional excretion of sodium; HRS: Hepatorenal syndrome; ATN: Acute tubular necrosis; MPGN: Membranoproliferative glomerulonephritis; IF: Interstitial fibrosis; GS: Glomerulosclerosis.

diagnosis<sup>[5]</sup>. Results of this study challenge this understanding. Our findings indicated that urinary sodium excretion was similarly low in cirrhotic patients with renal dysfunction due to tubular injury (ATN), glomerular disease (MPGN), irreversible renal damage (advanced IF/GS) or normal renal histology (HRS). There was also no correlation between the degree of IF or GS and the 24-h urinary sodium excretion. These results indicate that a low urinary sodium excretion is present in the majority of cirrhotic patients with renal dysfunction and does not reflect an intact renal tubular integrity but rather reflects the avid renal sodium retention state in these patients irrespective of the cause of renal dysfunction. It is also important to mention that diuretic use did not affect urinary sodium indices or the performance of FeNa < 1% in HRS diagnosis which support the avid sodium retention state in these patients with advanced cirrhosis.

FeNa is more sensitive than urinary sodium concentration in detecting prerenal causes of renal dysfunction as the serum sodium level is factored into the equation.

**Figure 3** Scatter plot depicting the relationship between the percentage of interstitial fibrosis on kidney biopsy and 24-h urine sodium excretion. Correlation was overall poor ( $r = 0.07$ ,  $P = 0.54$ ).

**Figure 4** Scatter plot depicting the relationship between the percentage of glomerulosclerosis on kidney biopsy result and 24-h urine sodium excretion ( $r = 0.2$ ,  $P = 0.07$ ). Correlation was better than the one observed with percentage of interstitial fibrosis but still did not reach statistical significance.

Previously published reports, however, indicated that although FeNa was lowest in patients with HRS, FeNa did not differentiate HRS and other causes of renal dysfunction including ATN<sup>[6,10]</sup>. These studies did not include kidney biopsy evidence of HRS (normal renal histology) and the diagnosis of HRS was made solely on clinical grounds<sup>[10,11]</sup>.

The main strength of the current study is that we used kidney biopsy findings to diagnose HRS, ATN and other renal pathologies. By using histological data, we were able to confirm that FeNa < 1% is present in almost 90% of cirrhotic patients with renal dysfunction. Although FeNa was lowest in HRS and FeNa < 1% was present in 100% of patients with HRS, FeNa did not differentiate between HRS and other causes of acute or chronic renal dysfunction. Of note a previous prospective study demonstrated that FeNa < 1% was present in only 0% to 4% of patients with ATN and no history of liver disease<sup>[12]</sup>. In contrast, in the current study 10 of 12 patients (83%) with biopsy evidence of ATN had a FeNa < 1%. Previous studies also demonstrated that FeNa < 1% had a sensitivity and specificity of 58%-78% and 75%-81% in diagnosing prerenal azotemia, respectively, in subjects without liver disease and varied according to diuretic use<sup>[13]</sup>. The results of the current study indicate

that the sensitivity and specificity of FeNa < 1% in the diagnosis of HRS is much different than in non-cirrhotic patients with prerenal azotemia and that they are not affected by diuretic use. This difference is likely due to the intense renal vasoconstriction manifesting in cirrhotic patients with subsequent increase in renal sodium reabsorption and the diuretic resistant state these patients develop with worsening liver disease.

The performance of FeNa < 1% in diagnosing HRS was overall poor but the test had high sensitivity and high NPV (both 100%), indicating that in patients with negative test results (*i.e.*, FeNa > 1%) HRS diagnosis should be excluded.

The current study is limited by the small number of patients particularly those with normal biopsy findings and HRS diagnosis which could have affected the results. Another important limitation of the study is the lack of detailed information on dietary sodium intake and doses and class of the diuretic medications used. We also measured FeNa at a single time point prior to the kidney biopsy to minimize the selection bias. Future studies should address if serial measurements of FeNa in a given patient will confer similar results.

In conclusion, the current study indicates that FeNa < 1% is common finding in patients with ESLD and renal dysfunction and has a poor accuracy in diagnosing HRS. Our results also indicate that HRS diagnosis should be avoided in patients with FeNa > 1%. Further studies with large number of patients are needed to confirm the findings of this study.

## COMMENTS

### Background

Kidney dysfunction is common in patients with end-stage liver disease (ESLD). It is estimated that nearly 20% to 25% of patients with ESLD will have some type of kidney dysfunction during their course of disease.

### Research frontiers

Classic teaching has utilized fractional excretion of sodium (FeNa) cut-off of < 1% or > 1% to differentiate between prerenal [including hepatorenal syndrome (HRS)] and intrinsic renal dysfunctions especially those caused by acute tubular necrosis. While this FeNa cut-off has been a useful discriminatory tool in cirrhotic patients presenting with elevated serum creatinine, its accuracy has not been tested in diagnosing HRS against a gold standard such as kidney biopsy.

### Innovations and breakthroughs

The authors program utilizes kidney biopsy in evaluating selected liver transplant candidates with renal dysfunction.

### Applications

The authors measured FeNa at a single time point prior to the kidney biopsy to

minimize the selection bias. Future studies should address if serial measurements of FeNa in a given patient will confer similar results.

### Peer-review

In patients with end stage cirrhosis and renal dysfunction (glomerular filtration rate < 40) the estimated FeNa < 1 could not discriminate between HRS and intrarenal kidney injury. The findings are quite relevant, since FeNa is used most often to exclude intrarenal disease in cirrhotic patients.

### Abstract

#### AIM

To evaluate the outcome of patients with bilobar colorectal liver metastases (CRLM) and identify clinicopathological variables that influenced survival.

#### METHODS

Patients with bilobar CRLM were identified from a prospectively maintained hepatobiliary database during the study period (January 2010-June 2014). Collated data included demographics, primary tumour treatment, surgical data, histopathology analysis and clinical outcome. Down-staging therapy included Oxaliplatin- or Irinotecan- based regimens, and Cetuximab was also used in patients that were *K-RAS* wild-type. Response

to neo-adjuvant therapy was assessed at the multi-disciplinary team meeting and considered for surgery if all macroscopic CRLM were resectable with a clear margin while preserving sufficient liver parenchyma.

## RESULTS

Of the 136 patients included, thirty-two (23.5%) patients were considered inoperable and referred for palliative chemotherapy, and thirty-four (25%) patients underwent liver resection. Seventy (51.4%) patients underwent down-staging therapy, of which 37 (52.8%) patients responded sufficiently to undergo liver resection. Patients that failed to respond to down-staging therapy ( $n = 33$ , 47.1%) were referred for palliative therapy. There was a significant difference in overall survival between the three groups (surgery *vs* down-staging therapy *vs* inoperable disease,  $P < 0.001$ ). All patients that underwent hepatic resection, including patients that had down-staging therapy, had a significantly better overall survival compared to patients that were inoperable ( $P < 0.001$ ). On univariate analysis, only resection margin significantly influenced disease-free survival ( $P = 0.017$ ). On multi-variate analysis, R0 resection ( $P = 0.030$ ) and female ( $P = 0.036$ ) gender significantly influenced overall survival.

## CONCLUSION

Patients undergoing liver resection with bilobar CRLM have a significantly better survival outcome. R0 resection is associated with improved disease-free and overall survival in this patient group.

**Key words:** Colorectal liver metastases; Chemotherapy; Liver resection

**Core tip:** The management of colorectal liver metastases (CRLM) has evolved over the last decade. More patients are being subjected to potentially curative liver resection following down-staging therapy and the introduction of specialist multi-disciplinary team meetings. The introduction of biological agents has also increased resection rates. The current study analysed patients with bilobar CRLM referred to our centre. Patients that underwent liver resection had a significantly better survival outcome following our multi-disciplinary approach.

Resection margin influences the outcome of patients with bilobar colorectal liver metastases. *World J Hepatol* 2016; 8(34): 1502-1510 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i34/1502.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i34.1502>

## INTRODUCTION

Hepatic resection is the only potentially curative treat-

ment for patients with colorectal liver metastases (CRLM) and the 5-year survival rate is up to 50%<sup>[1,2]</sup>. Patients with extensive, bilateral disease present a surgical challenge in removing all macroscopic disease while preserving sufficient functional liver remnant. Studies have shown that 20%-30% of all patients with CRLM are resectable at the time of diagnosis<sup>[3]</sup>, with bilobar distribution of metastases a major contributing factor for unresectability<sup>[4]</sup>.

More recently, the introduction of biological agents and the improved efficacy of down-staging chemotherapy regimens to treat bilobar CRLM have increased the proportion of patients with initially unresectable disease to subsequently operable disease. In addition, neo-adjuvant chemotherapy can potentially treat systemic disease to lower the risk of distant spread, and allow the identification of patients with biologically aggressive tumours that progress on chemotherapy that would not benefit from liver surgery<sup>[5]</sup>. Down-staging chemotherapy regimens are more toxic than palliative regimens, and hence, it is essential that there is multi-disciplinary team approach in determining the management plan for these patients<sup>[6]</sup>. However, long term outcomes for these patients following down-staging therapy and liver resection are indeterminate.

The aim of this study was to evaluate the outcomes of patients with bilobar CRLM following multi-disciplinary therapy. The secondary aim was to identify clinicopathological variables that influenced disease-free and overall survival in this group of patients.

## MATERIALS AND METHODS

### Patients

Patients with bilobar CRLM were identified from a prospectively maintained hepatobiliary database at Queen's Medical Centre (QMC), Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom during a 4-year period from January 2010 to June 2014. QMC is a tertiary referral center for Nottinghamshire and surrounding regions located in the north of East Midlands, United Kingdom. Pre-operative radiological assessment included a computed tomography (CT) scan of the thorax, abdomen and pelvis and magnetic resonance imaging (MRI) of the liver. Patients with indeterminate lesions, in particular lung nodules, and patients with synchronous presentation underwent a positron emission tomography scan. Synchronous presentation was defined as the presence of liver metastases when colorectal cancer was diagnosed. Prior to any treatment, all patients including patients referred from the surrounding regions were discussed in a specialist multidisciplinary team (MDT) meeting consisting of hepatobiliary surgeons, hepatologists, oncologists, radiologists and pathologists. Patients were selected for liver resection without any prior neo-adjuvant therapy if all macroscopic CRLM were resectable to achieve a clear margin while preserving sufficient liver parenchyma.

Collated data included patient demographics, type of surgical resection, histopathology analysis and clinical

outcome. This study has been registered and approved by the Clinical Audit Department, Nottingham University Hospitals NHS Trust. Since this is a retrospective study, individual patient consent was not required, and all local ethical guidelines with respect to retrospective studies in this Trust were adhered to.

### **Down-staged therapy and adjuvant chemotherapy**

Patients scheduled for preoperative systemic chemotherapy had 3-6 mo of neo-adjuvant treatment. The regimens used were either Oxaliplatin based: Two weekly FOLFOX [5-fluorouracil (FU) 400 mg/m<sup>2</sup> bolus, and 2400 mg/m<sup>2</sup> over 46 h, Leucovorin and Oxaliplatin 85 mg/m<sup>2</sup>] or three weekly CAPOX (Capecitabine 1000 mg/m<sup>2</sup> BD for 14 d and Oxaliplatin 130 mg/m<sup>2</sup>).

However, in patients tested and found to be *K-RAS* wild-type, two weekly FOLFIRI (Irinotecan 180mg/m<sup>2</sup>, 5-FU 400 mg/m<sup>2</sup> bolus, and 2400 mg/m<sup>2</sup> over 46 h) was administered with concurrent Cetuximab (400 mg/m<sup>2</sup> cycle 1, then 250 mg/m<sup>2</sup> cycle 2 onwards).

The response to neo-adjuvant therapy was assessed after 3-6 mo of therapy by CT scan and repeat MRI of the liver if required. Patients were then re-discussed at the MDT and considered for surgery based on absence of new disease, tumour response and extent of disease. Patients deemed to have resectable disease were scheduled for a liver resection, 4-6 wk after their last cycle of chemotherapy. Resectable disease was defined as excision of all macroscopic CRLM to achieve a clear margin while preserving sufficient liver parenchyma based on pre-operative radiological imaging.

Following liver resection, chemotherapy was considered in patients with tumour present at the margin (R1 resection).

### **Surgery**

Liver resection was performed using the Cavi-Pulse Ultrasonic Surgical Aspirator. Intra-operative ultrasound was performed to confirm the findings of pre-operative imaging and to assist in surgical planning. The number of hepatic Couinaud's<sup>[7]</sup> segments resected was determined by the procedure performed as stated in the Brisbane nomenclature<sup>[8]</sup>. Type of surgical procedure was dependent on the resection of all macroscopic disease and achieving a clear resection margin, while preserving sufficient remnant liver. The extent of hepatic resection in this study was classified into two groups; less than hemihepatectomy and hemihepatectomy or more radical resection. Pre-operative PVE was performed if the FRL volume was estimated to be 20% or less of the total liver volume. Liver-first approach was defined when the hepatic resection was performed first prior to colonic or rectal resection<sup>[9,10]</sup>.

In patients where the liver-first approach was adopted, primary tumour resection was usually scheduled 4-8 wk following liver resection, or after completion of chemoradiotherapy for patients with locally advanced rectal cancer. All patients underwent re-staging with a CT scan and MRI to ensure there was no evidence of liver

recurrence or distant metastases. Colorectal resection was performed according to accepted oncological standards, with complete meso-rectal excision for rectal cancers and lymph node dissection for colonic cancers.

### **Histology**

Histopathological data of the resected liver specimen were collated. This included: Tumour size in maximum diameter; tumour number; and status of resection margin. R0 resection was defined as no microscopic evidence of tumour at or within 1 mm of the margin. Lymphatic, peri-neural, biliary and vascular invasion were also determined<sup>[11]</sup>.

### **Follow-up**

Patients were followed up in specialist hepatobiliary clinics. Following initial post-operative review at one month, all patients were examined in the outpatient clinic at 3, 6, 12, 18 and 24 mo and annually thereafter. At each clinical review, carcino-embryonic antigen levels were measured. All patients in this study had a minimum follow-up of 6 mo following hepatic resection for CRLM.

Surveillance imaging included CT scan of the thorax, abdomen and pelvis. Patients underwent 6-monthly CT scan during the first two post-operative years, followed by annual CT scans thereafter. Liver MRI was used to characterise suspicious hepatic lesions demonstrated on CT. Development of symptoms of recurrence at any time-point prompted earlier review than scheduled.

Overall and disease-free survival was recorded, with disease-free survival being defined as the time from primary hepatic resection to the first documented disease recurrence on imaging. Overall survival was defined as the time interval between the date of commencement of neo-adjuvant/induction therapy and the date of death or most recent date of follow-up if the patient was still alive. Following detection of recurrent disease on surveillance imaging, all patients were discussed at the MDT meeting. Patients who had non-resectable disease were referred to the oncologists for consideration of palliative chemotherapy.

### **Statistical analysis**

Categorical data was presented as frequency and percentage. The Kaplan-Meier method was used to assess the actuarial survival and disease-free survival, and presented as median (range). Univariate analysis was performed to assess for a significant difference in clinico-pathological characteristics that influenced disease recurrence and survival. A multivariate analysis was performed by Cox regression (Step-wise forward model) for variables significant on univariate analysis. Statistical analyses were performed using the SPSS for Windows™ version 16.0 (SPSS Inc, Chicago, Ill, United States), and statistical significance was taken at the 5% level. The statistical methods of this study were reviewed and performed by Gomez D, QMC, Nottingham, United Kingdom.

**Table 1 Clinical data of patients with bilobar colorectal liver metastases in this study**

Demographic, clinical and pathological factors	Total (n)
<b>All patients (n = 136)</b>	
<b>All surgery patients (n = 71)</b>	
Demographic factors	
Age > 65 yr	68
Male gender	99

Vascular invasion present	28
Peri-neural invasion present	9
Biliary invasion present	25
Resection margin (R0)	40

## RESULTS

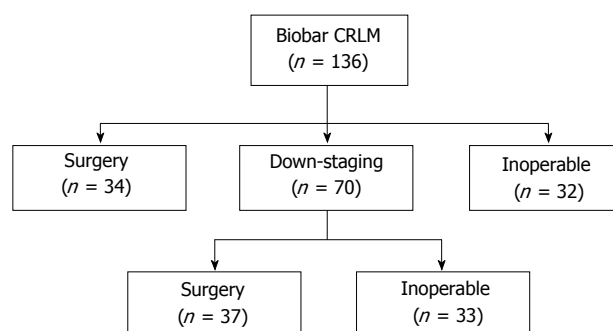

### Patients

During the study period, a total of 136 patients (Table 1) with bilobar CRLM were discussed in the unit's MDT, of which 34 (25.0%) patients underwent surgery with curative intent as their primary treatment (Figure 1). There were 32 (23.5%) patients that had extensive disease and were referred for palliative therapy.

Seventy (51.4%) patients were considered for down-staging therapy, in view to consider liver resection depending on response to therapy. Besides receiving either an Oxaliplatin-based ( $n = 60$ ) or Irinotecan-based ( $n = 10$ ) regimen, 30 (42.8%) patients also had biological agents as part of their down-staging treatment. Within the group of patients that received down-staging therapy, 37 (52.8%) patients had a response to their down-staging therapy and underwent hepatic resection, while the remaining patients [ $n = 33$  (47.2%)] did not undergo surgical resection. These patients did not respond to their down-staging therapy, which included: (1) having new metastases; (2) disease progression; and (3) inability to remove all macroscopic liver disease whilst leaving sufficient remnant liver. This decision was based on MDT review of up to date radiological imaging following down-staging therapy.

### Liver resection

Overall, there were 71 (52.2%) patients that underwent liver resection, of which twenty-two patients had a hemi-hepatectomy or more. The most common surgical procedures performed was multiple non-anatomical resections ( $n = 40$ , 56.3%). Twenty-one patients were female and the median age at the diagnosis was 65 (range: 44-84) years. Seven (9.8%) patients had portal vein embolization prior to liver resection. There were 35

**Figure 1 Outcome of patients with bilobar colorectal liver metastases in this study.** CRLM: Colorectal liver metastases.

patients with synchronous disease, of which 17 patients had a liver-first approach. There was no post-operative mortality.

### Survival outcome

The median overall survival for all patients in this study was 18 (1-48) mo (Figure 2). There was a significant difference in overall survival between the three groups (Surgery vs Down-staging therapy vs Inoperable disease,  $P < 0.001$ ; Figure 3). All patients that underwent hepatic resection, including patients that had down-staging therapy, had a significantly better overall survival compared to patients that were inoperable [24 (6-48) mo vs 17 (1-43) mo;  $P < 0.001$ ; Figure 4]. The disease-free survival for patients that underwent liver resection was 8 (range: 2-36) mo.

### Prognostic factors influencing disease-free and overall survival

With respect to disease-free survival, patients with a clear (R0) resection margin following liver resection had a significantly better disease-free survival compared to patients with a R1 resection ( $P = 0.017$ ; Table 2 and Figure 5).

Patients with a R0 resection ( $P = 0.022$ ; Figure 6) and female gender ( $P = 0.024$ ; Figure 7) has a significantly better overall survival compared to patients with a R1 resection and male gender on univariate analysis. On the multi-variate analysis, both R0 resection and female gender were independent predictors of improved overall survival (Table 3).

## DISCUSSION

With the improvement in chemotherapy agents and the increased efficacy with the addition of biological agents, many centers have reported an increased number of patients being converted from initially unresectable, to resectable disease<sup>[12,13]</sup>. However, although there are an increased number of patients undergoing liver resection with curative intent, some authorities may suggest that these patients are unlikely to be cured<sup>[14]</sup>. Nevertheless, these patients have a better overall survival in comparison to patients treated with palliative systemic

chemotherapy, with some authors reporting a median survival up to 45 mo<sup>[12,15]</sup>. In the present study, patients with bilobar disease who underwent surgery had a significantly better overall survival compared to patients who failed down-staged chemotherapy and/or treated with palliative chemotherapy.

### Conversion rate

The addition of biological agents to current Oxaliplatin- and Irinotecan- based regimens has led to further improvements in response rates. In a large randomised control trial, Folprecht *et al.*<sup>[16]</sup> showed an increased response rate up to 68% with the addition of Cetuximab. Similarly, Masi *et al.*<sup>[17]</sup> observed that the addition of Bevacizumab to Oxaliplatin- and Irinotecan- based regimens increased the response rate up to 80%. In the present study, the unit's down-staging therapy protocol had a response rate and a conversion of unresectable to resectable disease of more than 50%. These results were consistent with data reported by the groups of Van Cutsem *et al.*<sup>[18]</sup> and Bokemeyer *et al.*<sup>[19]</sup> that observed a conversion rate of approximately 60% following down-staging chemotherapy.

### Survival data

Adam *et al.*<sup>[13]</sup> recently published their long-term survival results following down-sizing chemotherapy and hepatic resection in patients with CRLM and demonstrated that 24 (16%) of 148 patients were alive and disease-free with a minimum of 5-year follow-up. Several studies have shown the improvements in survival after the addition of anti-VEGF/EGFR<sup>[20-22]</sup>. Recently, a number of case series describing 10-year actual survivors after liver resection of CRLM have been published<sup>[23,24]</sup>. The present series demonstrated that hepatic resection for patients with bilobar CRLM had a median disease-free and overall survival of 8 and 24 mo, respectively.

### MDT approach

Definitions of resectable disease have evolved over time, with current consensus suggesting that disease should be considered technically resectable as long as complete macroscopic resection is feasible, whilst maintaining

Numbers at risk

**Figure 3** Difference in overall survival in patients that underwent surgery, down-staging therapy followed by surgery or palliative therapy and inoperable patients.

sufficient future liver volume<sup>[25]</sup>. However, there remains concern that not all patients with technically resectable liver-limited metastases benefit from surgery; with approximately half of these patients will develop recurrences within three years of liver resection<sup>[26]</sup>. Therefore, it is crucial that the decision-making process around treatment strategies for metastatic colorectal cancer are made in a MDT environment that consists of specialist hepato-biliary surgeons, radiologists and oncologists that can define optimal patient management on a case by case basis. A recent study demonstrated that almost two-thirds of patients with tumours deemed unresectable by non-specialists were considered potentially resectable

Surgery (*n* = 71): 24 (6-48) mo

by a panel of specialist hepato-biliary surgeons based on radiological imaging<sup>[27]</sup>.

### Prognostic factors

The role of margin status as a predictor of outcome following resection for CRLM is controversial. Bodingbauer *et al.*<sup>[28]</sup> observed that resection margin and size of margin width did not correlate significantly with survival following resection for CRLM. In a series of 1019 patients, and co-investigators demonstrated that a resection margin > 1 cm was an independent predictor of survival following resection for CRLM<sup>[29]</sup>. Rees *et al.*<sup>[1]</sup> also demonstrated that positive resection margins were an independent predictor of poorer survival. However,

Numbers at risk				
Patients	0	12	36	48
R0 resection (n = 40)	40	34	12	4
R1 resection (n = 31)	31	21	6	2

**Figure 6** Difference in overall survival in patients with R0 resection compared to patients with R1 resection.

Figueras *et al.*<sup>[30]</sup> showed that a margin width < 1 cm in patients who underwent resection for CRLM did not significantly influence recurrent disease in a cohort of 609 patients. Homayounfar *et al.*<sup>[31]</sup> demonstrated that R0 resection in patients with bilobar CRLM have improved survival rates following multi-modal therapy<sup>[32]</sup>. In the present series, a clear resection margin, defined as no microscopic evidence of tumour at or within 1 mm of the margin, was an independent predictor of both disease-free and overall survival. Due to the differences in results observed with respect to resection margin between published studies, it may be that only a selected group of patients undergoing resection for CRLM are influenced by a clear margin. In the present series that focused on patients with bilobar CRLM, that would be considered as having a high tumour burden, benefited from a R0 margin. This could be due to the fact that these patients have an aggressive tumour profile and it is crucial that complete tumour clearance is obtained. Hence, for these patients, “down-sizing” chemotherapy should certainly be considered prior to resection to aid in achieving a clear resection margin. Furthermore, many groups advocate a trial of neo-adjuvant chemotherapy in patients with a high tumour burden, as disease progression on chemotherapy would be a contraindication to surgery<sup>[33]</sup>. Nevertheless, with the increase use of chemotherapy, there is an increase in prevalence of patients undergoing hepatic resection with a background of chemotherapy-related injury, such as steato-hepatitis<sup>[34]</sup> and sinusoidal obstruction syndrome<sup>[35]</sup>. In such cases, the quality, rather than quantity of the remnant liver becomes an important issue to consider prior to extensive resection.

The present study also showed that female gender was an independent prognostic factor for improved overall survival. There are currently no other studies that have reported this finding.

There are limitations in this study. This is a retrospective study, and focused on a group of patients with bilobar liver metastases. These are patients with bad

Numbers at risk				
Patients	0	12	36	48
Male (n = 50)	50	36	11	4
Female (n = 21)	21	20	9	2

**Figure 7** Difference in overall survival in female patients compared to male patients following surgery for colorectal liver metastases.

tumour biology and in most cases, will require down-staging therapy. Nevertheless, although these group of patients have a higher tumour burden; their prognosis can be improved with a MDT approach that focuses on multi-modal therapy.

Patients with bilobar CRLM treated with liver resection as a primary treatment or following down-staging therapy have a better overall survival compared to patients who failed down-staging therapy and/or treated with palliative chemotherapy. Obtaining a clear resection margin in these cases significantly influences outcome. In this group of patients, multi-modal therapy is crucial to achieve a better survival outcome.

## COMMENTS

### Background

Hepatic resection is the only potentially curative treatment for patients with colorectal liver metastases (CRLM) and the 5-year survival rate is up to 50%.

### Research frontiers

The introduction of biological agents and the improved efficacy of down-staging chemotherapy regimens to treat bilobar CRLM have increased the proportion of patients with initially unresectable disease to subsequently operable disease. In addition, neo-adjuvant chemotherapy can potentially treat systemic disease to lower the risk of distant spread, and allow the identification of patients with biologically aggressive tumours that progress on chemotherapy that would not benefit from liver surgery.

### Innovations and breakthroughs

In the present study, patients with bilobar disease who underwent surgery had a significantly better overall survival compared to patients who failed down-staged chemotherapy and/or treated with palliative chemotherapy.

### Applications

Patients with bilobar CRLM treated with liver resection as a primary treatment or following down-staging therapy have a better overall survival compared to patients who failed down-staging therapy and/or treated with palliative chemotherapy.

### Peer-review

This article is interesting but I think epidemiological data are more interesting

than univariate and multivariate analysis, which is the part highlighted by the authors. Structure of the manuscript is correct.

### Abstract

#### AIM

To investigate potential predictors for treatment response to nucleos(t)ide analogues (NAs) in hepatitis B e antigen (HBeAg)-positive chronic hepatitis B (CHB) patients.

#### METHODS

Seventy-six HBeAg-positive CHB patients received 96-wk

NAs optimized therapy (lamivudine and adefovir dipivoxil) were studied retrospectively. Serum hepatitis B surface antigen, HBeAg, hepatitis B core antibody, hepatitis B virus (HBV) DNA and alanine aminotransferase levels were quantitatively measured before and during the treatment at 12 and 24 wk. Stepwise logistic regression analyses were performed to identify predictors for treatment response, and areas under the receiver operating characteristic curves (AUROC) of the independent predictors were calculated.

## RESULTS

Forty-three CHB patients (56.6%) achieved virological response (VR: HBV DNA  $\leq$  300 copies/mL) and 15 patients (19.7%) developed HBeAg seroconversion (SC) after the 96-wk NAs treatment. The HBeAg level (OR = 0.45,  $P$  = 0.003) as well as its declined value (OR = 2.03,  $P$  = 0.024) at 24-wk independently predicted VR, with the AUROC of 0.788 and 0.736, respectively. The combination of HBeAg titer < 1.3 lg PEIU/mL and its decreased value > 1.6 lg PEIU/mL at 24-wk predicted VR with a sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) of 85%, 100%, 100% and 83%, respectively, and the AUROC increased to 0.923. The HBeAg level (OR = 0.37,  $P$  = 0.013) as well as its declined value (OR = 2.02,  $P$  = 0.012) at 24-wk also independently predicted HBeAg SC, with the AUROC of 0.828 and 0.814, respectively. The HBeAg titer < -0.5 lg PEIU/mL combined with its declined value > 2.2 lg PEIU/mL at 24-wk predicted HBeAg SC with a sensitivity, specificity, PPV, NPV of 88%, 98%, 88% and 98%, respectively, and the AUROC reached 0.928.

## CONCLUSION

The combination of HBeAg level and its declined value at 24-wk may be used as a reference parameter to optimize NAs therapy.

**Key words:** Response predictor; Quantitative detection; Hepatitis B e antigen; Hepatitis B virus DNA; Chronic hepatitis B; Nucleos(t)ide analogues

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Few studies have systematically evaluated quantitative hepatitis B surface antigen, hepatitis B e antigen (HBeAg), hepatitis B core antibody, hepatitis B virus DNA and alanine aminotransferase for predicting treatment response to nucleos(t)ide analogues (NAs) in HBeAg-positive chronic hepatitis B (CHB). In this study, on-treatment HBeAg level as well as its declined value at 24-wk were identified to be the best predictors not only for 96-wk virological response (VR) but also for HBeAg seroconversion (SC). The combination of HBeAg level and its decline at 24-wk strongly predicted 96-wk VR and HBeAg SC with the AUROC of 0.923 and 0.928, respectively. Thus monitoring an early on-treatment HBeAg level and its decline may help to optimize NAs therapy for CHB patients.

## INTRODUCTION

Hepatitis B virus (HBV) infection is a global public health problem and an estimated 240 million persons are chronically infected worldwide, among which 20%-30% will develop cirrhosis and hepatocellular carcinoma (HCC)-the major complications of chronic hepatitis B (CHB)<sup>[1]</sup>. Antiviral treatment has been proved to be an effective and potent way to reverse the process of liver fibrosis or cirrhosis and decrease the incidence rate of liver complications<sup>[2]</sup>. However, due to the persistence of HBV covalently closed circular DNA (cccDNA) in the nucleus of infected hepatocytes, HBV cannot be completely eradicated by current antiviral drugs, and a long-term treatment are necessary for most patients. It is now clear that sustained viral suppression and hepatitis B e antigen (HBeAg) seroconversion (SC) are two important markers of treatment response for CHB patients receiving antiviral therapy, which is usually associated with a good long-term outcome<sup>[3]</sup>. Generally, after a 1-year course of the current available nucleos(t)ide analogues (NAs) or peginterferon (Peg-IFN) therapy, 7%-76% of patients achieved undetectable serum HBV DNA and 16%-32% developed HBeAg SC for patients with HBeAg-positive CHB<sup>[3]</sup>. Therefore, it is crucial to identify pre-treatment and early on-treatment biomarkers that can effectively predict long-term treatment response and use these biomarkers to choose appropriate antiviral drugs and treatment regimens to optimize therapy and improve efficacy.

Serum HBV DNA is the most widely used virological marker in the management of CHB patients<sup>[2,3]</sup>. A study from Zeuzem *et al*<sup>[4]</sup> reported that both baseline ALT  $\geq$  2  $\times$  upper limit of normal (ULN) (OR = 2.47,  $P$  = 0.0012) and non-detectable serum HBV DNA at treatment week 24 (OR = 2.61,  $P$  < 0.001) were associated with HBeAg SC after 2-year telbivudine (LdT) treatment, and among patients with non-detectable serum HBV DNA at 24-wk as well as favorable pretreatment characteristics [alanine aminotransferase (ALT)  $\geq$  2  $\times$  ULN and HBV DNA < 9 lg copies/mL], 52% obtained HBeAg SC at 2-year of therapy<sup>[4]</sup>. However, the detection of serum HBV DNA is costly and may not always objectively serve as a reliable indicator of sustained response to antiviral therapy<sup>[5]</sup>. Unlike HBV DNA, serum hepatitis B surface antigen (HBsAg), HBeAg and hepatitis B core antibody (anti-HBc) are classical serological markers for HBV infection and are used in clinical diagnosis routinely. The level of HBsAg was identified as an outcome predictor for Peg-IFN therapy among HBeAg-positive CHB patients<sup>[6]</sup>; however,

its predictive value in NAs treatment was inconsistent based on the reported data<sup>[7,8]</sup>. Serum HBeAg level was proposed to be a better outcome predictor for NAs treatment according to recent studies<sup>[8-12]</sup>. However, most of studies applied the semi-quantitative measurement of HBeAg, and some had a limited sample size or a short period of follow-up. Thus the predictive value of the quantitative HBeAg level needs to be further evaluated. In addition, benefiting from a newly developed double-sandwich anti-HBc immunoassay, anti-HBc quantification was identified as a novel biomarker for predicting treatment response<sup>[13]</sup>. Nevertheless, very few studies have systematically evaluated the predictive power of these biomarkers for NAs treatment response.

In the current study, HBeAg-positive CHB patients received 96-wk NAs optimized therapy [lamivudine (LAM) and adefovir dipivoxil (ADV)] were retrospectively investigated. Serum HBsAg, HBeAg, anti-HBc, HBV DNA and ALT were quantitatively tested, and the baseline as well as early on-treatment levels of these parameters were analyzed using logistic regression model to assess their functions in predicting 96-wk virological response (VR) and HBeAg SC.

## MATERIALS AND METHODS

### Patients

We retrospectively analyzed a cohort of HBeAg-positive CHB patients who underwent the 96-wk LAM and ADV optimized therapy between 2011 and 2014 in China. The treatment was continued for CHB patients after week 96, and the data were not available from the patients after 96 wk. The inclusion criteria of patients enrolled for antiviral therapy were briefly summarized as follows: 18-65 years old, HBsAg positive for at least 6 mo, HBeAg positive and hepatitis B e antibody (anti-HBe) negative,  $10^5$  copies/mL  $\leq$  HBV DNA  $\leq$   $10^9$  copies/mL, ALT  $\geq$  2  $\times$  ULN, and no history of antiviral therapy with NAs or interferon within previous six months. The patients were treated with LAM 100 mg/d, and ADV (10 mg/d) was added on when serum HBV DNA > 300 copies/mL at week 24 or a virological breakthrough (> 1 lg increase of serum HBV DNA from nadir or re-detectable after achieving an undetected level) occurred during the 96-wk treatment. Laboratory measurements were done every 12 wk before week 24, and every 24 wk from week 24 to week 96. The main endpoints were VR (defined as HBV DNA  $\leq$  300 copies/mL) and HBeAg SC at 96-wk. A total of 76 patients completed the 96-wk follow-up and finally included in the analyses. The study was approved by the Institutional Review Board of Peking University Health Science Center and conducted in accordance with the ethical standards of the Helsinki Declaration. The informed consents were obtained from recruited patients.

### Laboratory measurements

HBV DNA was quantified by Roche COBAS TaqMan HBV test (Roche Diagnostics, Mannheim, Germany)

with a linear range of 20-10<sup>8</sup> IU/mL (1 IU/mL = 5.82 copies/mL). Serological HBV markers (HBsAg, anti-HBs, HBeAg, anti-HBe) were measured by Chemiluminescent Microparticle ImmunoAssay using ARCHITECT i2000SR analyzer (Abbott Diagnostics, North Chicago, IL, United States). HBeAg level was quantified by World Health Organization (WHO) HBeAg reference standard (Paul-Ehrlich-Institute, Germany) also using ARCHITECT i2000SR analyzer<sup>[14]</sup>. Anti-HBc quantification was conducted by using a newly developed double-sandwich immunoassay (Wantai, Beijing, China) validated by WHO anti-HBc standards<sup>[15]</sup>. Biochemical tests (ALT, AST) were detected by the department of laboratory in four hospitals.

### Statistical analysis

Categorical variables were compared using  $\chi^2$  or Fisher's exact tests. Continuous variables were compared using the Student's *t* test or Mann-Whitney test. Stepwise logistic regression analysis was performed to identify independent predictors for VR and HBeAg SC. The predictive value of the independent predictor was further evaluated using areas under the receiver operating characteristic curve (AUROC). The best cut-off value was determined in the condition of the highest Youden index (the sum of sensitivity and specificity minus 1). And the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were calculated at the specified cut-off value. All analysis was done using SPSS 19.0 (SPSS, Chicago, IL, United States). A *P* value < 0.05 was considered as statistically significant.

## RESULTS

### Baseline characteristics

After the 96-wk NAs treatment, 56.6% (43/76) CHB patients achieved VR and 19.7% (15/76) patients developed HBeAg SC. Only 1 patient eliminated HBsAg. The baseline parameters such as age, HBsAg, HBeAg, anti-HBc, HBV DNA and ALT were comparable between patients achieved HBeAg SC and those did not. Compared to patients without VR, those obtained VR had significantly higher baseline ALT level ( $247.95 \pm 150.58$  U/L vs  $169.13 \pm 156.56$  U/L, *P* = 0.029), while HBsAg, HBeAg, anti-HBc, HBV DNA levels were not significantly different between two groups (Table 1).

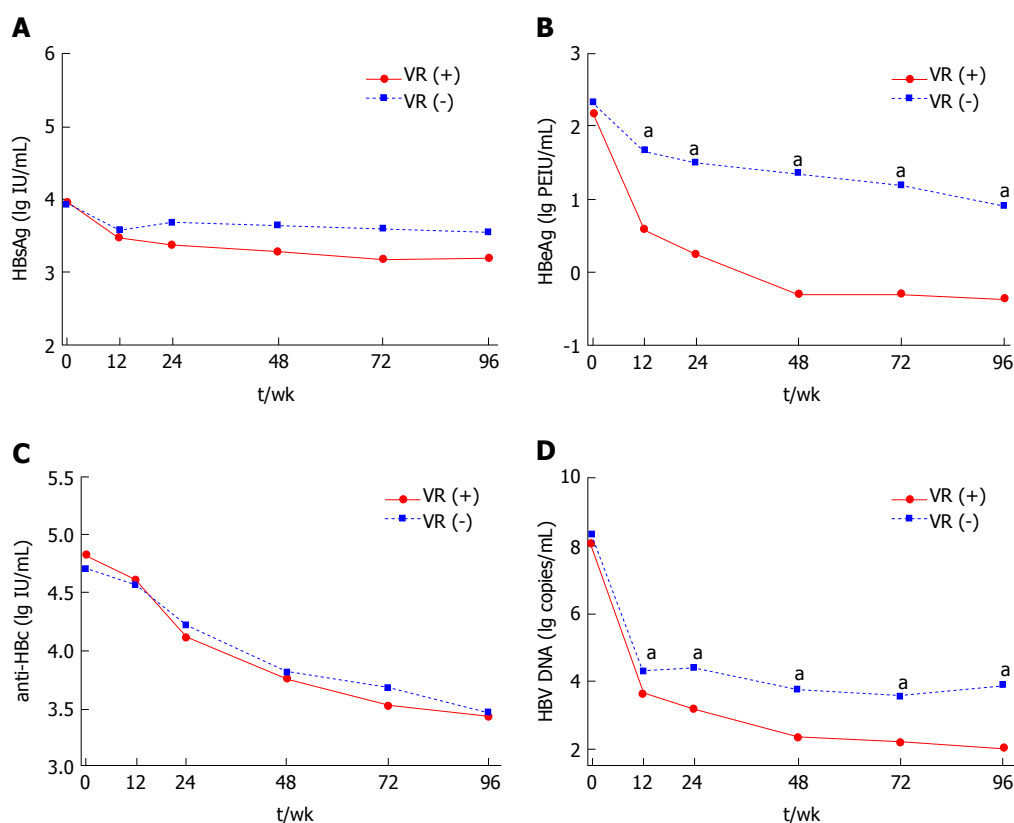

### Dynamic changes in serum levels of HBsAg, HBeAg, anti-HBc and HBV DNA during 96-wk treatment

Serum HBsAg, HBeAg, anti-HBc and HBV DNA levels were all significantly decreased from baseline to week 96 of therapy (HBsAg,  $3.95 \pm 0.83$  lg IU/mL to  $3.36 \pm 0.86$  lg IU/mL; HBeAg,  $2.24 \pm 1.31$  lg PEIU/mL to  $0.20 \pm 1.13$  lg PEIU/mL; anti-HBc,  $4.77 \pm 0.46$  lg IU/mL to  $3.45 \pm 0.65$  lg IU/mL; HBV DNA,  $8.16 \pm 1.34$  lg copies/mL to  $2.85 \pm 1.36$  lg copies/mL; all *P* < 0.001). Significant lower HBeAg and HBV DNA levels were found in patients with VR as compared with patients without VR at every

VR (+)/VR (-), with/without virological response at week 96 (virological response: HBV DNA ≤ 300 copies/mL); SC (+)/SC (-), with/without HBeAg seroconversion at week 96. HBsAg: Hepatitis B surface antigen; ALT: Alanine aminotransferase; HBV: Hepatitis B virus; VR: Virological response; SC: HBeAg seroconversion; ULN: Upper limit of normal.

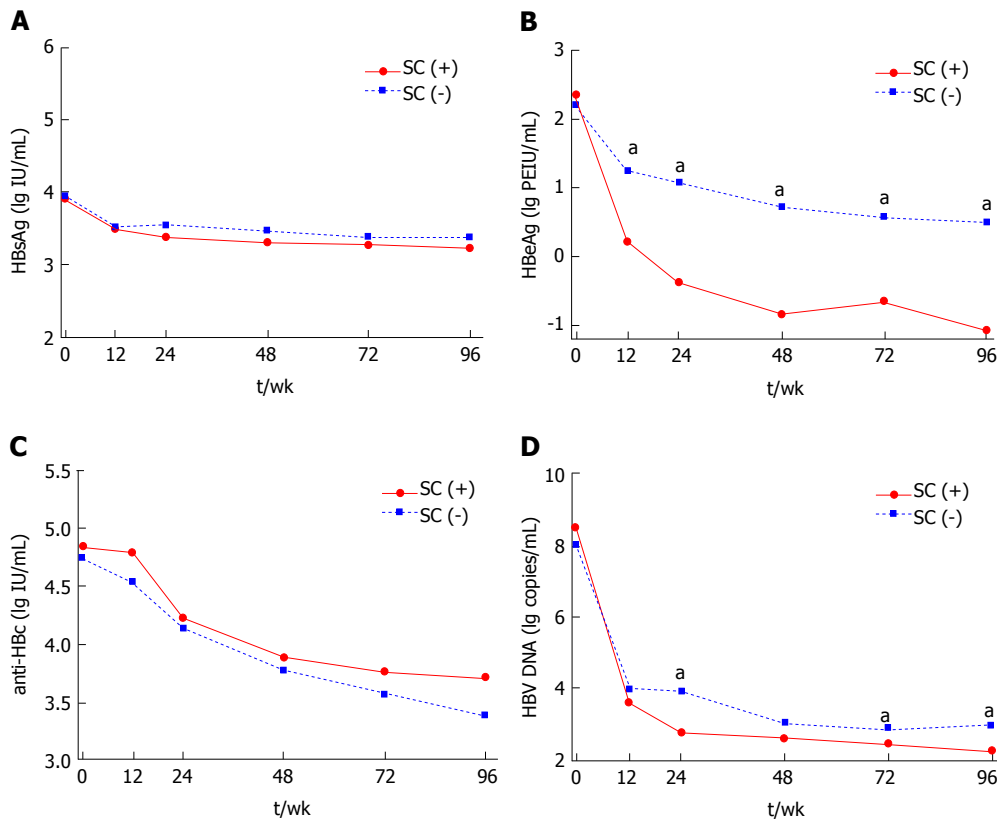

**Figure 1** Dynamic changes of hepatitis B surface antigen (A), hepatitis B e antigen (B), hepatitis B core antibody (C) and hepatitis B virus DNA (D) levels from baseline to 96-wk in chronic hepatitis B patients received nucleos(t)ide analogues therapy stratified by virological response at 96-wk. <sup>a</sup>*P* < 0.05; VR (+): Virological response, HBV DNA ≤ 300 copies/mL; VR (-): Without virological response; HBsAg: Hepatitis B surface antigen; HBeAg: Hepatitis B e antigen; anti-HBc: hepatitis B core antibody; HBV: Hepatitis B virus; VR: Virological response.

follow-up time-point except baseline (*P* < 0.05), while HBsAg and anti-HBc levels were comparable between two groups (Figure 1). Similarly, HBsAg and anti-HBc levels between patients with and without HBeAg SC were also comparable from baseline to week 96 (Figure 2A and C). However, HBeAg levels were significant lower in patients with HBeAg SC than in patients without HBeAg SC at every follow-up time-point except baseline (*P* < 0.05) (Figure 2B). And a significant difference in HBV DNA levels between patients with and without HBeAg SC

was only observed at week 24, 72 and 96 (*P* < 0.05), as shown in Figure 2D.

#### Baseline and on-treatment parameters associated with 96-wk virological response

At baseline, ALT and ALT ≥ 5 × ULN were associated with VR according to univariate analysis, and multivariate analysis indicated that sex (OR = 3.76, 95%CI: 1.09-13.01, *P* = 0.037) and ALT ≥ 5 × ULN (OR = 7.09, 95%CI: 2.32-21.67, *P* < 0.001) independently predicted VR, re-

**Figure 2** Dynamic changes of hepatitis B surface antigen (A), hepatitis B e antigen (B), hepatitis B core antibody (C) and hepatitis B virus DNA (D) levels from baseline to 96-wk in chronic hepatitis B patients received nucleos(t)ide analogues therapy stratified by hepatitis B e antigen seroconversion at 96-wk. <sup>a</sup> $P < 0.05$ ; SC (+): HBeAg seroconversion; SC (-): Without HBeAg seroconversion; HBsAg: Hepatitis B surface antigen; HBeAg: Hepatitis B e antigen; anti-HBc: hepatitis B core antibody; HBV: Hepatitis B virus; SC: HBeAg seroconversion.

spectively. At week 12, univariate analysis revealed that HBeAg, HBeAg decline, ALT decline, and HBV DNA were associated with VR, and multivariate analysis identified that HBeAg (OR = 0.62, 95%CI: 0.40-0.95,  $P = 0.03$ ) and HBeAg decline (OR = 2.58, 95%CI: 1.25-5.33,  $P = 0.01$ ) independently predicted VR, respectively. At week 24, HBeAg, HBeAg decline, ALT decline, HBV DNA and HBV DNA decline were associated with VR *via* univariate analysis, and multivariate analysis found that HBeAg (OR = 0.45, 95%CI: 0.27-0.77,  $P = 0.003$ ) and HBeAg decline (OR = 2.03, 95%CI: 1.10-3.74,  $P = 0.024$ ) independently predicted VR, respectively (Table 2).

#### Baseline and on-treatment parameters associated with 96-wk HBeAg seroconversion

At week 12, HBeAg, HBeAg decline, and HBV DNA decline were associated with HBeAg SC through univariate analysis, and HBeAg decline (OR = 2.47, 95%CI: 1.46-4.16,  $P = 0.001$ ) independently predicted HBeAg SC *via* multivariate analysis. At week 24, univariate analysis presented that HBeAg, HBeAg decline, HBV DNA and HBV DNA decline were associated with HBeAg SC, and multivariate analysis identified that HBeAg (OR = 0.37, 95%CI: 0.17-0.81,  $P = 0.013$ ) and HBeAg decline (OR = 2.02, 95%CI: 1.17-3.49,  $P = 0.012$ ) independently predicted HBeAg SC, respectively (Table 2).

Based on the results of above analysis, both of the

HBeAg level and its on-treatment declined value at 12-wk (or 24-wk) as independent predictors were further evaluated using AUROC for predicting 96-wk VR and HBeAg SC.

#### Predictive value of HBeAg titer as well as its declined value at week 12 and 24 for 96-wk virological response

At week 12, the HBeAg titer and its declined value predicted VR with an AUROC of 0.733 (95%CI: 0.617-0.849,  $P = 0.001$ ) and 0.709 (95%CI: 0.590-0.827,  $P = 0.002$ ), respectively, and the best cut-off value for the HBeAg titer and its decline was 0.8 lg PEIU/mL and 0.84 lg PEIU/mL, respectively. Twenty-two patients achieved HBeAg titer < 0.8 lg PEIU/mL as well as the declined value > 0.84 lg PEIU/mL at 12-wk, and among them 91% (20/22) reached VR, whereas only 29% obtained VR among 28 patients without meeting the above two standards. HBeAg titer combined with on-treatment decline at 12-wk predicted VR with an AUROC of 0.812 (95%CI: 0.687-0.936,  $P < 0.001$ ) and the sensitivity, specificity, PPV, NPV was 71%, 91%, 91% and 71%, respectively.

At week 24, the HBeAg titer and its declined value predicted VR with an AUROC of 0.788 (95%CI: 0.683-0.892,  $P < 0.001$ ) and 0.736 (95%CI: 0.620-0.851,  $P < 0.001$ ), respectively, and the best cut-off value for the HBeAg titer and its decline was 1.3 lg PEIU/mL and 1.6 lg PEIU/mL, respectively. All the 22 patients with HBeAg titer < 1.3

HBeAg: Hepatitis B surface antigen; HBeAg: Hepatitis B e antigen; Anti-HBc: Hepatitis B core antibody; ALT: Alanine aminotransferase; HBV: Hepatitis B virus; VR: Virological response (HBV DNA  $\leq$  300 copies/mL); SC: HBeAg seroconversion; ULN: Upper limit of normal.

lg PEIU/mL and the declined value  $>$  1.6 lg PEIU/mL at 24-wk achieved VR, whereas only 17% of 23 patients without meeting the above two standards obtained VR. HBeAg titer combined with its decline at 24-wk strongly predicted VR with an AUROC of 0.923 (95%CI: 0.838-1.000,  $P < 0.001$ ) and the sensitivity, specificity, PPV, NPV was 85%, 100%, 100% and 83%, respectively (Table 3).

#### **Predictive value of HBeAg titer as well as its declined value at week 12 and 24 for 96-wk HBeAg seroconversion**

At week 12, the HBeAg declined value predicted HBeAg SC with an AUROC of 0.767 (95%CI: 0.623-0.911,  $P = 0.001$ ), and the best cut-off value for HBeAg decline was 1.8 lg PEIU/mL. The HBeAg declined value  $>$  1.8 lg PEIU/mL at 12-wk predicted HBeAg SC with a sensitivity, specificity, PPV, NPV of 60%, 87%, 53% and 90%, respectively.

At week 24, the HBeAg titer and its declined value predicted HBeAg SC with an AUROC of 0.828 (95%CI: 0.712-0.944,  $P < 0.001$ ) and 0.814 (95%CI: 0.676-0.953,

$P < 0.001$ ), respectively, and the best cut-off value for the HBeAg titer and its decline was -0.5 lg PEIU/mL and 2.2 lg PEIU/mL, respectively. Eight patients achieved HBeAg titer  $<$  -0.5 lg PEIU/mL and the declined value  $>$  2.2 lg PEIU/mL at 24-wk, among them 88% (7/8) achieved HBeAg SC; whereas only 2% of 51 patients who did not meet the above two standards obtained HBeAg SC. HBeAg titer combined with its declined value at 24-wk strongly predicted HBeAg SC with an AUROC of 0.928 (95%CI: 0.791-1.000,  $P < 0.001$ ) and the sensitivity, specificity, PPV, NPV was 88%, 98%, 88% and 98% (Table 4).

## **DISCUSSION**

Achieving a long-term suppression of serum HBV DNA through antiviral therapy is one of important targets of treatment for CHB patients. Several studies tried to investigate the value of an early on-treatment change of HBV markers such as HBeAg in predicting VR to NAs therapy. A study presented that the HBeAg titer decreased by 1 lg PEIU/mL at 12-wk predicted VR

HBeAg: Hepatitis B e antigen; SC: HBeAg seroconversion; AUROC: Area under the receiver operating characteristic curve; PPV: Positive predictive value; NPV: Negative predictive value.

(HBV DNA < 20 IU/mL) after 48-wk entecavir (ETV) therapy with a sensitivity, specificity, PPV, NPV of 67.6%, 87.9%, 86.2% and 70.7%, respectively<sup>[10]</sup>. However, the predictive value of HBeAg titer and its declined value at 12-wk for a long-term treatment response ( $\geq$  2 years) was not reported. In this study, we found that HBeAg titer < 0.8 lg PEIU/mL combined with its declined value > 0.84 lg PEIU/mL at 12-wk predicted VR after 96-wk LAM and ADV optimized therapy with a sensitivity, specificity, PPV, NPV of 71%, 91%, 91% and 71%, respectively, and accompanied with an AUROC of 0.812. In addition, although some studies indicated that the on-treatment HBeAg level or declined value at 24-wk was a predictor for NAs treatment response<sup>[9,12]</sup>, the sample size was small or HBeAg was detected using a semi-quantitative method which cannot accurately quantify HBeAg level, thus limited the validity of the prediction. For example, Zhang *et al.*<sup>[12]</sup> detected serum HBeAg semi-quantitatively and found that the on-treatment declined value of HBeAg (> 65%) at 24-wk was the best predictor for treatment response (HBeAg seroconversion and accompanied by undetectable serum HBV DNA) after 96-wk ETV therapy, and the PPV, NPV, AUROC was 83.3%, 93.6% and 0.885, respectively. However, the finding may have difficulty in applying clinical practice since the absent of accurate quantitative HBeAg levels. In our study, the HBeAg titer (OR = 0.45,  $P$  = 0.003) and its declined value (OR = 2.03,  $P$  = 0.024) at 24-wk were found to predict 96-wk VR with the AUROC of 0.788 and 0.736, respectively.

Moreover, the combination of HBeAg titer < 1.3 lg PEIU/mL and its decrease > 1.6 lg PEIU/mL at 24-wk predicted 96-wk VR with a sensitivity, specificity, PPV, NPV of 85%, 100%, 100% and 83%, respectively, and the AUROC increased to 0.923, which had a better predictive value than the semi-quantitative method reported by Zhang *et al.*<sup>[12]</sup>. With respect to the cost of semi-quantitative and quantitative tests of HBeAg, it is comparable between them. Twenty-two patients in our cohort matched the combination standard and they all achieved 96-wk VR. The results suggested that if patients reached HBeAg titer < 1.3 lg PEIU/mL and declined > 1.6 lg PEIU/mL at 24-wk, there will be a better viral suppression during the continued NAs therapy.

In addition to achieve long-term suppression in serum HBV DNA, HBeAg SC is another important indicator to evaluate the efficacy of antiviral therapy in HBeAg-positive CHB patients. In our study, the declined value of HBeAg at 12-wk (OR = 2.47,  $P$  = 0.001) independently predicted 96-wk HBeAg SC with an AUROC of 0.767, and for the predictive value of HBeAg declined value at 24-wk, an AUROC increased to 0.814. Lee *et al.*<sup>[8]</sup> found that the decline of HBeAg at month 6 was a strongest predictor for HBeAg SC after 2 years of ETV treatment with an AUROC of 0.820 ( $P$  = 0.004), which was similar to our result (AUROC = 0.814). However, Lee's study used the declined value of HBeAg alone to predict treatment response and did not consider combining other indicators. Our data showed that both HBeAg titer as well

as its declined value at 24-wk were independent predictors for 96-wk HBeAg SC, and it strongly predicted HBeAg SC with an AUROC of 0.928 if combining HBeAg titer  $< -0.5$  lg PEIU/mL and declined value  $> 2.2$  lg PEIU/mL at 24-wk. A study from Shin *et al.*<sup>[11]</sup> revealed that HBeAg titer  $< 0.62$  lg PEIU/mL after 48 wk of ETV therapy was a strongest predictor for HBeAg SC at year 3 with an AUROC of 0.86 ( $P < 0.001$ ), which was inferior to the combined prediction validity of HBeAg level and declined value at 24-wk in our study (AUROC = 0.928). Our study presented that 88% (7/8) of patients with HBeAg titer  $< -0.5$  lg PEIU/mL and declined value  $> 2.2$  lg PEIU/mL at 24-wk achieved 96-wk HBeAg SC, whereas only 2% (1/51) of patients without meeting above standards obtained HBeAg SC, thus got a NPV of 98%. Among the 51 patients with unfavorable 24-wk HBeAg titer, 46 patients were added on ADV at 24-wk due to serum HBV DNA  $> 300$  copies/mL. The results suggested that patients with HBeAg titer  $> -0.5$  lg PEIU/mL as well as declined value  $< 2.2$  lg PEIU/mL after 24 wk of LAM therapy will rarely achieve HBeAg SC during the following NAs treatment, even adding on ADV still cannot improve the efficacy. So the patients with unfavorable 24-wk HBeAg titer should be considered to switch to other drugs or use other regimens for a better treatment outcome.

Results of logistic regression analysis in the current study showed that no baseline parameters were associated with 96-wk HBeAg SC, which was consistent with Lee's report<sup>[8]</sup>, who did not find correlations between baseline level of HBeAg (or HBsAg, HBV DNA) and HBeAg SC after 2 years of ETV therapy either. However, other studies showed that pre-treatment serum HBeAg was associated with HBeAg SC during ETV treatment<sup>[10,12]</sup>. The inconsistent results may due to that treatment period was relatively short or HBeAg was detected semi-quantitatively in the latter's studies<sup>[10,12]</sup>. Several recent studies revealed that B lymphocytes played a key role in the regulation of host immune responses to HBV, while anti-HBc was produced and secreted by hepatitis B core antigen-specific B lymphocytes, therefore the serum anti-HBc level may be a surrogate marker for the host immune response to HBV<sup>[16,17]</sup>. Fan *et al.*<sup>[13]</sup> demonstrated that the baseline level of anti-HBc independently predicted HBeAg SC after 2 years of LdT and ADV optimized therapy (OR = 1.99,  $P = 0.001$ ). However, our results presented that baseline anti-HBc was not associated with HBeAg SC or VR after 96-wk LAM and ADV optimized therapy (HBeAg SC, OR = 1.60,  $P = 0.459$ ; VR, OR = 1.68,  $P = 0.308$ ). The discrepancy may due to the little difference of baseline anti-HBc level between patients with and without HBeAg SC (0.10 lg IU/mL) in our study, while the difference in baseline anti-HBc was 0.24 lg IU/mL in Fan's study. Besides, previous studies identified that the elevation of ALT was contributed to T lymphocyte mediated hepatolysis occurred in CHB patients, therefore baseline ALT level may reflect T lymphocyte immune response to HBV which is related to the outcome after antiviral treatment<sup>[18]</sup>. Zeuzem *et al.*<sup>[4]</sup> reported that the

pre-treatment ALT level was associated with VR and baseline ALT  $\geq 2 \times$  ULN could independently predict non-detectable serum HBV DNA after 2 years of LdT treatment (OR = 2.00,  $P = 0.0071$ ). In agreement with these findings, we also found that baseline ALT  $\geq 5 \times$  ULN independently predicted 96-wk VR (OR = 7.09,  $P < 0.001$ ) with the AUROC of 0.700 ( $P = 0.003$ , data not shown), which suggested that patients with a higher pre-treatment ALT level maybe situated in a better immune status and will have an active virological response to NAs treatment.

All the parameters (HBsAg, HBeAg, anti-HBc and HBV DNA) presented continuous descent during the 96-wk treatment. Serum HBV DNA dropped significantly from baseline 8.16 lg copies/mL to 96-wk 2.85 lg copies/mL ( $P < 0.001$ ) and 56.6% (43/76) patients obtained HBV DNA  $\leq 300$  copies/mL in our cohort, showing a similar data to the GLOBE study<sup>[19]</sup>, in which 55.6% HBeAg-positive patients achieved HBV DNA  $< 300$  copies/mL with serum HBV DNA declined by 6.1 lg copies/mL after 2-year LdT treatment. The antiviral effect of NAs agents was reducing viral replication by the inhibition of HBV DNA polymerase, but having limited impacts on the level of HBsAg<sup>[20]</sup>. In our study, HBsAg decreased slowly by 0.59 lg IU/mL after 96-wk therapy. Heathcote *et al.*<sup>[21]</sup> also reported that the mean HBsAg level in HBeAg-positive CHB patients decreased by 0.66 lg IU/mL after 2 years of tenofovir disoproxil (TDF) treatment, which was similar to our data. In addition, anti-HBc level decreased from baseline 4.77 lg IU/mL to 96-wk 3.45 lg IU/mL in our cohort, with an average decrease of 1.32 lg IU/mL. In Fan's report<sup>[13]</sup>, 1.26 lg IU/mL of an average decrease of anti-HBc level was observed in HBeAg-positive CHB patients after 104-wk LdT and ADV optimized therapy (baseline 4.20 lg IU/mL to 104-wk 2.94 lg IU/mL). The average declines in anti-HBc levels were comparable between the two studies, although the baseline anti-HBc level was relatively higher in our study. Concerning the dynamic change of HBeAg, Shin *et al.*<sup>[11]</sup> reported that HBeAg level reduced from baseline 2.23 lg PEIU/mL to 0.96 lg PEIU/mL after 96-wk ETV therapy and 17.1% (14/82) achieved HBeAg SC. In the present study, HBeAg level decreased from baseline 2.24 lg PEIU/mL to 96-wk 0.20 lg PEIU/mL and 19.7% (15/76) obtained HBeAg SC, which presented comparable HBeAg reduction and HBeAg SC rate as compared to Shin's study.

Comparing dynamic changes in HBeAg level between patients with and those without 96-wk VR (or HBeAg SC), our results showed that baseline HBeAg levels were comparable between two groups. Further, HBeAg levels in patients obtained 96-wk VR (or HBeAg SC) were significantly lower than those without VR (or HBeAg SC) from 12-wk to the end of follow-up ( $P < 0.05$ , as shown in Figures 1B and 2B). With respect to dynamic changes of HBV DNA levels, the same trend of decline was observed. The patients achieved 96-wk VR had a significant lower HBV DNA level at every follow-up time-point except baseline when compared with those

without VR ( $P < 0.05$ ), while the significant differences in HBV DNA levels between patients with and without HBeAg SC were only observed at week 24, 72 and 96 (Figures 1D and 2D). These results indicated that HBeAg may have a better predictive value than HBV DNA for treatment response in HBeAg-positive CHB. At the same time, our finding showed that both the HBV DNA level as well as its declined value at 24-wk (or 12-wk) were significantly associated with 96-wk VR and HBeAg SC when performed univariate analysis ( $P < 0.05$ ). However, HBV DNA levels and its declines would not associate with 96-wk VR and HBeAg SC anymore if all parameters including HBeAg levels and its declines were enrolled in multivariate analysis. Other studies also pointed out that HBeAg levels as well as its declines may maintain a better predictive value than HBV DNA to predict NAs treatment response in HBeAg-positive CHB patients<sup>[10,11]</sup>. HBeAg is generated by transcription and translation of HBV cccDNA, and previous studies had reported that serum HBeAg level was significantly correlated with intrahepatic HBV cccDNA ( $r = 0.507$ ,  $P = 0.010$ )<sup>[22]</sup>. Thus, the decline in serum HBeAg level may reflect the reduction of HBV cccDNA and represented a good treatment outcome. In addition, viral persistence and the development of CHB was associated with viral manipulation and evasion of the host's immune system, while HBeAg has been reported to attenuate the host immune response to the nucleocapsid protein and down-regulate the innate and adaptive immune responses<sup>[23,24]</sup>. Therefore, the decline in HBeAg level might weaken this effect and thus the patients may present a better immune control for HBV infection.

There were some limitations in our study. Firstly, LAM and ADV used in the cohort are no longer the first-line antiviral drugs. However, NAs drugs have a similar antiviral mechanism, and HBeAg SC rates in CHB patients are comparable between ETV (or TDF) therapy and an optimized therapy with LAM and ADV. Hence, we propose that the combination parameter of HBeAg level and its declined value at 24-wk might be used as a reference parameter to predict the efficacy of ETV or TDF treatment. Secondly, treatment endpoint evaluated in our study was on-treatment response. For virological response, off-treatment response may be more important than on-treatment response.

To our knowledge, this is the first report that identified the combination of on-treatment quantitative HBeAg level and its decline as the predictor of positive response to long term NAs therapy among HBeAg-positive CHB patients. In particular, the combination of HBeAg titer and its decline at 24-wk strongly predicted 96-wk VR and HBeAg SC with the AUROC of 0.923 and 0.928, respectively. This combination predictor was identified through a retrospective investigation based on the cohort of HBeAg-positive CHB patients received LAM and ADV optimized therapy. We will conduct a prospective study to evaluate and confirm the predictive validity of the combination parameter in the cohort of ETV or TDF therapy in the future, and anticipate that the combination

of on-treatment HBeAg level and its declined value could serve as a reference parameter to guide NAs therapy.

## COMMENTS

### Background

The antiviral effect of current available nucleos(t)ide analogues (NAs) or peginterferon drugs are not satisfied. To improve the efficacy, it is crucial to explore the pre-treatment and early on-treatment biomarkers to effectively predict long-term treatment response. However, very few studies have systematically evaluated the predictive power of quantitative hepatitis B surface antigen (HBsAg), hepatitis B e antigen (HBeAg), hepatitis B core antibody (anti-HBc), hepatitis B virus (HBV) DNA and alanine aminotransferase (ALT) for NAs treatment response.

### Research frontiers

In the current study, serum HBsAg, HBeAg, anti-HBc, HBV DNA and ALT were quantitatively tested during the 96-wk NAs therapy, and the baseline as well as early on-treatment levels of these parameters were comprehensively analyzed to assess their functions in predicting 96-wk virological response (VR) and HBeAg seroconversion (SC).

### Innovations and breakthroughs

This is the first report that the combination parameter of on-treatment quantitative HBeAg level and its declined value was found to predict 96-wk treatment response to lamivudine and adefovir dipivoxil optimized therapy for HBeAg-positive chronic hepatitis B (CHB) patients. In particular, the combination of HBeAg titer and its decline at 24-wk strongly predicted 96-wk VR and HBeAg SC with the AUROC of 0.923 and 0.928, respectively.

### Applications

The combination variable of on-treatment HBeAg level and its declined value may serve as a reference parameter to optimize NAs therapy for HBeAg-positive CHB patients.

### Peer-review

HBV is a major cause of chronic liver disease including chronic hepatitis, liver cirrhosis and hepatocellular carcinoma. Reactivation of HBV is closely related to acute exacerbation of HBV carriers which sometimes leads to liver failure. Introduction of NAs dramatically changed the landscape of HBV treatment that is useful weapon to suppress HBV replication. NAs can only suppress HBV replication but not eradicate HBV. Therefore several problems remains including setting of endpoint and adequate cessation of NAs.

## Abstract

### AIM

To determine the seroprevalence of hepatitis B surface antigen (HBsAg) among pregnant women attending antenatal clinic in Honiara, Solomon Islands.

### METHODS

This descriptive cross-sectional study was carried out in seven area health centers in Honiara. From March to June

2015, identification of eligible pregnant women in each site was conducted using systematic random sampling technique. A total of 243 pregnant women who gave written informed consent were enrolled. Standardized tool was used to record demographics, obstetric history and serology results. HBsAg and hepatitis B e antigen (HBeAg) were tested using point-of-care rapid diagnostic test. All HBsAg positive samples were verified using enzyme-linked immunosorbent assay.

## RESULTS

The mean age of participants was  $26 \pm 6$  years. The overall hepatitis HBsAg prevalence was 13.8% with higher rate (22%) reported in women between 30-34 years of age. Majority of HBsAg positive participants were Melanesians (29 out of 33). None of the pregnant women in the 15-19 years and  $\geq 40$  years tested positive for HBsAg. There was no statistically significant difference in HBsAg prevalence by age, ethnicity, education and residential location. The overall HBeAg seroprevalence was 36.7%. Women between 20-24 years of age had the highest rate of 54.5%. Low level of knowledge about hepatitis B vaccination was reputed. Overall, 54.6% of participants were not aware of their hepatitis B vaccination status and only 65.2% of mothers reported their child had been vaccinated.

## CONCLUSION

Hepatitis B is a disease of public health importance in Solomon Islands and emphasize the need for integrated preventative interventions for its control.

**Key words:** Hepatitis B; Chronic hepatitis; Hepatitis B surface antigen; Hepatitis B e antigen; Seroprevalence; Pregnant women; Solomon Islands

**Core tip:** The objective of this study was to determine the prevalence of chronic hepatitis B infection in a cohort of antenatal women in Honiara. The overall hepatitis HBsAg and hepatitis B e antigen (HBeAg) prevalence was 13.8% and 36.7%, respectively. Our study for the first time reported HBeAg prevalence in pregnant women. Furthermore, the study revealed low level of knowledge about hepatitis B vaccination whereby 54.6% of participants were not aware of their vaccination status. Hepatitis B is a disease of public health importance in Solomon Islands and emphasize the need for efficient delivery of integrated services for its prevention and control.

Seroprevalence of hepatitis B surface antigen in pregnant women attending antenatal clinic in Honiara Solomon Islands, 2015. *World J Hepatol* 2016; 8(34): 1521-1528 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i34/1521.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i34.1521>

## INTRODUCTION

Hepatitis B virus (HBV) infection occurs worldwide. It is estimated that over two billion people have been infected with 360 million individuals who remain chronically infected<sup>[1]</sup>. There are around 600000 deaths every year due to the consequences of hepatitis B<sup>[2]</sup>. Hepatitis B is highly endemic in Africa, South-East Asia and the Pacific (excluding Japan, Australia and New Zealand), the Amazon Basin and parts of the Middle East, central Asia and some countries in Eastern Europe. In these areas, about 70% to 90% of the population are exposed to the virus during the first four decades of life, and eight to 20% of people then become chronically infected<sup>[3,4]</sup>. It is estimated that around 45% of the world population live in areas where there are high levels of hepatitis B infection<sup>[4]</sup>.

Hepatitis B virus is a DNA virus classified within the family hepadnaviridae. It is transmitted by percutaneous and permucosal exposure to infected blood and other body fluids, mainly semen and vaginal fluid<sup>[5]</sup>. The predominant mode of transmission varies depending on the endemicity of the disease in a given population. In areas of high endemicity, HBV is mostly acquired in early childhood from mother to child at birth or from person to person in early childhood. Exposure at an earlier age increases likelihood of progress to chronic infection. In low endemic areas, sexual transmission is the predominant route<sup>[1,2]</sup>.

Vaccination is the most cost effective way for the prevention of hepatitis B. The World Health Organization (WHO) recommends the inclusion of hepatitis B vaccine in routine immunization programs in all countries<sup>[1]</sup>. Four doses of vaccines are given, the first one within 24 h after birth followed by three vaccines in infancy. The complete vaccine series induces protective antibody levels in more than 95% of infants, children and young adults. Protection lasts at least 20 years and is likely lifelong<sup>[1]</sup>.

The Solomon Islands is located in the southwest Pacific, stretching about 1700 km from the eastern tip of Papua New Guinea to the northern-most islands of Vanuatu. The Island chain is comprised of nine administrative provinces: Guadalcanal, Malaita, Western, Rennell Bellona, Central, Makara Ulawa, Choiseul, Isabel and Temotu. According to the 2009 census, total population is estimated at 515870 of which 80% live in rural areas<sup>[6]</sup>. In 2013, Solomon Islands was ranked 157 out of 187 countries and territories on the Human Development Index. The country is one of the world's least developed countries and the 2013 Human Development Index was below the average for countries in the low human development group as well as below the average for countries in East Asia and the Pacific region<sup>[7]</sup>.

The current WHO model for Ante Natal Care (ANC) recommend that all pregnant women have at least four ANC assessments by a skilled attendant. WHO also encourages countries to develop national guidelines to

outline the essential minimum packages of ANC based on the local epidemiology and priorities<sup>[8]</sup>. In Solomon Islands, ANC is based on the Manual of Obstetrics and Gynecology for Doctor, Midwives and Nurses in Solomon Islands, 2005<sup>[9]</sup>. This recommends early ANC assessment (after 2-3 missed period) to determine expected date of delivery and identify and treat common conditions such as anemia and syphilis. The first ANC visit includes thorough history taking, physical examination, administering first dose of tetanus toxin, and bloods for hemoglobin, malaria and syphilis and urine for glucose and protein. Antenatal screening for hepatitis B is not part of the routine care.

Hepatitis B infection is hyper endemic in Solomon Islands. A large study conducted in Honiara central hospital in 1994 reported overall Hepatitis B surface antigen (HBsAg) prevalence of 19.6% which ranged from 14.6% in females to 23.4% in males<sup>[10]</sup>. Surveillance reports and prevalence studies in population sub-groups such as pregnant women and blood donors also reported high level of chronic infection, with 14.5%-16% in pregnant women and 25% in blood donors<sup>[11,12]</sup>. HBV C3 and D4 are the two prevalent subgenotypes in Solomon Islands and in the Pacific region<sup>[13-16]</sup>, Utsumi *et al*<sup>[13]</sup>, further reported genotype to be specific with ethnicity where genotype was C were predominant in Melanesians while genotype was D was common among Micronesians. The prevalence of hepatitis B e antigen (HBeAg) was higher among carrier of HBV subtype C compared to carriers of subtype B however it was not statistically significant. In this study there was no statistically significant difference between carriers of the two genotypes in terms of sex, liver function test (AST, serum albumin and total bilirubin) and anti-HBe seroprevalence. Previous study in Solomon Islands reported significantly higher prevalence of HBeAg among carriers of genotype C which could be associated with severe hepatic inflammation and complications<sup>[14]</sup>. However, these studies were not designed to further evaluate the relationship between genotype and clinical progression as they were cross-sectional prevalence studies.

There is paucity of information on the prevalence of complications of HBV infection such as cirrhosis and primary hepatocellular carcinoma in Solomon Islands. Historically, the island reported a high incidence of liver cancer among males<sup>[17]</sup>. According to the 2014 WHO report, liver cancer was the single most common cause of cancer in males<sup>[18]</sup>. Mortality from HBV related complications in Solomon Island remains unknown. Hepatocellular carcinoma is common in neighboring Melanesian islands of Fiji<sup>[19]</sup> and Papua New Guinea<sup>[20]</sup>.

The clinical course of chronic HBV infection generally does not change during pregnancy and chronic infection is not implicated in increased maternal morbidity or mortality<sup>[21,22]</sup>. Most pregnant women with chronic HBV infection are asymptomatic and often detected during routine ANC screening. Pregnancy related complications and perinatal outcomes of chronic HBV are not well elucidated. Some studies reported gestational diabetic,

antepartum hemorrhage, preterm labour and lower Apgar score to be associated with chronic infection<sup>[23,24]</sup>. Recent large scale studies from the United States and China revealed no association between maternal HBV infection and the risk of fetal growth retardation, pregnancy induced hypertension or preeclampsia<sup>[24,25]</sup>. In Solomon Islands, the impact of chronic HBV infection on pregnancy outcomes has not been investigated.

Hepatitis B vaccine was introduced in the national immunization program in 1990-1991 and is recommended for infants at birth, 6, 10 and 14 wk of age<sup>[26]</sup>. In 2009, the coverage of hepatitis B vaccine was 45% at birth and 81% for  $\geq 3$  vaccines<sup>[27]</sup>.

Ongoing transmission at birth and in early childhood is likely to continue to contribute to the significant burden of disease. This early exposure in life increases risk of chronic infection and its complications of liver cirrhosis and its sequelae, liver cancer and early death. There are no recent seroprevalence studies to document the current burden of disease. Therefore, this study aims to contribute to a clearer understanding of the current status of chronic infection in a cohort of antenatal women in Honiara, Solomon Islands.

## MATERIALS AND METHODS

A descriptive, cross-sectional study was carried out in seven area health centers (Kukum, Mataniko, Rove, Vura, Mbokonavera, White River and Mbokona) providing ANC in the catchment areas of Honiara City Council. Ethical clearance was obtained from the College Research and Ethics Committee of Fiji National University and the National Health Research and Ethics Committee of Ministry of Health and Medical Services, Solomon Islands (HRC14/28).

All pregnant women who presented for the first antenatal visit were eligible for the inclusion. Using the one sample population proportion formula, the sample size required was estimated as 239 (based on 16% prevalence of HBV among pregnant women<sup>[12]</sup>, 95%CI, 5% margin error, and 15% non-respondent). Enrolment of eligible pregnant women in each area health center was conducted proportionally based on the monthly average of first ANC bookers using systematic random sampling technique. Potential study participants were invited to participate and those that gave written consent were enrolled. A total of 243 pregnant women were enrolled between March to June 2015. Information was collected using standardized proforma data collection tool which included demographics (age, ethnicity, residential location, education level and occupation), obstetric and medical history as well as HBsAg and HBeAg serology results.

One milliliter of blood that was collected for routine ANC testing was aliquoted and stored at  $-4^{\circ}\text{C}$  in the national referral hospital laboratory. The specimens were thawed back to room temperature for testing according to the manufacturer's instructions<sup>[28]</sup>. All samples were tested for HBsAg with Standard Diagnostics Bioline,

the HBsAg testing kit (30 Tests/kit, Cat. No. 01FK10W, Standard Diagnostics, Inc, South Korea). This is a point of care qualitative immunochromatography testing strip method for the detection of HBsAg. Further testing for HBsAg was performed on all positive sera and 5% of randomly selected nonreactive samples using Murex HBs version 3 enzyme linked immunosorbent assay (ELISA) - horseradish peroxidase conjugated kit which have a specificity of 99.97% and sensitivity of 100% respectively (DiaSorin, S.p.A. United Kingdom branch). Duplicate samples including positive and negative controls were included and the procedure was carried out in accordance to the manufacturer's instructions<sup>[29]</sup> with the washing step done manually. Samples that were positive on both rapid test kits and the ELISA were considered HBsAg positive. From the 33 positive samples for HBsAg, 30 samples were analyzed for HBeAg using the ABON HBV combo test kit (ABON Biopharm, Hangzhou Co., Ltd). The remaining 3 samples were insufficient for further testing. The testing procedure and interpretation was carried out according to the manufacturer's instructions. Positive results were indicated by two red bands; one in the test region and other in the control region. Negative results were indicated by one red band on the control region.

The data was entered into Microsoft Excel spreadsheet and analyzed using Statistical Package for the Social Sciences software version 22. A descriptive analysis was used to determine the demographic, obstetric and medical profile of study participants. The overall HBsAg and HBeAg prevalence was calculated as well as determination by age group, ethnicity and location of residence. Results are presented as proportion, means with standard deviation.  $\chi^2$  test and Fishers' exact tests were used to compare the proportions between hepatitis B seropositive vs sero-negative and demographic variables. Results were considered statistically significant at  $P < 0.05$ .

## RESULTS

A total of 243 pregnant women attending their first antenatal visit were enrolled in the study. Three pregnant women with incomplete information were subsequently excluded from analysis. The data from remaining 240 were used for analysis. The mean age of participants was  $26 \pm 6$  years (range 16 to 45). Majority of participants were Melanesians (91%), Polynesians and Micronesians represented 5.4% and 3.3% respectively. Most pregnant women (62.1%) achieved secondary or tertiary level education, with 7.9% reporting no education. Majority of the pregnant women who took part in the study were unemployed (58.7%). Nearly half of the study participants (46%) were peri-urban dwellers (Table 1).

The average presentation for first ANC visit was in the 6 mo of pregnancy. Most women presented for the first time in their second trimester (58.2%). Majority of women were not aware of their hepatitis B vaccination status (54.6%), with only 4.6% reporting prior vac-

cination. The median number of children was 1 per participant, with most had at least one child (58.3%). Women with children under the age of 5 years (47.9%) were asked about the hepatitis B vaccination of their child/children. Of these, 65.2% of mothers said their child/children had been vaccinated, 27% were uncertain and the remaining 7.8% not having received hepatitis B vaccine.

A total of 33 sera tested positive for HBsAg, with a sero-prevalence of HBsAg among study participants of 13.8%. Highest rate of hepatitis B infection was seen in participants between the ages of 30-34 year (22%). None of the pregnant women in the 15-19 years ( $n = 33$ ) and  $\geq 40$  years ( $n = 2$ ) tested positive for HBsAg. Majority of HBsAg positive participants were Melanesian (29 out of 33). In this study the highest rates of sero-prevalence were reported among Polynesians (23.1%) followed by Melanesians (13.2%). No statistically significant difference in HBsAg prevalence by age group, ethnicity, education level and residential location is seen (Table 2). A total of 44 samples (33 positive and 11 representing 5% of the negative results) were tested with Murex HBs version 3 ELISA for quality assurance. There was 100% concordance in results.

Of the 33 HBsAg positive pregnant women, 30 were tested for HBeAg. The overall prevalence of HBeAg was 36.7%. Higher prevalence was recorded among women between 20-24 years old (54.5%) followed by 25-29 years old (27.3%). All the HBeAg positive women were from Melanesian ethnic group and 54.5% reside in urban areas.

## DISCUSSION

The urgency to address the needs of hepatitis B associated disease and resultant suffering is now being actively addressed with particular attention to those countries with high rates of chronic infection. The hyper prevalence of hepatitis B in the Pacific islands is well accepted but remains poorly defined with gaps in recent data on disease burden. There are complex reasons for this and this study contributes to current understanding in a select cohort of people in Solomon Islands.

We report hepatitis B sero-prevalence rate of 13.8% in this descriptive cross-sectional study of pregnant women attending for their first antenatal visit in seven area health centres in Honiara. Data preceding this dates back to 2008, with comparable rates of 13.7% (41/298) reported amongst a similar antenatal cohort in Honiara, Gizo and Munda<sup>[12]</sup>. Their study determined HBsAg using ELISA (Determine and Serodia). Slightly higher rates of 15.8% were reported amongst women aged 15 to 24 years vs 11.9% in women aged 25-44 years<sup>[12]</sup>. Our study report similar rates of sero-prevalence based on rapid point of care tests in a similar antenatal cohort and hence have similar biases. These studies are both likely to underestimate the burden of disease due to convenience sampling bias in select age in the female population presenting to health care facilities. However,

**Table 1** Demographic characteristics of study participants (*n* = 240)

it does not distract from the high rate of 13.8%. Other previous data are limited to small studies, in select populations. Study on healthy blood donors reported higher prevalence of HBsAg of 19.6% and 22.3%<sup>[10,11]</sup>. Further national random representative sero-surveys are needed to provide a much more accurate assessment of disease burden in Solomon Islands.

We report a trend with increased rates seen with increasing age with peak prevalence of 22% in the 30-34 year group. The increased rates with increasing age may reflect ongoing new infections through sexual contact or other routes including health services. This is proceeded by further decline in the older age group (35-39 years), and no cases seen over the age of 40 years. This decline in the older age group may represent spontaneous sero-conversion over time and nil cases due to small sampling size. No HBsAg positive patients are noted in the youngest cohort (15-19 years). This is likely due to the efforts childhood vaccination program. This draws further attention in the need to ensure high rates of birth dose and vaccination coverage to improve herd immunity and hence overall prevalence over time. Initial effort to assess current vaccination coverage rates as well as addressing the barriers to delivery such as cold chain, birth outside health care facilities and lack of awareness are required.

Amongst the ethnic groups, the highest rates were seen amongst the Polynesian cohort with a prevalence of 23.1% compared with Melanesian and Micronesian (13.2% and 12.5% respectively), lack of statistical significance may be attributed to total numbers recruited for this study, with the largest sampling size from the Polynesian cohort. Similar reports of difference in hepatitis B in

HBsAg: Hepatitis B surface antigen.

ethnic groups are reported from 1994 with highest rates of hepatitis B seen in Micronesians (28.1%), followed by Melanesians (20%) and then Polynesians (8.4%)<sup>[10]</sup>. This ethnic variation is well reported from other parts of the Pacific islands and further understanding of this relevance will assist in the contribution to the understanding of the disease, mode of transmission, disease progress and management strategies. Further work into this is clearly warranted.

Although the prevalence of hepatitis B is noted to be higher in those from rural settings (28%) as compared to those from urban and periurban settings (12.5% and 11.7%), this does not reach statistical significance. There is likely to be a number of factors contributing to this difference including vaccination coverage as well as ongoing risk of horizontal transmission modality and access to health care. Hepatitis B rate is also likely to have geographical variations in different islands. Improved understanding to address this gap is warranted with majority of the population (80.2%) in Solomon Islands living in rural areas where access to clean water and sanitation is not reliable<sup>[7]</sup>. These resource barriers are likely contributors to higher rates of hepatitis B, and ongoing risks of new infection.

Our study for the first time reports the prevalence of HBsAg among pregnant women in Solomon Islands. The overall prevalence of 36.7% is comparable to the rates reported among mothers and the general population. Furusyo *et al.*<sup>[10]</sup>, reported an overall prevalence of 41.3% among 315 HBsAg positive adult patients attending

general outpatients and blood donors. The prevalence did not differ by sex however patients from Melanesian ethnic groups had significantly higher HBeAg seropositive compared to the other two ethnic groups. Another study among mothers of children who received vaccination reported HBeAg prevalence of 40.7%<sup>[30]</sup>. Subsequently in 2001, seroprevalence of 35% was reported among 206 blood donors with chronic hepatitis<sup>[14]</sup>. All studies reported a progressive decline in HBeAg sero-prevalence with increasing age. Wilson *et al*<sup>[31]</sup>, reported high prevalence of HBeAg among pregnant women in the Pacific region which ranged from 48% in Kiribati to 70% in Fiji. HBeAg determines infectivity. High prevalence of HBeAg in pregnant women coupled with low up take of birth dose vaccine in Solomon Island increase the risk for vertical transmission of HBV to their newborns.

Only 4.6% of women screened had received previous hepatitis B vaccination. This low rate represents an opportunity to increase awareness and improve vaccination coverage. More than half the women were not aware of their vaccination status. Despite the routine introduction of childhood vaccination for hepatitis B in 1990-1991, only 65.2% of women with children under the age of 5 were able to report that their child/children had received vaccination. One in three mothers was not aware of their child's vaccination status. This gap in awareness about the vaccination requires attention, with opportunities for education for community as well as health care workers. Birth dose vaccination coverage as well as completion of the three doses remains a significant challenge in resource poor setting and efforts to evaluate this in Solomon islands and address the specific barriers is needed. In particular, challenges include remote settings, lack of cold chain, engagement of health care workers and competing needs of antenatal care, as well as access to vaccines. Solomon Islands have one of the lowest birth dose coverage (45%) in the WHO-Western Pacific Region<sup>[27]</sup>. There are potential solutions to address these gaps that require resource allocation and prioritization with burden compounded by the remote settings. Hence, programs that explore integration into currently systems are should be considered. Even with optimal vaccination delivery, the protective coverage of vaccination is 70% in those born to positive mothers vs 81% to those born to hepatitis B negative mothers<sup>[31]</sup>. Hence, efforts to address this ongoing risk of vertical transmission and its associated high risk of progression to chronic lifelong infection are needed.

The screening tool used for this study was a point of care test (Standards Diagnostics). The 5% of negative samples tested by Murex HBsAg version 3 ELISA method is considered as quality control in the study. According to testing kit evaluation made by independent studies (including WHO), on a number of commercial HBsAg rapid tests, the Murex HBsAg version 3 ELISA is able to detect 0.13-0.21 IU/mL surface antigen concentration with a clinical sensitivity of 100% by one study<sup>[32,33]</sup>. Standard Diagnostics testing kits allows for rapid detection of the HBsAg which is an antigen associated

with hepatitis B. This antigen usually becomes positive very soon after infection and persists if the person is unable to develop protective antibodies, indicating chronic infection if present after 6 mo. These rapid point of care test kits are utilized mostly in resourced limited settings, are cheap, easy to use and interpret and requires less laboratory skills and does not need instruments. On the other hand, ELISA which is the most preferred screening technique with accuracy of 99.9% is time consuming, laborious and needing proficient skills to perform<sup>[34,35]</sup>. Thus rapid HBsAg tests serves as the common testing methods in the Solomon Islands for screening of antenatal mothers, blood donors and patients.

HBV viral load testing remain outside the scope of most of these resource poor settings both in terms of cost of equipment, consumables as well as training for laboratory staff. Additional information is required on the performance characteristics of these rapid tests in terms of their current on field performance and factors that may affect it including cut off viral load, contribution of diversity in hepatitis B variants and the effect of hepatitis B therapy. Other tests that are potentially of use include the use of hepatitis B surface antibody tests and core antibody tests which could add value to the overall understanding of the viral replication status and hence infectivity with potential role in the monitoring of patients who are found to be positive on screening. Further, rapid tests may not be able to detect occult hepatitis B infection, this remaining an area of further study. Although these rapid tests have a clear role, the need for additional laboratory services needs to be considered. Models including the establishment of reference labs could be explored.

The cost effectiveness of routine screening for HBsAg has not been fully investigated. Routine screening of pregnant women for hepatitis B has not been included in the WHO optimum service package for ANC. This could be due to concern over its cost effectiveness and support for mathematical modeling for funding purposes would help clarify. Currently, some PICs countries have included routine screening for Hepatitis B in their ANC package<sup>[36-39]</sup>. In Fiji and French Polynesia, screening is recommended during the first ANC visit and newborns of seropositive mothers are given immunoglobulin as well as birth dose vaccines at birth followed by three subsequent vaccine doses<sup>[36,37]</sup>. Similarly in Vanuatu, universal screening of pregnant women for HBsAg was commenced in Port Vila hospital in 2013<sup>[39]</sup>. In Solomon Islands, introduction of routine screening of pregnant women for HBsAg before childbirth would have two benefits. First, it will enable prompt identification of newborns of positive mothers for the provision of vaccine immediately after birth and subsequent follow up for completion of vaccination. Secondly, in high endemic areas it provides opportunity to immunize HBsAg negative pregnant women (if they have not been immunized) who are at high risk of infection in the community. Identification, screening and vaccination of contacts of positive patients could also be implemented. This targeted immunization coupled with ongoing promotion of current universal

immunization program could provide an opportunity to increase uptake of birth dose and overall hepatitis B vaccine coverage in infants.

Clearly, allocation of resources to allow this both in terms of cost and supporting services related to its delivery is required but need commitment from government. Solomon Islands could provide an example of models of care with an integrated program including awareness, prevention, screening, diagnostics, therapy and management through engagement and education. Specific local needs and resources require attention with focus on efficient delivery of care integrating hepatitis B programs into currently existing program as not to unnecessarily to the existing burden of stretched resources. This could form part of a national strategic plan for the delivery of hepatitis B services in Solomon Islands.

This study found a high rate of HBsAg and HBeAg prevalence among pregnant women in Honiara, with low level of awareness and vaccination uptake among women and their children. The challenges in hepatitis service in Solomon Islands are both unique and similar to those of the many of islands and atolls of the Pacific. Availability and access to care can be addressed by small steps and integration of currently available resources and programs without the need for introduction of separate programs and its associated funding requirements and complex strategies. Rapid point of care tests for screening and diagnosis are also available for further study. The WHO treatment and care guidelines in 2015 provide a framework with direction to further promote momentum on a broader scale to address the multiple facets needed to support hepatitis related service delivery in the resource poor setting<sup>[40]</sup>.

## ACKNOWLEDGMENTS

We would like to express our sincere gratitude to all pregnant women who gave consent and participated in the study, without their participation this study would not have been completed. The research team would also like to thanks the nurses in the seven area health centers and Honiara City Council health division staff and who kindly supported the study.

## COMMENTS

### Background

The Solomon Islands is located in the Southwest Pacific and has total population of 515870. Hepatitis B surface antigen (HBsAg) prevalence of 19.6% was reported among the general population in 1994. Surveillance reports and prevalence studies in population sub-groups such as pregnant women and blood donors also reported high level of chronic infection, with 14.5%-16% in pregnant women and 25% in blood donors. Hepatitis B vaccine was introduced in the national immunization program in 1990-1991 and is recommended for infants at birth, 6, 10 and 14 wk of age. In 2009, the coverage of hepatitis B vaccine was 45% at birth and 81% for  $\geq 3$  vaccines.

### Research frontiers

Hepatitis B infection is hyper endemic in Solomon Islands. Ongoing trans-

mission at birth and in early childhood is likely to continue to contribute to the significant burden of disease. However, there are no recent seroprevalence studies to document the current burden of disease. The research hotspot is to contribute a clearer understanding of the current status of chronic HBV infection in a cohort of antenatal women and provide evidence based information for national HBV prevention and control strategies.

## Innovations and breakthroughs

The hyper prevalence of hepatitis B in Solomon Island is well accepted but remains poorly defined with gaps in recent data on disease burden. This study enrolled 240 pregnant women attending antenatal care in Honiara and found a high rate of HBsAg and hepatitis B e antigen (HBeAg) prevalence with low level of awareness and vaccination uptake among pregnant women and their children respectively.

## Applications

This study found a high rate of HBsAg and HBeAg prevalence among pregnant women which suggests the increased risk of perinatal transmission of HBV. Moreover, the study provided background information on hepatitis B disease burden and described the various challenges and proposed integrated approach for HBV control in Solomon Islands.

## Peer-review

The study design, material-methods are appropriate for the aim. The results are typical for a HBV endemic population but somewhat limited. It would have been more interesting if anti-HBs and anti-HBc total results of the study group were also provided.

### Abstract

#### AIM

To study the prevalence, characteristics, risk factors and mortality at 28 d of acute-on-chronic liver failure (ACLF).

#### METHODS

A total of 100 cirrhotic patients admitted to our hospital for more than one day were included during the period between June 2013 and December 2015. We used the European Association for the Study of the Liver-Chronic Liver Failure-Consortium diagnostic criteria for ACLF, considering it as the acute decompensation of cirrhosis associated with the presence of one or more organ failure. For the diagnosis of organic failure the Chronic Liver Failure-Sequential Organ Failure Assessment score was used. Our population was divided into patients with and without ACLF. Clinical characteristics, presence of precipitating events, potential risk factors for developing ACLF and causes of mortality were analyzed. Mortality at 28 d was evaluated.

#### RESULTS

Twenty-nine patients (29%) developed ACLF criteria. Alcoholism, detected in 58 patients (58%), was the

major etiological agent of cirrhosis. Bacterial infections were recognized as a precipitating event in 41.3% of cases and gastrointestinal bleeding in 27.5%. No precipitating event was identifiable in 27.5% of patients with ACLF. Comparing patients with and without ACLF, statistically significant risk factors were: Child Pugh score  $10.2 \pm 2.1$  vs  $8.4 \pm 1.6$  ( $P < 0.0001$ ), MELD score  $20.7 \pm 8.5$  vs  $12.3 \pm 4$  ( $P < 0.0001$ ), presence of ascites 27 (93%) vs 43 (60.5%) ( $P = 0.001$ ), leukocytosis  $15300 \pm 8033$  per cubic millimeter vs  $10770 \pm 5601$  per cubic millimeter ( $P < 0.0001$ ), and high plasma levels of C reactive protein values  $50.9 \pm 46.4$  mg/L vs  $28.6 \pm 23.4$  mg/L ( $P < 0.0019$ ). Mortality rate was 62% (18 patients) vs 5.6% (4 patients), respectively ( $P < 0.0001$ ).

## CONCLUSION

We observed that the ACLF is a frequent entity in this group of patients and has a significantly higher mortality rate.

**Key words:** Acute-on-chronic liver failure; Acute liver decompensation; Cirrhosis; Ascites; Mortality

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Acute-on-chronic liver failure (ACLF) is an increasingly recognized entity that is gaining acceptance in recent times. It is characterized by an acute impairment of an underlying chronic liver disease with high short-term mortality, produced by the development of organic failures and associated with precipitating event. However, little is known about the development and progression of this syndrome. Guided by the European Association for the Study of the Liver-Chronic Liver Failure-Consortium diagnostic criteria and the CANONIC study, we could establish that the prevalence of ACLF in our center was 29%, and that Child Pugh advanced stage, MELD score, presence of ascites and inflammation parameters were significant risk factors for ACLF.

Dominguez C, Romero E, Graciano J, Fernandez JL, Viola L. Prevalence and risk factors of acute-on-chronic liver failure in a single center from Argentina. *World J Hepatol* 2016; 8(34): 1529-1534 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i34/1529.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i34.1529>

## INTRODUCTION

Acute-on-chronic liver failure (ACLF) is an increasingly recognized entity that includes the acute deterioration of a chronic liver disease, usually associated with a precipitating event, the development of one or more organ failure and high short-term mortality.

The term ACLF was initially coined in 1995<sup>[1]</sup>. There are more than thirteen different definitions up to date. Until worldwide diagnostic criteria are accepted, two consensual

definitions are commonly used<sup>[2]</sup>. The first, belonging to the Asian Pacific Association for the Study of the Liver, considers that the ACLF is an "acute hepatic insult manifesting as jaundice and coagulopathy, complicated within four weeks by ascites and/or encephalopathy in a patient with previously diagnosed or undiagnosed chronic liver disease"<sup>[3]</sup>. According to the second definition, developed in a joint symposium of the European Association for the Study of the Liver (EASL) and the American Association for the Study of Liver Diseases, ACLF is an "acute deterioration of pre-existing chronic liver disease, usually related to a precipitating event, and associated with increased mortality at three months due to multi-system organ failure"<sup>[4]</sup>.

Recently, an European consortium exclusively dedicated to the study of liver failure in patients with chronic liver disease (EASL-CLIF-Consortium) conducted the CANONIC study with the aim to define the ACLF and be able to identify those cirrhotic patients with a high risk of short-term mortality. Based on the analysis of 1343 cirrhotic patients, the EASL-CLIF-Consortium proposed as diagnostic criteria the acute decompensation of the liver disease (defined by the development of ascites, encephalopathy, gastrointestinal bleeding or bacterial infection) associated with the presence of one or more organ failure. The organ failure was defined by the Chronic Liver Failure-Sequential Organ Failure Assessment (CLIF-SOFA) score (Table 1) and a mortality at 28 d higher than 15%<sup>[5,6]</sup>.

Acute decompensation of cirrhosis is the leading cause of hospitalization in cirrhotic patients<sup>[7]</sup>. In many of these patients complications develop in the absence of organic failure, but in others they are associated with impaired function of kidneys, liver or other organs. The last group of patients, falling within the definition of ACLF, are those with a high risk of short term mortality.

The CANONIC study showed that ACLF is an extremely relevant and very common syndrome, with a prevalence of around 30%, differing from a mere acute decompensation by the presence of organ failure, the mortality rate 15 times higher, the clinical characteristics, the association with precipitating events and the parameters of systemic inflammation<sup>[8-10]</sup>.

Due to the lack of a worldwide accepted definition and diagnostic criteria, many aspects of this syndrome, such as prevalence, natural history, precipitating factors, clinical features and pathophysiological mechanisms remain unknown<sup>[11,12]</sup>.

The aims of our study were to determine the prevalence of ACLF in the cirrhotic patients of our institution using the diagnostic criteria established by the CANONIC study, to describe the clinical characteristics of ACLF, to assess the risk factors for developing ACLF, and to evaluate the mortality at 28 d, comparing the cases with and without ACLF.

## MATERIALS AND METHODS

In this prospective observational study we analyzed

**Table 1** Chronic liver failure-sequential organ failure assessment score

Organ/system	0	1	2	3	4
Liver (bilirubin, mg/dL)	< 1.2	≥ 1.2 to ≤ 2	≥ 2 to < 6	≥ 6 to < 12	≥ 12
Kidney (creatinine, mg/dL)	< 1.2	≥ 1.2 to < 2	≥ 2 to < 3.5	≥ 3.5 to < 5 or dialysis	≥ 5 or dialysis
Cerebral (HE grade)	No HE	I	II	III	IV
Coagulation (RIN, platelet count)	< 1.1	≥ 1.1 to < 1.25	≥ 1.25 to < 1.5	≥ 1.5 to < 2.5	≥ 2.5 or platelet count ≤ 20000 per cubic millimeter
Circulation (mean arterial pressure, mmHg), inotropic drugs (μg/kg per minute)	≥ 70	< 70	Dopamine ≤ 5 or dobutamine or terlipressin	Dopamine > 5 or E ≤ 0.1 or NE ≤ 0.1	Dopamine > 15 or E > 0.1 or NE > 0.1
Lungs (SpO <sub>2</sub> /FiO <sub>2</sub> )	> 512	> 357 a ≤ 512	> 214 a ≤ 357	> 89 to ≤ 214	≤ 89

The text in bold indicates the diagnostic criteria for organ failure. HE: Hepatic encephalopathy; E: Epinephrine; NE: Norepinephrine; FiO<sub>2</sub>: Fraction of inspired oxygen; SpO<sub>2</sub>: Pulse oximetric saturation.

patients with cirrhosis, diagnosed by a previous liver biopsy or by indirect signs (clinical examination, laboratory, imaging and endoscopy), who were hospitalized for more than one day in the Sanatorio Güemes, which is one of the biggest high complexity medical centers in Argentina, located in Buenos Aires City, with a capacity of 480 beds.

The protocol was approved by our institutional review board and patients gave the usual written informed consent for hospitalization, no additional procedures other than those indicated by the physicians, based on routine practice and international standards, were performed. Considering this fact, our institutional reviewers considered that another special consent was not required.

Patients were recruited between June 2013 and December 2015. Data were obtained from medical records, including previous episodes of decompensation (ascites, encephalopathy, spontaneous bacterial peritonitis, esophageal varices, variceal bleeding or hepatocellular carcinoma), physical examination, laboratory analysis, presence of potential precipitating factors (infections, active alcohol intake, gastrointestinal bleeding), and etiology of cirrhosis.

For the diagnosis of organic failure the CLIF-SOFA score was used (Table 1). Our population was divided into patients with and without ACLF. Within the group with ACLF the type and number of affected organs were analyzed and divided in 3 grades. ACLF grade 1 included patients with single kidney failure; patients with single failure of the liver, coagulation, circulation, or respiration who had a serum creatinine level ranging from 1.5 to 1.9 mg/dL and/or mild to moderate hepatic encephalopathy; and patients with single cerebral failure, who had a serum creatinine level ranging from 1.5 to 1.9 mg/dL. ACLF grade 2 included patients with failure of two organs and ACLF grade 3 included patients with failure of three or more organs.

After discharge, the mortality at 28 d was evaluated by monitoring on an outpatient basis or by telephone calls when patients did not attend the visit.

Clinical characteristics of each group, presence of precipitating events, potential risk factors for developing ACLF and causes of mortality were analyzed. Within the analyzed clinical parameters, the West-Haven scale for

encephalopathy grades was used<sup>[13]</sup>; ascites was classified in mild (mild ascites only detectable by ultrasound), moderate (moderate ascites evident by moderate symmetrical distension of abdomen) and severe (large or gross ascites with marked abdominal distension)<sup>[14]</sup>; circulation dysfunction implied arterial hypotension (mean arterial pressure below 70 mmHg) or requirement of inotropic drugs; and respiratory failure implied the need for mechanical ventilation.

Laboratory data included a complete blood analysis allowing the calculation of MELD and Child-Pugh scores. Inflammation parameters were evaluated by white blood cell count and C-reactive protein (CRP).

Both the clinical parameters and the laboratory results were recorded when patients were enrolled, when they showed some intercurrent or organic decompensation, and at discharge or previously to death.

### Statistical analysis

For statistical analysis, the  $\chi^2$  test or the Fisher test were used for dichotomous variables as appropriate. For continuous variables the Student *t* test was used. For risk factors, the OR with their respective 95%CI were calculated as association measures.

## RESULTS

A total of 100 patients were included, of which 67 were male (67%) and 33 female (33%). The mean age was  $60 \pm 11$  years and mean Child-Pugh score was  $9 \pm 1.9$ . Regarding to the etiology of cirrhosis, alcohol was found in 58 patients (58%), followed by hepatitis C infection and cryptogenic disease (Table 2).

The total of patients who fulfilled criteria for ACLF was 29 (29%), 10 of them (34.4%) were grade 1, 5 (17.3%) grade 2 and 14 (48.3%) grade 3 (Table 3). Seventeen patients (59%) had criteria for ACLF at admission to the hospital and 12 (41%) developed it during hospitalization, with an average time of presentation of 10 d. Renal failure was the prevalent organ failure for ACLF grade 1. For ACLF grade 2, coagulation failure was the prevalent finding followed by renal and respiratory failure. For ACLF grade 3, the prevalence of all organ failures was high with a significant impact in the circulatory and respiratory

ACLF: Acute-on-chronic liver failure.

system (Table 4).

Analyzing the possible precipitating factors in patients with ACLF, an infectious cause was recognized in 12 (41.3%), being pneumonia the main source of infection, and gastrointestinal bleeding in 8 (27.5%). One patient (3.4%) developed ACLF after a renal failure secondary to acute diarrhea. There was not an evident precipitating factor in 8 cases (27.5%) (Table 5). In the group of patients without ACLF, we observed the following clinical events: Gastrointestinal bleeding in 27 patients (38%), bacterial infections in 20 (29%), other causes such as constipation in 5 (7%) and no event in 19 (26%).

When patients with and without ACLF were compared, we observed, respectively: Male 23 (79%) vs 44 (62%) [ $P = 0.11$ , OR = 2.36 (95%CI: 0.78-7.43)], age  $60 \pm 11$  years vs  $60 \pm 11$  years ( $P = 1.00$ ), active alcohol intake in the last 3 mo 9 (31%) vs 22 (31%) [ $P = 1$ , OR = 1.00 (95%CI: 0.23-2.79)], Child Pugh  $10.2 \pm 2.1$  vs  $8.4 \pm 1.6$  ( $P < 0.0001$ ), MELD score  $20.7 \pm 8.5$  vs  $12.3 \pm 4$  ( $P < 0.0001$ ), previous episodes of ascites 18 (62%) vs 29 (41%) [ $P = 0.07$ , OR = 2.37 (95%CI: 0.89-6.33)], previous episodes of encephalopathy 9 (31%) vs 10 (14%) [ $P = 0.08$ , OR = 2.74 (95%CI: 0.87-8.69)], presence of esophageal varices 18 (62%) vs 37 (52%) [ $P = 0.38$ , OR = 1.5 (95%CI: 0.57-3.99)], prior variceal hemorrhage 4 (13.7%) vs 10 (14%) [ $P = 1.00$ , OR = 0.97 (95%CI: 0.23-3.84)], presence of ascites during hospitalization 27 (93%) vs 43 (60.5%) [ $P = 0.001$ , OR = 8.79 (95%CI: 1.80-8.10)], white blood cell count  $15300 \pm 8.033$  per cubic millimeter vs  $10770 \pm 5.601$  per cubic millimeter ( $P < 0.0001$ ), natremia  $133.3 \pm 6.9$  mEq/L vs  $135.1 \pm 5.3$  mEq/L ( $P = 0.16$ ), and CRP values  $50.9 \pm 46.4$  mg/L vs  $28.6 \pm 23.4$  mg/L ( $P < 0.0019$ ) (Table 6).

Twenty patients were hospitalized in the intensive care unit, 14 received mechanical ventilation and none had artificial liver support because it is not available

**Table 4** Type and number of organ failure *n* (%)

Organs failure	ACLF 1	ACLF 2	ACLF 3

at our center. ACLF resolved or improved in 11 patients (38%) during hospitalization: 7 patients (70%) in grade 1, 3 (60%) in grade 2 and only 1 (7%) in grade 3. In the group of ACLF, 18 patients (62%) died, due to septic shock 10, type 1 hepatorenal syndrome 3, shock without focus 3, upper gastrointestinal bleeding 1 and bronchoaspiration 1. The mortality was 30% in ACLF grade 1, 40% in grade 2 and 92% in grade 3. In the group without ACLF, 4 patients (5.6%) died, due to infection 3 and cardiac failure 1.

## DISCUSSION

ACLF is a syndrome different from traditional decompensated cirrhosis, not only because of the presence of organ failure and high mortality rate but also because of the alcoholic etiology of cirrhosis, the prevalence of some specific triggers such as bacterial infection and the higher level of systemic inflammation<sup>[15,16]</sup>. To recognize ACLF allows to identify those patients at high risk for death due to organ failure and the CANONIC study provided much more precise diagnostic criteria<sup>[4,5,15]</sup>. So, we followed these criteria in our center and we found a prevalence of 29%, similar to the 30.9% found in the CANONIC study<sup>[5,10]</sup>. It is interesting to point out that cirrhotic patients may develop ACLF during their stay in the hospital, with an incidence of 14.4%. This figure is quite higher than the 10.8% observed in the CANONIC study<sup>[5]</sup>.

It is noteworthy that 65.8% of our patients who developed ACLF had more than one organ involved (grades 2 and 3). This finding differs from the results of the CANONIC study showing that 64.3% of patients had only one organ involvement<sup>[5]</sup>. A possible explanation for this discrepancy may be that our patients had advanced stages of cirrhosis (Child-Pugh C 72%) and high prevalence of alcoholism as etiology of the cirrhosis (58% vs 48.6% in the CANONIC study). An advanced disease

**Table 6** Comparative results between groups with and without acute on chronic liver failure *n* (%)

	ACLF	No ACLF	<i>P</i> value	OR	95%CI
Age (yr $\pm$ SD)	60 $\pm$ 11	60 $\pm$ 11	1.00		
Male	23 (79)	44 (62)	0.11	2.3	0.78-7.43
Child Pugh (score $\pm$ DS)	10.2 $\pm$ 2.1	8.4 $\pm$ 1.6	< 0.0001

Serum sodium (mEq/L $\pm$ SD)	133.3 $\pm$ 6.9	135.1 $\pm$ 5.3	0.16		
CRP (mg/L $\pm$ SD)	50.9 $\pm$ 46.4	28.6 $\pm$ 23.4	0.002		
Mortality	18 (62)	4 (5.6)	< 0.0001		

OR: Odds ratio; 95%CI: Confidence interval 95%; SD: Standard deviation; CRP: C-reactive protein; ACLF: Acute-on-chronic liver failure.

may have been the trigger of irreversible pro- and anti-inflammatory mechanisms<sup>[10,17,18]</sup>. The commonest organ failure was the kidney failure (66%)<sup>[19,20]</sup>. The prevalence of circulatory and respiratory failure was high (51% and 58%) but significant only in patients with ACLF grade 3.

As expected by previous references, bacterial infections primarily and gastrointestinal bleeding secondly were the main precipitating events<sup>[5,21]</sup>. It is important to note that in 27.5% of cases we did not identify an evident precipitating factor to explain ACLF in 27.5% of cases, a fact that was previously observed by other authors<sup>[5]</sup>.

We found that Child-Pugh score, MELD score, presence of ascites, elevated leukocyte count and high CRP values parameters were significant risk factors for the development of ACLF. Although Child-Pugh and MELD scores were not considered as risk factors, the statistical significance of ascites, kidney dysfunction, hepatic encephalopathy, bilirubin, serum creatinine and international normalized ratio in the CANONIC study allows us to infer that our findings agree with these observations. The role of leukocyte count and CRP as inflammatory parameters were also emphasized by these authors<sup>[5,9]</sup>.

As it was previously observed, mortality was significantly higher in our patients with ACLF. Mortality in our patients with ACLF grade 1 was higher when compared with the figures reported by Gustot *et al.*<sup>[22]</sup> (30% vs 6% to 18%), but it was similar in patients with ACLF grade 2 and 3 (40% to 92% vs 42% to 92%). As it was also observed by these authors, mortality increased significantly when three or more organs were involved<sup>[5,10,22]</sup>.

The main strength of our investigation is the prospective design that allowed a rigorous collection of data and its main weakness is that it was performed in a single center with a limited number of patients. Despite this limitation, we can draw several conclusions from our results. ACLF is a syndrome that occurs with high frequency in cirrhotic patients hospitalized for decompensated liver disease, reaching a prevalence of 29%

in our centre. As noted in the literature, ACLF is a very dynamic syndrome. It resolved or improved in 38% of our patients, a figure lower than the 49% observed by Gustot *et al.*<sup>[22]</sup>. Patients may enter the hospital with ACLF but they may also develop it during their stay, there are risk factors that may predict its development and mortality significantly increases when it occurs. Consequently, it is important to recognize this entity, to be aware of its development, to correct the precipitating factors and perhaps to install a more aggressive therapy, in order to reduce the high mortality<sup>[15,23-25]</sup>. To overcome the limitations of our study and to achieve a better knowledge of the epidemiology and clinical characteristics of ACLF in our country, it would be desirable to transfer our bounded experience to a multicenter prolonged study.

## COMMENTS

### Background

Acute-on-chronic liver failure (ACLF) is an increasingly recognized entity that includes the acute deterioration of a chronic liver disease, usually associated with a precipitating event, the development of one or more organ failure and high short-term mortality. However, little is known about the development and progression of this syndrome. This study aimed to determine the prevalence of ACLF and describe the characteristics of this syndrome; assess the risk factors and analyze the mortality at 28 d.

### Research frontiers

Until the development of the CANONIC study there was no established definition of ACLF and the published definition were based only on expert opinions. In this study using the CANONIC diagnostic criteria, the authors describe the clinical characteristics, the prevalence and natural history of ACLF in cirrhotic patients of the authors' institution.

### Innovations and breakthroughs

As suggested in the literature, the authors observed that the ACLF is a frequent entity in this group of patients and has a significantly higher mortality rate.

### Applications

As ACLF is a frequent syndrome, it is important to recognize this entity, to be aware of its development and to install supportive measures in order to reduce the high mortality.

# Terminology

Acute-on-chronic liver failure: Acute deterioration of cirrhosis associated with organ/s failure and short term mortality.

# Peer-review

The paper is well written and includes information about a relevant topic.

### Abstract

Right umbilical portion (RUP) is a rare congenital anomaly associated with anomalous ramifications of the hepatic vessels and biliary system. As such, major hepatectomy requires a careful approach. We describe the usefulness of the Glissonean approach in two patients with vessel anomalies, such as RUP. The first patient underwent a right anterior sectionectomy for intrahepatic cholangiocarcinoma. We encircled several Glissonean pedicles that entered the right anterior section along the right side of the RUP. We temporarily clamped each pedicle, confirmed the demarcation area, and finally cut them. The operation was performed safely and was successful. The second patient underwent a left trisectionectomy for perihilar cholangiocarcinoma. We secured the right posterior Glissonean pedicle. The vessels in the pedicle were preserved, and the other vessels and contents were resected. Identifying the vessels for preservation facilitated the safe lymphadenectomy and dissection of the vessels to be resected. We successfully performed the operation.

**Key words:** Right anterior sectionectomy; Right umbilical portion; Glissonean approach; Left trisectionectomy; Glissonean pedicle; Cholangiocarcinoma; Hepatocellular carcinoma

**Core tip:** Right umbilical portion (RUP) is a rare congenital anomaly, and its presence is associated with anomalous ramifications of the hepatic artery, portal vein, and biliary system. Major Hepatectomies for patients with this anomaly are complicated and require a careful approach. The Glissonean approach is acknowledged as a successful technique. The targeted Glissonean pedicle to

be resected or preserved is easily identified by clamping; thus, the Glissonean approach can be used in various situations of hepatic resection. This report describes the usefulness of the Glissonean technique, especially in cases with an anomaly, such as RUP.

Ome Y, Kawamoto K, Park TB, Ito T. Major hepatectomy using the glissonean approach in cases of right umbilical portion. *World J Hepatol* 2016; 8(34): 1535-1540 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i34/1535.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i34.1535>

## INTRODUCTION

Right umbilical portion (RUP) is a rare congenital anomaly, and its reported incidence ranges from 0.2% to 1.2%<sup>[1-6]</sup>. The presence of RUP is associated with anomalous ramifications of the hepatic artery, portal vein, and biliary system. During anatomical liver resection, only the vessels feeding the area intended for resection should be resected, whereas the other vessels should be preserved. Consequently, major hepatectomies for cases with RUP are complicated and require a careful approach and attention to the anomalous branching of those vessels. Only a few hepatectomy cases with RUP have been reported in the English literature. Here, we report two successful cases with RUP who safely underwent anatomical hepatectomy. We also describe the usefulness of the Glissonean approach.

## CASE REPORT

### Case 1

A 70-year-old man with hepatitis C presented with a liver tumour. He had a past medical history of distal gastrectomy for gastric ulcer, Graves' disease, and diabetes mellitus. Laboratory tests showed normal levels of carcinoembryonic antigen (CEA), CA19-9 and alpha-fetoprotein (AFP) but elevated PIVKA-II at 808 mAU/mL. The indocyanine green retention rate at 15 min was 12.9% and the Child-Pugh score was 5 points, Grade A. He was diagnosed with intrahepatic cholangiocarcinoma or combined hepatocellular and cholangiocarcinoma located in segment 8. A computed tomography (CT) scan also revealed that his gallbladder was attached to the left side of the liver; RUP was noted (Figure 1).

The patient underwent right anterior sectionectomy (Figure 2). Laparotomy showed that the gallbladder was attached to the round ligament. After the mobilization of the right lobe, the gallbladder was resected. Then, the right anterior Glissonean pedicles, which ramified along the right side of the RUP, were extrahepatically separated and encircled with tape. We temporarily clamped each pedicle and confirmed the demarcation area and blood flow *via* ultrasonography. The demarcation area was the same as the three-dimensional image visualization *via* preoperative simulation. The liver parenchyma was

transected along the demarcation line using the Pringle manoeuvre. We finally ligated and cut the encircled right anterior Glissonean pedicles. The operation succeeded without injuring any of the vessels intended for preservation. The operation required 244 min, and the estimated blood loss was 776 mL.

Macroscopic findings showed an irregular mass, 25 mm in size. A histological examination revealed that the tumour was a poorly differentiated intrahepatic cholangiocarcinoma that invaded the intrahepatic portal vein. The patient was diagnosed as stage II (T2N0M0). All of the surgical margins were negative. He recovered uneventfully and was discharged on postoperative day 6.

### Case 2

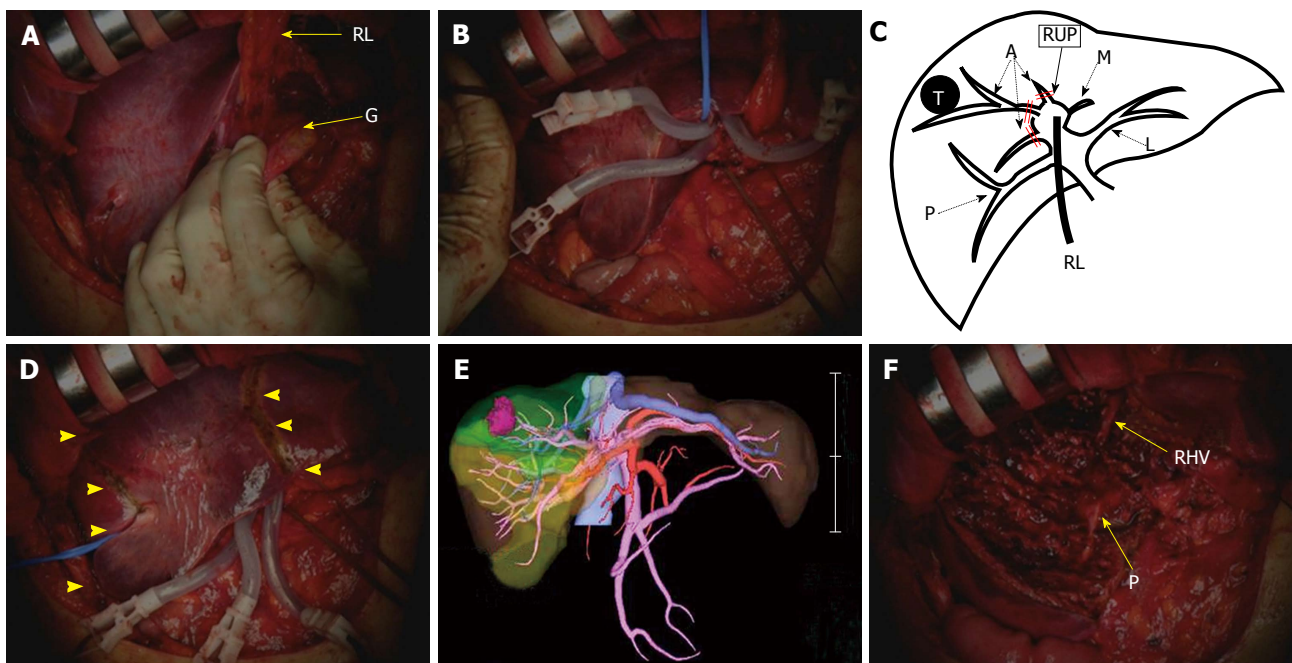

A 70-year-old woman presented with general fatigue and intrahepatic bile duct dilatation. Tumour markers, such as AFP, PIVKA-II and CEA, were normal, but CA19-9 was elevated at 843.6 U/mL. Other laboratory tests showed elevated ALP at 601 IU/L, elevated  $\gamma$ -GTP at 318 IU/L, and impaired serum albumin at 3.3 g/dL. Bilirubin was normal. The indocyanine green retention rate at 15 min was 4.6% and the Child-Pugh score was 6 points, Grade A. She was diagnosed with perihilar cholangiocarcinoma and RUP *via* ultrasound, CT and magnetic resonance cholangiopancreatography (Figure 3). The tumour involved the confluence of the left lateral, left medial, and right anterior hepatic ducts; the right posterior branch was intact.

The patient underwent left trisectionectomy with extrahepatic bile duct resection (Figure 4). First, Kocher's manoeuvre and lymphadenectomy around the pancreas head were performed. The distal common bile duct was transected at the level of the pancreas. Then, we performed lymphadenectomy in the hepatoduodenal ligament. The gallbladder was dissected and we secured and encircled the right lateral Glissonean pedicle with tape. The portal vein, the hepatic artery, and the hilar plate were separated from the other structures just proximal to the secured Glissonean pedicle. The vessels entering the pedicle were preserved and the other vessels and contents were resected. In the preoperative simulation, only one right posterior branch of the hepatic artery was identified. During the operation, however, two arteries were found entering the right posterior section. We preserved the vessels that nourished the right posterior section and resected the root of the left hepatic artery, the right anterior hepatic artery, and the common trunk of the left lateral portal vein and RUP; Next, the demarcation area was confirmed. The left side of the liver was fully mobilized, and the liver parenchyma was transected along the demarcation line; Finally, we cut the right posterior hepatic duct, and the specimen was removed. Hepaticojejunostomy to the right posterior bile duct and jejunojejunostomy were conducted, and the operation was successfully completed. The operative time was 697 min, and the estimated blood loss was 716 mL.

A histological examination showed moderately differen-

negative. The postoperative course was uneventful and this patient was discharged on postoperative day 13.

## DISCUSSION

RUP, previously known as a left-sided gallbladder, is a rare congenital anomaly. However, we occasionally encounter it in our daily medical procedures (*e.g.*, cholecystectomy). RUP is an anatomical anomaly in which the umbilical portion exists between the right anterior and left medial section. The right-sided round ligament adheres to the RUP. Other theories exist regarding liver segmentation with RUP. One is that segment 4 is absent<sup>[5]</sup>. Another

is that the right side of the RUP is comparable with the dorsal segment of the right anterior section and the left side of the RUP with the ventral segment of the right anterior section<sup>[7]</sup>. In this report, we defined RUP as the umbilical portion that exists between the right anterior and left medial section. Nagai *et al.*<sup>[1]</sup> reviewed the literature concerning this anomaly and classified the type of portal branching according to bifurcation type and trifurcation type. Nineteen cases with RUP have undergone hepatectomy in the English-language literature<sup>[1,3,6,8-15]</sup> (Table 1). RUP is associated with anomalous ramifications of the hepatic artery, portal vein, and biliary system; thus, surgery for cases with

**Table 1** The reported patients with right umbilical portion who underwent hepatectomy in the English-language literature

Ref.	Age (yr)	Sex	Disease	Surgical procedure	Type of intrahepatic portal venous branching
Uesaka <i>et al</i> <sup>[8]</sup>	53	Male	Liver metastasis of bile duct cancer	Right hepatectomy	Trifurcation type

Case 1	70	Male	Intrahepatic cholangiocarcinoma	Right anterior sectionectomy	Trifurcation type
Case 2	70	Female	Perihilar cholangiocarcinoma	Left trisectionectomy with extrahepatic bile duct resection	Trifurcation type

RUP requires careful procedures, especially with regard to hepatic resection. Previous reports described the importance of the thorough preoperative and intraoperative recognition of the various anomalies associated with RUP to prevent operative accidents.

CT and three-dimensional imaging have been developed, and preoperative simulation is of great help. We must preoperatively evaluate and recognize the anatomy precisely in cases with this anomaly. However, some vessels go unrecognized during the preoperative survey but can be encountered during the procedure, as was observed in case 2. Thus, paying special attention during the operation is important.

The Glissonean approach is acknowledged as a potentially successful technique for liver surgery, and it is widely performed for liver resection. The ramification pattern of the hepatic artery, portal vein and bile duct in the hepatoduodenal ligament often varies across patients. However, the Glissonean pedicle peripheral to the hilar plate, which is wrapped by connective tissue and contains the hepatic artery, portal vein, and bile duct, enters its proper area and never contains branches that nourish other areas. Consequently, the Glissonean pedicle transection peripheral to the extrahepatic hilar plate is a safe and sure method that enables the cutting of the intended vessels without damaging the vessels to

be preserved. Secondary and tertiary branches of the Glissonean pedicle peripheral to the hilar plate can usually be approached and transected extrahepatically. When the targeted Glissonean pedicle is transiently and selectively clamped, we can recognize the area to be resected. Surgeons do not have to consider any variations in the hepatoduodenal ligament. The Glissonean approach is a successful method, especially in cases with anomalous ramifications of the hepatic artery, portal vein and biliary system. The Glissonean pedicle to be resected was separated in case 1, whereas that to be preserved was encircled in case 2. The Glissonean approach can be used in various situations of hepatic resection and it contributes to a safe and secure liver surgery.

In conclusion, we successfully performed two major hepatectomies using the Glissonean approach in cases with RUP. The Glissonean approach is a useful method and contributes to a safe procedure for cases with an anomalous anatomy such as RUP.

## COMMENTS

### Case characteristics

A 70-year-old man with hepatitis C presented with a liver tumour without any symptoms; a 70-year-old woman presented with general fatigue and intrahepatic bile duct dilatation.

## Clinical diagnosis

Intrahepatic cholangiocarcinoma or combined hepatocellular and cholangiocarcinoma of the right umbilical portion (RUP); perihilar cholangiocarcinoma of the RUP.

## Differential diagnosis

Metastatic liver tumour; intrahepatic cholangiocarcinoma and inflammatory biliary stenosis.

## Laboratory diagnosis

The level of tumour marker PIVKA-II was elevated at 808 mAU/mL; other tumour markers were normal; the level of tumour marker CA19-9 was elevated at 843.6 U/mL; other tumour markers were normal.

## Imaging diagnosis

A computed tomography (CT) scan showed RUP and a 25-mm sized tumour peripherally enhanced in the arterial phase in segment 8; a CT scan showed RUP and a 25-mm sized tumour in the left side of the perihilar region, which caused dilatation of intrahepatic distal bile duct and almost occluded the RUP.

## Pathological diagnosis

A pathological examination showed a poorly differentiated intrahepatic cholangiocarcinoma invading the intrahepatic portal vein; the pathological findings revealed a moderately differentiated cholangiocarcinoma invading RUP.

## Treatment

The patient was treated with right anterior sectionectomy; the patient was treated with left trisectionectomy.

## Related reports

Only nineteen cases of hepatectomy among patients with RUP have been reported in the English-language literature.

## Term explanation

RUP is a congenital anomaly in which the umbilical portion exists between the right anterior section and left medial section.

## Experiences and lessons

This report emphasizes that the Glissonean approach is useful, especially in cases with anomalous ramifications of the hepatic artery, portal vein and biliary system such as RUP. This procedure contributes to a safe and secure liver surgery.

## Peer-review

This paper is the first report about major hepatectomy using the Glissonean approach in cases with RUP, and demonstrates the safety and usefulness of the Glissonean approach for hepatectomy in cases with anomalies such as RUP, and this report is very important guidance for surgeons who perform major hepatectomy for cases with RUP.

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Ahmed O Kaseb, MD, Associate Professor, Department of Gastrointestinal Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX 77030, United States

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Sorafenib is thus far the only systemic treatment for hepatocellular carcinoma (HCC) based on the results of two randomized controlled trials performed in Western and in Eastern countries, despite a poor response rate (from 2% to 3.3%) following conventional evaluation criteria. It is now recognized that the criteria (European Association of the Study of the Liver criteria, modified response evaluation criteria in solid tumors) based on contrast enhanced techniques (computed tomography scan, magnetic resonance imaging) aimed to assess the evolution of the viable part of the tumor (hypervascularized on arterial phase) are of major interest to determine the efficacy of sorafenib and of most antiangiogenic drugs in patients with HCC. The role of alpha-fetoprotein serum levels remains unclear. In 2016, in accordance with the SHARP and the Asia-Pacific trials, sorafenib must be stopped when tolerance is poor despite dose adaptation or in cases of radiological and symptomatic progression. This approach will be different in cases of available second-line therapy trials. Some recent data (in renal cell carcinoma) revealed that despite progression in patients who received sorafenib, this drug can still decrease tumor progression compared to drug cessation. Then, before deciding to continue sorafenib post-progression or shift to another drug, knowing other parameters of post-progression survival (Child-Pugh class, Barcelona Clinic Liver Cancer, alpha-fetoprotein, post-progression patterns in particular, the development of extrahepatic metastases and of portal vein thrombosis) will be of major importance.

**Key words:** Tumor evaluation; Response evaluation criteria in solid tumors; Sorafenib; Hepatocellular

carcinoma; Modified response evaluation criteria in solid tumors

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The response rate of sorafenib in hepatocellular carcinoma is low using standard parameters and is better assessed using new criteria based on tumor vascularization (European Association of the Study of the Liver criteria, modified response evaluation criteria in solid tumors). In case of minor progression, if sorafenib is well tolerated, knowing the predictors of post-progression survival will be of value in deciding whether to continue or stop sorafenib.

Raoul JL, Adhoute X, Gilabert M, Edeline J. How to assess the efficacy or failure of targeted therapy: Deciding when to stop sorafenib in hepatocellular carcinoma. *World J Hepatol* 2016; 8(35): 1541-1546 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i35/1541.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i35.1541>

## INTRODUCTION

In the majority of solid tumors, assessing the efficacy or failure of a systemic treatment is based on the tumor size, which is measured either bidimensionally using the World Health Organization criteria (WHO) criteria or unidimensionally using response evaluation criteria in solid tumors (RECIST). The response rate is used as a surrogate marker of drug efficacy in clinical trials, and in clinical practice, the evolution of tumor size is a major parameter to decide whether to stop or continue treatment. In a palliative setting, a treatment is continued as long as the disease is controlled (stable disease or response) and the regimen is tolerated. This approach is less simple with targeted therapies. In gastrointestinal stromal tumors, the efficacy of imatinib was associated with modifications in tumor content and not always with a decrease in tumor size. That finding leads researchers to propose new response criteria<sup>[1]</sup> not only based on tumor size but also based on combining size and density shown on computed tomography (CT) scans. The efficacy of bevacizumab that is associated with chemotherapy is also underestimated under the standard criteria. In a large series, Chun *et al*<sup>[2]</sup> demonstrated that CT scan-based morphologic criteria correlated better with the histological response than the response by RECIST in patients with liver metastases of colorectal cancer treated with bevacizumab-containing chemotherapy. In hepatocellular carcinoma (HCC), despite a low and disappointing response rate (2%) using conventional criteria in a phase II trial<sup>[3]</sup>, sorafenib is thus far the only systemic treatment<sup>[4,5]</sup> that has been demonstrated to improve overall survival. In this era of great expectations regarding new drugs, we would like

to briefly review these response evaluation criteria used in patients with HCC and the determination of when to continue or stop sorafenib treatment.

## CONVENTIONAL CRITERIA FOR EVALUATING TUMOR RESPONSE: WHO AND RECIST

The WHO criteria for defining a response to treatment are based on bidimensionally measured lesions (*i.e.*, the product of the greatest tumor diameter and the greatest perpendicular distance summed over all measured tumors). The RECIST guidelines were published in 2000, with the major change being that the RECIST 1.0 uses unidimensional measurements of the sum of the longest diameters of the tumors. All unmeasurable lesions are considered to be "non-target" lesions, and lymph nodes are not distinguished from extranodal lesions. Progression is defined by an increase of at least 20% of the sum of the longest diameter and the appearance of new lesions or the progression of a non-target lesion. In 14 studies, the application of the WHO criteria and RECIST to the same patients with a large range of cancers has shown similar results<sup>[6]</sup>. A few years later, the RECIST 1.1 criteria were published<sup>[7]</sup>, which better defined the minimal target size and reduced the number of allowed target lesions to 2 per organ and to a total of 5. It was also stated that a lymph node was considered as a target only if the short axis was larger than 15 mm. Ascites, pleural effusion, and lymph nodes from 10 mm to 14 mm on the short axis were considered as non-measurable lesions. Progression of non-target lesions was, by definition, considered to be a sign of disease progression. In a comparison of RECIST 1.0 with RECIST 1.1 in patients with lung cancer treated by erlotinib, the latter group demonstrated a slightly better performance<sup>[8]</sup>.

However, all these criteria were subject to failure in HCC. Ascites or pleural effusions are usually related to the underlying liver cirrhosis, lymph nodes are frequent and may be large in the case of viral hepatitis, and the appearance of non/malignant small liver nodules is common. Moreover, most non-surgical treatments target tumor vascularization (chemo-embolization, radio-embolization, antiangiogenic drugs), and efficacy might be poorly reflected by size only.

## NEW CRITERIA SPECIFICALLY DEDICATED TO HCC

Thus, new, more appropriate criteria were required to assess treatment efficacy in patients with HCC. European Association of the Study of the Liver (EASL) criteria were introduced during the EASL conference in Barcelona in 2000. They were based on bidimensional WHO criteria and the targeting of viable tumors, which were defined as those that showed contrast material-enhancing areas in the arterial phase of a dynamic CT

scan<sup>[9]</sup>. These criteria were later adapted to RECIST<sup>[10]</sup>; in addition to this new definition of target lesions, non-target lesions were revisited, and new hepatic nodules were considered as evidence of progression only if they had typical imaging and a longest diameter of at least 10 mm. Cytopathological confirmation of the neoplastic nature of any effusion that appeared or worsened was required. These new parameters, named modified RECIST (mRECIST), were considered to be a better tool for assessing HCC tumors<sup>[11]</sup>. Several Japanese authors proposed response evaluation criteria in cancer of the liver (RECICL), based on the bidirectional measurement of tumors showing arterial enhancement and considering non-hypervascularized tumors<sup>[12]</sup>. In a series of 156 patients receiving sorafenib for more than 30 d, response rates and the evaluation of overall survival by mRECIST and RECICL were similar. Recently, mRECIST was prospectively validated<sup>[13]</sup> in a phase 3 study (brivanib in second-line treatment). In this study comparing 395 patients who progressed after sorafenib was administered or were intolerant (brivanib to placebo; 2:1 ratio), tumor assessment every 6 wk by contrast-enhanced CT or magnetic resonance imaging was performed by a central review using mRECIST. A partial response was achieved in 8% of patients who received brivanib and 2% of patients who received placebo; the median overall survival was 16.4 mo for mRECIST responders and 8.3 mo for non-responders, and mRECIST evaluation had a prognostic value in multiparametric analysis.

Another way to evaluate tumor vascularization is contrast-enhanced ultrasound. In a short series of 19 patients (16 who received sorafenib and 3 who received sunitinib), this technique seemed effective at distinguishing progressors from non-progressors at 1 mo<sup>[14]</sup>. In a prospective series of 37 patients treated with sorafenib and explored by contrast-enhanced ultrasound before treatment and on days 7, 14 and 28, Sugimoto *et al.*<sup>[15]</sup> found that this technique was not only predictive of tumor response (tumor vascularization) but also of major adverse events (liver parenchyma vascularization). Additional data are still necessary to validate these results.

The impact of alpha-fetoprotein (AFP) evaluation is unclear. In a series of 72 patients who had an elevated baseline AFP and were treated with different antiangiogenic drugs (thalidomide, bevacizumab), a decline of > 20% from the baseline AFP level within the first 4 wk (early AFP response) was associated with a higher response rate and a longer PFS and OS<sup>[16]</sup>. In contrast, in patients who received brivanib<sup>[17]</sup>, a longer survival rate was not associated with either an early AFP response (*i.e.*, a decrease by more than 20% from baseline within the first 4 week) or an AFP response (*i.e.*, an AFP decrease by more than 50% from baseline). In a Japanese retrospective study<sup>[18]</sup>, the best way to assess prognosis was a combination of mRECIST and AFP ratio (AFP under treatment/AFP before treatment), but this ratio (< or > 1) was only associated with survival at 8 wk.

## COMPARISON OF THESE RESPONSE EVALUATION CRITERIA IN HCC CASES

After transarterial chemoembolization (TACE) and percutaneous ablation in 55 patients, Forner *et al.*<sup>[19]</sup> demonstrated that RECIST missed all complete responses (including patients treated by curative options) and underestimated the extent of tissue necrosis. The authors concluded that RECIST should not be used and that dynamic imaging techniques and evaluations must become the standard for assessing treatment efficacy. In a series of 143 patients with HCC who underwent TACE, a comparison of various response criteria showed that volumetric functional imaging is better correlated with outcome than other parameters and that AFP serum levels<sup>[20]</sup> and new 3D-imaging approaches are of great value in differentiating the responders from the non-responders to TACE<sup>[21]</sup> and can be used early to predict outcome after initial TACE. Shim *et al.*<sup>[22]</sup> compared WHO, RECIST, EASL and mRECIST in a cohort of 332 patients with intermediate HCC treated by TACE. They concluded that the enhancement models (EASL guidelines and mRECIST) were the best independent predictors of overall survival after chemoembolization. Similarly, the same results were found in an English series of 83 patients<sup>[23]</sup>. Thus, measuring the viable part of the tumor seems to be the best option after loco-regional treatment of HCC.

In the seminal SHARP<sup>[4]</sup> and AP<sup>[5]</sup> trials, the response rates using RECIST were 2% and 3.3% for patients who received sorafenib and 1% and 1.3% for those who received placebo, respectively; however, the overall survival analysis was clearly in favor of sorafenib, showing a discrepancy between the response rate by RECIST and outcome, with sorafenib efficacy being related to an increase in the time to progression. Many retrospective series have analyzed tumor responses using different criteria for patients receiving sorafenib. Their common features were that the evaluation of the viable part of the tumor based on arterial enhancement provided better results than the usual parameters and showed a real response rate and, thus, should be used for assessing treatment efficacy. Edeline *et al.*<sup>[24]</sup>, in a series of 53 patients, determined that 1 out of 10 patients considered as PD by RECIST was scored as SD using mRECIST. Forty-two patients evaluated as stable by RECIST were reassessed as complete response in 1 case, partial response in 10 cases, SD in 29 cases and PD in 2 cases using mRECIST. Then, the objective response rate of 1.9% by RECIST increased to 22.6% with mRECIST. The mRECIST result was associated with outcome, as those initially considered as SD by RECIST but as responders ( $n = 11$ ), stable ( $n = 29$ ) or progressive ( $n = 2$ ) by mRECIST had different median overall survival rates of 17.1, 9.7 and 3.7 mo, respectively. However, there was no difference between these two criteria regarding the median time to progression. Another retrospective study<sup>[25]</sup> compared RECIST 1.1 with vascularization-based criteria

**Table 1** Parameters of post-progression survival for patients receiving sorafenib

Performance status
Child-Pugh class
BCLC class
CLIP score

(Choi criteria, EASL criteria, and mRECIST). The response rates were 3%, 51%, 28% and 28%, respectively, in a cohort of 64 patients treated using sorafenib. The tumor response following RECIST 1.1 did not correlate well with the overall survival rate, whereas other criteria were more appropriate to identify responders with longer survival rates. In two phase II trials (101 patients) evaluating brivanib, an independent review compared the outcomes between the WHO criteria and mRECIST<sup>[17]</sup>. The response rates were higher with mRECIST vs WHO in both cohorts, and PD assessed by mRECIST, was associated with a poorer overall survival rate than when assessed using the WHO criteria.

Thus, these vascularization-based criteria are better than size-only criteria to categorize responders. However, the essential problem exists: How do we define when sorafenib treatment is no longer effective? Progression can be related to an increase in tumor size (or of its viable part) and also to the appearance of new liver nodules (considering vascularization, size, and evolution), effusion and ascites (cytology required), and lymph nodes (size and vascularization). These parameters are listed in a recent paper from the BCLC<sup>[26]</sup>. However, is progression a strict criterion to stop sorafenib treatment?

## IN 2016, WHEN TO STOP SORAFENIB?

In the SHARP trial, treatment was continued until both radiological and symptomatic progression or unacceptable toxicity occurred. In our experience, many patients seem to clinically benefit from the drug despite progression; in clinical practice, progression is not always a clear indication to stop sorafenib, particularly if there is no second-line trial available. In patients with poor prognostic factors at progression (worsening of performance status or of Child-Pugh status), cessation of the drug is recommended. In contrast, if the patients are candidates for second-line therapies, then inclusion is the best option if available. In other cases, we can postulate that sorafenib may retain some efficacy in certain instances despite tumor progression and that cessation of the drug might lead to an acceleration of tumor growth. In metastatic renal cell cancer, some data

**Figure 1** Proposed algorithm for deciding to continue or stop sorafenib in patients with hepatocellular carcinoma. ce CT scan: Contrast-enhanced computed tomography scan; ce MRI: Contrast-enhanced magnetic resonance imaging; DC: Disease controlled; PD: Progressive disease; BSC: Best supportive care.

show that, at progression, the tumor growth rate is lower than before initiation of the treatment using sorafenib and lower than will be observed after cessation of the drug. More interestingly, in renal cell carcinoma, this persistent activity beyond progression with an apparent flare-up effect after drug discontinuation of the drug was observed only with sorafenib and not with everolimus<sup>[27]</sup>. Then, even after progression, this treatment can participate in slowing down the disease. However, continuing sorafenib treatment after progression can be of interest only for patients who have a reasonable life expectancy and an excellent tolerance of the drug. Analysis of post-progression survival (Table 1) showed that, in addition to performance status, Child-Pugh score, and macrovascular invasion at progression, some other parameters are valuable. These include AFP, time to progression (correlation between time to progression using sorafenib and post-progression survival)<sup>[28]</sup>, and pattern of progression<sup>[29]</sup>. Post-progression survival is significantly worse for patients who developed new extrahepatic lesions compared to patients with intra- or extra-hepatic growth or new intrahepatic lesions. These data in a Spanish cohort were later confirmed in Asian patients<sup>[30,31]</sup>. Thus, continuing sorafenib is a possibility if second-line trials are unavailable or if the patient cannot be included. This is particularly relevant for patients who had mild intrahepatic progression, who had a good PS with no worsening in BCLC or the Child-Pugh scores, and who had progressed very slowly (Figure 1).

## CONCLUSION

Contrast-enhanced imaging techniques using mRECIST criteria are the best objective approach to appreciate the efficacy of vascularization targeting agents, particularly sorafenib. The value of AFP serum levels is not clear and not sufficient to impact therapeutic decisions. The enrollment of progressing patients in second-line trials is the best option. If this is not possible, then sorafenib must be discontinued if patients have poor prognostic factors or poor tolerance. In contrast, if patients do not have worsening PS or Child-Pugh classification or

if macrovascular invasion occurs, then sorafenib can be pursued; however, we must consider the important prognostic values of the progression pattern.

## Abstract

### AIM

To investigate the influence of *PNPLA3* genotype in heavy drinkers on serum markers and liver stiffness (LS) during alcohol withdrawal and its association with histology.

### METHODS

Caucasian heavy drinkers ( $n = 521$ ) with a mean alcohol consumption of 192.1 g/d (median alcohol consumption: 169.0 g/d; 95%CI: 179.0-203.3) were enrolled at the Salem Medical Center, University of Heidelberg. LS was measured by transient elastography (Fibroscan, Echosens SA, Paris, France). LS and serum markers were prospectively studied in these patients with all stages

of alcoholic liver disease (steatosis, steatohepatitis, fibrosis) prior and after alcohol detoxification with a mean observation interval of  $6.2 \pm 3.2$  d. A liver biopsy with histological analysis including the Kleiner score was obtained in 80 patients.

## RESULTS

The *PNPLA3* rs738409 genotype distribution for CC, CG and GG was 39.2%, 52.6% and 8.2%. GG genotype primarily correlated with histological steatohepatitis ( $r = 0.404$ ,  $P < 0.005$ ), ballooning ( $r = 0.319$ ,  $P < 0.005$ ) and less with steatosis ( $r = 0.264$ ,  $P < 0.05$ ). Mean LS was lowest in CC carriers (13.1 kPa) as compared to CG and GG carriers (17.6 and 17.2 kPa). Notably, LS primarily correlated with fibrosis stage ( $r = 0.828$ ,  $P < 0.005$ ), ballooning ( $r = 0.516$ ,  $P < 0.005$ ), steatohepatitis ( $r = 0.319$ ,  $P < 0.005$ ) but not with steatosis. After alcohol withdrawal, LS did not change in CC carriers, significantly decreased in CG-carriers from 17.6 to 12.7 kPa but to a lesser extent in GG carriers from 17.6 to 14.5 kPa. This was due to prolonged resolution of inflammation with significantly elevated aspartate transaminase levels after alcohol withdrawal in GG carriers. Non-invasive fibrosis assessment by LS in all patients showed a significantly higher F0 rate as compared to the biopsy cohort (47% vs 6%) with 3.8% more CC carriers while 3.7% less were seen in the F4 cirrhosis group. Thus, about 20% of patients with alcoholic liver cirrhosis would be attributable to *PNPLA3* G variants. The OR to develop cirrhosis corrected for age, gender and body mass index was 1.295 (95%CI: 0.787-2.131) for CG + GG carriers.

## CONCLUSION

In heavy drinkers, *PNPLA3* GG primarily correlates with ballooning/steatohepatitis but not steatosis resulting in a delayed inflammation-associated resolution of LS. Consequently, sustained ballooning-associated LS elevation seems to be a potential risk factor for fibrosis progression in *PNPLA3* GG carriers.

**Key words:** Liver stiffness; Alcoholic liver disease; Adiponutrin; *PNPLA3*; Transient elastography; Alcohol withdrawal; Inflammation

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The role of the *PNPLA3* rs738409 variant (CG and GG) on histology and liver stiffness in response to alcohol detoxification was studied in a large monocentric cohort of heavy drinkers with various stages of ALD. About 20% of our patients with alcoholic liver cirrhosis were attributable to *PNPLA3* G variants with an OR to develop cirrhosis of 1.295. Our data further show that *PNPLA3* GG carriers primarily develop ballooning and not steatosis causing a delayed resolution of liver stiffness after alcohol withdrawal. We suggest that the delayed ballooning-associated stiffness elevation may contribute to fibrosis progression (see also the sinusoidal pressure hypothesis).

Primary liver injury and delayed resolution of liver stiffness after alcohol detoxification in heavy drinkers with the *PNPLA3* variant I148M. *World J Hepatol* 2016; 8(35): 1547-1556 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i35/1547.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i35.1547>

## INTRODUCTION

Alcoholic liver disease (ALD) is the most common chronic liver disease in the Western world<sup>[1]</sup>. ALD encompasses a broad spectrum of disorders ranging from simple steatosis to severe forms of liver injury, including alcoholic steatohepatitis, fibrosis and cirrhosis. Although the majority (80%-90%) of heavy drinkers with an alcohol consumption > 80 g/d develop steatosis, only 35% show signs of inflammation and about 8%-20% progress to cirrhosis<sup>[2]</sup>. The underlying molecular mechanisms of disease progression, especially why some patients rapidly progress to severe liver disease, are still poorly understood. In addition, it remains unclear whether steatosis necessarily precedes steatohepatitis or is a coinciding bystander. The role of environmental factors that affect disease progression such as drinking habits and comorbidities has been known for many years<sup>[3]</sup>. However, twin studies, the enhanced sensitivity of female drinkers and the fact that only a minority of patients progress to cirrhosis despite heavy drinking clearly suggest a genetic pre-disposition<sup>[4,5]</sup>.

Recent studies in multiethnic populations with non-alcoholic fatty liver disease (NAFLD) and ALD have demonstrated that the single-nucleotide polymorphism, the rs738409 variant, that encodes for an isoleucine to methionine substitution at position 148 (I148M) in the patatin-like phospholipase-3 (*PNPLA3*/*Adiponutrin*) gene is a strong disease modifier by influencing steatosis, liver enzymes and fibrosis progression<sup>[6-12]</sup>. So far, the function of *PNPLA3* and the effect of the amino acid substitution remain controversial. *PNPLA3* is closely related to *PNPLA2*/*ATGL*, the major hormone-sensitive lipase of adipose tissue, sharing 56% amino acid identity in the patatin-like domain<sup>[13,14]</sup>. *PNPLA3* is expressed in adipocytes, hepatocytes and hepatic stellate cells<sup>[15-18]</sup>. Despite many efforts, the physiologic role of *PNPLA3* and its direct action in the liver is still incompletely understood and it remains unclear whether the I148M substitution in *PNPLA3* directly causes steatosis, lipotoxicity, or both.

*PNPLA3* GG carriers not only more rapidly progress toward fibrosis but also show elevated liver stiffness (LS)<sup>[19]</sup>. Non-invasive measurement of LS by ultrasound-based elastographic techniques such as transient elastography (TE) are increasingly used to screen for liver fibrosis<sup>[9,20-25]</sup>. However, various conditions have been shown to increase LS in the absence of fibrosis including inflammation and liver damage<sup>[26-28]</sup>, congestion<sup>[29]</sup>, cholestasis<sup>[30]</sup>, arterial pressure<sup>[31]</sup> food intake<sup>[32,33]</sup> or amyloidosis<sup>[34,35]</sup>. For these reasons, we here study in

detail the impact of *PNPLA3* I148M substitution on LS and histology in a large population of heavy drinkers primarily admitted to the hospital for alcohol withdrawal. We further analyze the impact of alcohol withdrawal on LS depending on *PNPLA3* status. Our data further suggest that the sustained and drinking-associated LS elevation in *PNPLA3* GG carriers is most likely associated with ballooning and seems to contribute to fibrosis progression.

## MATERIALS AND METHODS

### Patients

Caucasian heavy drinkers (*n* = 521, 148 females/369

males, age range 22-87 years) with a mean alcohol consumption of 192.1 g/d (median alcohol consumption: 169.0; 95%CI: 179.0-203.3) were enrolled at the Department of Gastroenterology, Salem Medical Center in Heidelberg. Patients presented primarily for alcohol detoxification with a mean duration of chronic alcohol consumption of 19.9 years. Patient's characteristics are given in Table 1, a more refined *PNPLA3* genotype-associated data presentation is shown in Table 2. All patients underwent careful clinical examination, standard laboratory routine (venous blood sampling), abdominal ultrasound and liver stiffness measurement. Inclusion criteria were daily alcohol consumption > 60/80 g/d, age > 18 years, and successful assessment of LS. Other causes of liver diseases (exclusion criteria) were ruled out serologically in all patients by screening for AMA, ANA, HCV and HBV. The study protocol was reviewed and approved by the local Ethics Committee of the University of Heidelberg and all patients gave written informed consent prior to inclusion. Laboratory parameters, TE were performed both at day of admission and release with a mean observation interval of 6.2 ± 3.2 d.

### Liver histology and immunostainings

Eighty patients (15.4%) underwent liver biopsy using the Menghini technique (mean biopsy lengths 15.6 mm). Specimens were fixed in formalin and embedded in paraffin. Two experienced pathologists (TL and CL) blinded to the patient's data analyzed all liver biopsies independently. For histological analysis, 4 µm sections were dewaxed and stained with hematoxylin and eosin, Chromotrop-Anilinblue and Sirius-Red using standard procedures. Histological semiquantitative scoring of macro- and microvesicular steatosis, lobular inflammation, hepatocellular ballooning, Mallory-Denk bodies and apoptosis as well as fibrosis staging was performed exactly as described by Kleiner *et al.*<sup>[36]</sup>. In addition, fibrosis was also assessed using the semiquantitative method of Chevallier *et al.*<sup>[37]</sup> and collagen content was quantified by computer-assisted image analysis of Sirius-Red stained sections (morphometry). The histological diagnosis of steatohepatitis was based on the minimal criteria of steatosis (any degree), lobular inflammation and ballooning<sup>[38]</sup>.

### TE and non-invasive fibrosis assessment in ALD patients

LS was measured by TE (Fibroscan, Echosens SA, Paris, France) using the M<sup>[39]</sup> or XL probe<sup>[40,41]</sup>. TE was performed by physicians with at least 12 mo of experience in abdominal ultrasound and transient elastography on the right lobe of the liver in intercostal position according to established protocols<sup>[25]</sup>. Fibrosis stages were determined using the recently established aspartate transaminase (AST)-adapted cut-off values<sup>[42]</sup>. In patients with two measurements prior and after alcohol detoxification, the second measurements were used with less pronounced steatohepatitis and transaminase elevation, since such conditions correlate better with histology<sup>[9,25]</sup>. In addition, liver size, spleen size, ascites formation and semiquan-

titative liver steatosis (0-3) were assessed by abdominal ultrasound.

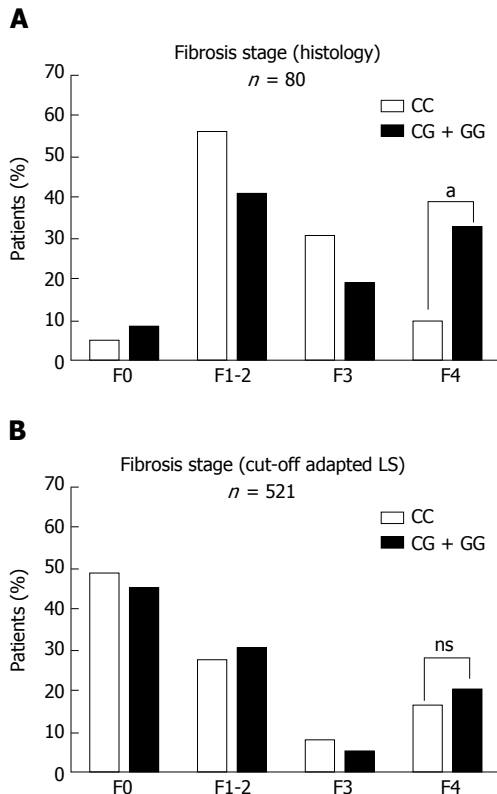

### ***PNPLA3* genotyping**

Genomic DNA was isolated from EDTA anti-coagulated blood using standard protocols. The *PNPLA3* coding SNP I148M was genotyped using tetra-primer ARMS polymerase chain reaction (PCR) technique on the GeneAmp PCR System 2400 (Applied Bioscience) using standard protocol. Primers were designed using Batch Primer 3 software<sup>[43]</sup>, synthesized by Eurofins MWG Operon (Ebersberg, Germany) and are available upon request. PCR reactions were performed in a total volume of 25 µL, containing approximately 30-50 ng of template DNA, 1 × PCR buffer, 2.5 mmol/L MgCl<sub>2</sub>, 0.2 mmol/L dNTPs, 2 nmol/L of outer primer and 20 nmol/L inner allele-specific primers and 1U of Taq polymerase (Roche, Penzberg, Germany). Post-PCR allelic discrimination was

carried out using horizontal non-denaturing polyacrylamide gel (10%) electrophoresis followed by ethidium bromide staining and visualization on a UV transilluminator. To ensure genotyping quality, we included negative controls and DNA samples with known *PNPLA3* genotypes as internal controls.

### **Statistical analysis**

We used descriptive statistics to compute equally distributed data, including means, standard deviations and frequencies. Not normally distributed data were log transformed before statistical analysis. Comparisons of the genotype distribution of CC, GG and combined CG and GG were performed and the Spearman correlation or  $\chi^2$  test for non-parametric variables (regression coefficient *r*, *P*) was used to determine the associations between laboratory findings, LS, histological scores and the genotypes. To determine whether there are significant

**Figure 1** Distribution of fibrosis stages using (A) histology (Kleiner fibrosis score F0-4) or (B) non-invasive liver stiffness measurement (aspartate transaminase-adapted cut-off values). <sup>a</sup> $P < 0.05$ . ns: Not significantly; LS: Liver stiffness.

differences between the variants (CC, CG, GG or CG combined with GG) we used a two-sample Student's *t*-test when the data were normally distributed. Binary logistic regression analysis was calculated to proof possible effects of genotype, gender, age and body mass index (BMI) on the outcome of AST-adapted cut-off values for fibrosis staging. Statistical calculations were performed with SPSS (version 21.0, IBM, SPSS) or SAS (version 9.4, SAS) software and two-sided *P* values  $< 0.05$  were considered statistically significant. Statistical methods of this study were reviewed by Thomas Bruckner from Institute of Medical Biometry and Informatics, University of Heidelberg, Heidelberg, Germany.

## RESULTS

### *PNPLA3* rs738409 GG carrier show more cirrhosis

The *PNPLA3* rs738409 genotype distribution in our cohort of 521 ALD patients was 39.2%, 52.6% and 8.2% ( $n = 204$ , 274 and 43) for CC, CG and GG (Table 2). Notably, fibrosis distribution differed markedly in the non-invasively ( $n = 521$ ) vs histologically ( $n = 80$ ) assessed cohorts (Figure 1), histologically characterized patients showed only a small fraction of F0 stages (6%,  $n = 5$ ). In contrast, the F0 fraction was much higher in the non-invasively assessed cohort by LS (47%,  $n = 245$ , Figure 1B). In both approaches, CG + GG carriers had more F4 cirrhosis as compared to CC carriers as shown in Figure

**Table 3** Risk factors associated with F4 cirrhosis

Factor	OR	95%CI	P value
<i>PNPLA3</i> G (CG + GG)	1.295	0.787-2.131	$> 0.05$
Gender	0.855	0.496-1.475	$> 0.05$
Age	1.040	1.017-1.064	$< 0.001$
BMI	1.037	0.983-1.093	$> 0.05$

BMI: Body mass index; OR: Odds ratio; *PNPLA3*: Adiponutrin.

1A (9.3% vs 32.4%) and 1B (16.3% vs 20.0%). CC carriers represented 42.1% of the F0 cohort but 35.5% of the F4 cohort. In other words, about 3.8% more CC carriers had F0 while they were 3.7% less frequent in the non-invasively assessed F4 cohort. Both cohorts did not differ significantly with respect to age and mean drinking duration (approximately 20 years). Linear regression analysis corrected for age, gender and BMI calculated an OR of 1.295 (95%CI: 0.787-2.131) for CG + GG carriers to develop F4 cirrhosis (Table 3). Taken together, our study indicates a *PNPLA3*-attributable effect on fibrosis stage. Notably and as could be expected, the non-invasively characterized cohort had a much larger proportion of non-fibrotic patients.

### *PNPLA3* rs738409 GG carriers have no pronounced metabolic phenotype

Since *PNPLA3* rs738409 SNP has been primarily identified in NAFLD patients, we next characterized typical features of the NAFLD phenotype. No significant differences were observed between CC, CG and GG carriers with regard to BMI (25.4 vs 25.1 vs 25.6), HbA1c (5.6% vs 5.6% vs 5.8%), and serum fasting glucose concentrations (112 mg/dL vs 108 mg/dL vs 111 mg/dL). This was also the case with regard to coronary heart disease, type II diabetes, smoking habits (assessed by pack years) and arterial hypertension (Table 2 and data not shown). Likewise, no significant differences were observed between levels of high-density lipoprotein and low-density lipoprotein cholesterol and triglycerides (TG) although TG levels were notably higher in GG carriers (Table 2). In summary, in this large cohort of heavy drinkers, GG is associated with advanced fibrosis in the absence of a typical NAFLD-associated metabolic phenotype.

### Ballooning/steatohepatitis is the predominant histological feature of *PNPLA3* rs738409 GG carrier

To learn more about histological association with the *PNPLA3* carrier status, we assessed steatosis, inflammation and fibrosis using the Kleiner and the semiquantitative Chevallier score. Interestingly, GG genotype primarily correlated with steatohepatitis ( $r = 0.404$ ,  $P < 0.005$ ), ballooning ( $r = 0.319$ ,  $P < 0.005$ ), less with steatosis ( $r = 0.264$ ,  $P < 0.05$ ) but not significantly with fibrosis (Table 4). In line with this, CC genotype correlated negatively with ballooning ( $r = -0.221$ ,  $P < 0.05$ ). These data were mirrored in the direct comparison of the genotypes. More fibrosis and ballooning was

**Table 4** Spearman rank correlation of *PNPLA3* carrier status and liver stiffness with histological parameters

Liver stiffness (kPa)	-0.045	0.017	0.037	1.000

Liver stiffness primarily correlates with fibrosis and liver damage but not significant with steatosis. In contrast, GG carrier status is tightly associated with liver injury and weakly with steatosis. <sup>a</sup>*P* < 0.05 vs <sup>b</sup>*P* < 0.01. *PNPLA3*: Adiponutrin.

present in the CG + GG carriers (Supplemental Table 1). Interestingly, neither a significant association was found with serum markers of liver damage (data not shown), with signs of liver cirrhosis in the ultrasound and with LS. Taken together, liver injury such as ballooning and steatohepatitis are the primary histological features associated with GG genotype in heavy drinkers while fibrosis and steatosis are less pronounced.

#### **LS is predominantly associated with fibrosis and ballooning/steatohepatitis but not steatosis**

Since previous studies indicated a higher LS in carriers of the *PNPLA3* risk allele (CG + GG) in various liver diseases and LS is increasingly used to screen for liver fibrosis, we next carefully analyzed the correlation of LS with histological subscores and the *PNPLA3* status (Table 4). As expected, LS showed a very tight and significant association with fibrosis stage ( $r = 0.828$ ,  $P < 0.005$ ) but also with ballooning ( $r = 0.692$ ,  $P < 0.005$ ) and steatohepatitis ( $r = 0.391$ ,  $P < 0.005$ ). Notably, no correlation was observed with steatosis ( $r = 0.096$ , ns). In addition, no significant correlation was seen between LS and *PNPLA3* genotype. Taken together, in a cohort of heavy drinkers, LS is correlated with fibrosis, liver injury and inflammation but not with steatosis and the *PNPLA3* status.

#### **Elevated LS in *PNPLA3* rs738409 GG carriers and a delayed resolution after alcohol withdrawal**

Mean LS was lowest in CC carriers (13.1 kPa) and significantly higher in CG carriers (17.6 kPa, Figure 2). LS was likewise elevated in GG carriers (17.2 kPa) without reaching statistical significance due to the limited number of patients (8.2%). Interestingly, almost no change was observed in CC carrier after alcohol withdrawal (12.0 kPa, LS2). In contrast, LS significantly decreased in CG

carriers to comparable 12.7 kPa after withdrawal from alcohol. Despite a longer observation interval of 6.6 d, LS decreased slower in GG and remained higher (14.5 kPa). This was most likely due to sustained inflammation/ballooning as reflected by elevated AST levels, which were significantly higher after alcohol withdrawal (Figure 2B, Table 2). In summary, GG-associated liver damage results in a reversible, inflammation-associated increase of liver stiffness. In addition, GG carriers show a slower resolution of liver damage and LS after withdrawal from alcohol.

## **DISCUSSION**

We here show in a large monocenter cohort of histologically and non-invasively characterized heavy Caucasian drinkers that the SNP rs738409 in *PNPLA3* (CG and GG) is primarily associated with ballooning/steatohepatitis but less with steatosis. Importantly and as seen previously, G carriers (CG + GG) had higher initial LS values as compared to CC carriers. Notably and in some contrast to the genotype analysis, LS was primarily correlated with fibrosis stage, ballooning/steatohepatitis but not at all with steatosis. GG carriers showed a slower resolution of liver damage and LS after withdrawal from alcohol. Since AST levels were significantly elevated in GG carriers after withdrawal from alcohol, we attributed this to delayed resolution of inflammation/ballooning.

Several findings of this study are unexpected and shed new light on the function of *PNPLA3* and its link to inflammation and fibrosis development. First of all, we see clear differences of the fibrosis distribution between the biopsy and non-invasively characterized cohorts. While only 6% showed no fibrosis (F0) in the biopsy cohort this number increased drastically to 47% in the non-invasive cohort. These numbers are especially

**Figure 2** *PNPLA3* carrier status and its effect on liver stiffness (A) and aspartate transaminase (B) levels prior and after alcohol detoxification (1 and 2). Mean observation of detoxification periods in days are indicated for each genotype. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ . AST: Aspartate transaminase; ALT: Alanine transaminase; LS: Liver stiffness.

impressive with regard to the high negative predictive values of transient elastography<sup>[24,25]</sup>. We believe that these findings clearly indicate an often underestimated selection bias of biopsies in ALD study cohorts. Obviously, significantly less patients with no or mild liver disease are asked or motivated to undergo liver biopsy, whereas more severe patients are willing to agree with the invasive procedure. We believe that this observation is a strong argument to enforce well non-invasively characterized ALD cohorts in future studies.

Second, another interesting finding of the non-invasively characterized cohort is the almost symmetric, mirror-like distribution of CC vs G (CG + GG) carriers in the F0 and F4 population over almost 20 years of alcohol consumption. Circa 4% less CC carriers were seen in the cirrhosis group, an equating circa 4% more CC carriers were observed in the F0 group. Thus, about 20% of patients with alcoholic liver cirrhosis would be attributable to *PNPLA3*-G variants. The odds ratio to develop F4 cirrhosis was 1.3 for our cohort, which corresponds to earlier reports<sup>[12,44]</sup>. Notably and in line with previous reports<sup>[45]</sup>, the genotype distribution did not follow the Hardy-Weinberg equilibrium which could point to phenotype (GG)-related increased mortality, *e.g.*, due to complications of cirrhosis such as primary liver cancer (HCC)<sup>[46]</sup>.

Third, the histological findings are intriguing and partly surprising. Up to date, our study presents the most detailed histological analysis with respect to *PNPLA3*

carrier status and ALD since previous GWAS studies had primarily relied on retrospective samples with laboratory tests such as transaminases and diagnosis of steatosis by ultrasound<sup>[10,12]</sup>. Our data clearly show that signs of liver injury such as steatohepatitis or ballooning are the major and predominant features of GG carriers. In contrast, other widely discussed findings such as steatosis or fibrosis are less pronounced. Our study suggests that rather ballooning and not steatosis is the key feature of the *PNPLA3* GG phenotype in heavy drinkers that later develop ALD. Whether steatosis is either just a consequence of apoptotic liver damage or a bystander needs to be further clarified.

Fourth, special novel insights are seen with the detailed analysis of LS prior and after alcohol withdrawal. It is especially surprising that *PNPLA3* status and LS are differentially associated with histology. These data may also serve as explanation for the rather weak effect of the *PNPLA3* status on LS and less pronounced results in the past<sup>[19]</sup>. Thus, LS is highly associated with fibrosis stage (Kleiner and Chevallier) ( $r = 0.79$ ) and with steatohepatitis/ballooning ( $r = 0.4$ - $0.7$ ) but not at all with steatosis ( $r = 0.09$ ). In contrast, the GG status primarily correlates with liver injury (ballooning, steatohepatitis) ( $r = 0.3$ - $0.5$ ) and weaker with steatosis ( $r = 0.26$ ). Moreover, a striking feature of the protective CC status is the fast resolution of transaminase levels after alcohol detoxification without notable changes of LS. We can only speculate why CC carriers do not respond with a significant LS decrease after alcohol withdrawal despite an almost normalization of liver transaminases. One explanation could be that only 30% of ALD patients with elevated transaminase levels show a change of LS after alcohol withdrawal<sup>[42]</sup>. In other words, liver injury as assessed by elevated AST levels not necessarily increases LS in all patients. It rather suggests that ballooning as predominant histological finding of GG carriers may not necessarily cause an increase of transaminase levels. Indeed, ballooning was not significantly associated with elevated AST levels. We therefore believe that GG carriers not only have higher inflammation but also seem to have a slower resolution of liver damage/ballooning. One possible explanation could be that *PNPLA3* directly affects pressure-mediated LS elevation according to the recently introduced pressure hypothesis of cirrhosis that also encompasses mechano-signaling<sup>[24]</sup>. In line with this the co-presence of steatosis in GG carriers could lower LS since steatosis and LS seem not to associate directly (tissue softening of fat).

One of the limitations of our study is the fact that the exact time point of stopping drinking cannot always be determined with absolute correctness nor the adherence to abstaining from alcohol. In addition, the individual response of both laboratory parameters and LS to alcohol withdrawal may also vary considerably. Nevertheless, we strongly feel that the delayed resolution of alcohol-induced inflammation and LS in GG carriers could contribute to fibrosis progression in drinkers who typically show a pulsatile exposure to alcohol and in line with the

recently proposed sinusoidal pressure hypothesis<sup>[47]</sup>. Consequently, GG carriers could have a longer overall exposure to liver inflammation and elevated LS finally resulting in fibrosis progression.

Taken together, liver damage (inflammation/ballooning) with increased LS appears to be the primary event in GG carriers in response to heavy alcohol consumption, which resolves after alcohol withdrawal. Interestingly, GG carriers require a longer period of medical care in the hospital for alcohol detoxification showing advanced liver fibrosis and pointing toward more severe alcohol-related health problems. However, as demonstrated by our non-invasive fibrosis assessment of the whole study population, *PNPLA3* carrier status accounts only for circa 20% of alcoholic cirrhosis corresponding to about 4% of our overall study cohort and suggesting additional other, hitherto not recognized pro-fibrogenic factors. On a final note, we would like to emphasize the importance of non-invasive characterization of ALD study cohorts in the light of potential study bias of solely biopsy-based designs.

## COMMENTS

### Background

Polymorphisms of *PNPLA3* gene (Adiponutrin) have been identified as important genetic progression factor both of nonalcoholic fatty liver disease and alcoholic liver disease (ALD), the most common liver diseases worldwide. However, *PNPLA3* function and its molecular role in liver fibrosis are still unsettled.

### Research frontiers

Several studies in different populations have confirmed the association of a *PNPLA3* polymorphism with chronic liver disorders ranging from steatosis, inflammation to fibrosis progression and even hepatocellular carcinoma. It has also been shown that *PNPLA3* I148M elevates liver stiffness, an increasingly used non-invasive parameter to screen for liver cirrhosis.

### Innovations and breakthroughs

This is the first study, which investigated in detail the impact of *PNPLA3* I148M status, first, on detailed histological subscores in heavy drinkers, and, second, on liver stiffness and other laboratory parameters in response to alcohol withdrawal.

### Applications

In heavy drinkers, *PNPLA3* GG primarily correlates with ballooning/steatohepatitis but not steatosis resulting in a delayed inflammation-associated resolution of liver stiffness (LS). Consequently, sustained ballooning-associated LS elevation seems to be a potential risk factor for fibrosis progression in *PNPLA3* GG carriers. Significantly more patients without fibrosis (F0) were seen in the non-invasively characterized cohort as compared to the liver biopsy cohort (47% vs 6%) underlining the potential bias of biopsy-based studies.

### Terminology

ALD is the most common chronic liver disease in the Western world. ALD encompasses a broad spectrum of disorders ranging from simple steatosis to severe forms of liver injury, including alcoholic steatohepatitis, fibrosis and cirrhosis. It has been shown, that the SNP rs738409 in *PNPLA3* encoding for an isoleucine to methionine substitution at position 148 (I148M) is a strong liver disease modifier responsible for disease progression.

### Peer-review

Rausch *et al* analyzed the influence of *PNPLA3* genotype in heavy drinkers on serum markers and LS during all stages of alcoholic liver disease (steatosis, steatohepatitis and fibrosis) prior and after alcohol detoxification. This is a study of great interest that can help the researchers in evolving in this field.

## Abstract

### AIM

To assess the effect of sofosbuvir (SOF) based regimens on glycemic and lipid control.

### METHODS

This is a retrospective analysis of hepatitis C virus (HCV)-infected patients treated and cured with a SOF regimen [SOF/ribavirin/interferon, SOF/simeprevir, or SOF/ledipasvir (LDV) ± ribavirin] from January 2014 to March 2015. Patients with hemoglobin A1C (HbA1C) and lipid panels within six months before and six months after therapy were identified and included in our study. Due to the known hemolytic effect of ribavirin, HbA1C was obtained a minimum of three months post-treatment for the patients treated with a ribavirin regimen. Medical history, demographics, HCV genotype, pre-therapy RNA, and liver biopsies were included in our analysis. The patients who started a new medication or had an adjustment of baseline medical management for hyper-

lipidemia or diabetes mellitus (DM) were excluded from our analysis.

## RESULTS

Two hundred and thirty-four patients were reviewed, of which 60 patients met inclusion criteria. Sixty-three point three percent were male, 26.7% were Caucasian, 41.7% were African American and 91.7% were infected with hepatitis C genotype 1. Mean age was  $60.6 \pm 6.7$  years. Thirty-nine patients had HbA1C checked before and after treatment, of which 22 had the diagnosis of DM type 2. HbA1C significantly decreased with treatment of HCV (pretreatment  $6.66\% \pm 0.95\%$  vs post-treatment  $6.14\% \pm 0.65\%$ ,  $P < 0.005$ ). Those treated with SOF/LDV had a lower HbA1C response than those treated with other regimens ( $0.26\% \pm 0.53\%$  vs  $0.71\% \pm 0.83\%$ ,  $P = 0.070$ ). Fifty-two patients had pre- and post-treatment lipid panels; there was a significant increase in low-density lipoprotein (LDL) and total cholesterol (TC) after treatment (LDL:  $99.5 \pm 28.9$  mg/dL vs  $128.3 \pm 34.9$  mg/dL,  $P < 0.001$ ; TC:  $171.6 \pm 32.5$  mg/dL vs  $199.7 \pm 40.0$  mg/dL,  $P < 0.001$ ). Pre-treatment body-mass index (BMI) did not differ from post-treatment BMI ( $P = 0.684$ ).

## CONCLUSION

Eradication of HCV with a SOF regimen resulted in a significant drop in HbA1C and an increase in LDL and TC post therapy.

**Key words:** Hepatitis C; Sofosbuvir; Hyperlipidemia; Hemoglobin A1c; Low-density lipoprotein

**Core tip:** In our retrospective study, we evaluated the changes in glucose and lipid metabolism in a group of hepatitis C patients treated and cured with a sofosbuvir-containing regimen. We used hemoglobin A1c (HbA1c) and lipid panels to assess those two parameters. Six months post eradication, we found a statistically significant drop in HbA1c and an increase in low-density lipoprotein and total cholesterol. The use of HbA1c, although not perfect, is easy to understand and is frequently used by primary care doctors as a tool to assess glucose control.

Morales AL, Junga Z, Singla MB, Sjogren M, Torres D. Hepatitis C eradication with sofosbuvir leads to significant metabolic changes. *World J Hepatol* 2016; 8(35): 1557-1563 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i35/1557.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i35.1557>

## INTRODUCTION

Hepatitis C virus (HCV) is a leading cause of chronic liver disease, with a prevalence of infection in the United States of approximately 1.6%<sup>[1]</sup>. It remains the leading cause of death from liver disease and is the leading

indication for liver transplantation in the United States despite recent medical advances in HCV therapy. HCV can cause major alterations in insulin resistance (IR) and lipid homeostasis<sup>[2-4]</sup>. HCV infection has been associated with the development of diabetes mellitus type 2<sup>[5,6]</sup> as well as a 3.5-fold increase in the prevalence of glucose alterations in non-diabetics<sup>[7]</sup>. The pathogenesis between HCV and IR seems to be multifactorial, with cytokine upregulation and direct interactions between viral particles and insulin signaling pathways<sup>[8-12]</sup>. In the traditional pegylated interferon (PegIFN) based regimens, IR was associated with decreased sustained virological response (SVR)<sup>[13]</sup>; multiple studies have shown an association between viral suppression or clearance and improvement of IR<sup>[14-17]</sup>.

Along with IR, steatosis is also very common in patients infected with HCV<sup>[18]</sup>. The exact mechanism has not been fully elucidated, but host lipid alterations seem to play a major role. The virus utilizes very low-density lipoproteins (LDLs) to infect hepatocytes and several other lipid secretory mechanisms to perpetuate replication<sup>[4]</sup>. Several proteins, including Seipin and the HCV core protein, have been shown to alter the production of free fatty acids, as well as the proper excretion of lipids, increasing steatosis in the host<sup>[19-21]</sup>. Hypocholesterolemia is another finding that seems to be closely related to HCV replication mechanisms. After successful treatment with interferon-based therapy, it has been shown that hypocholesterolemia was resolved, with significant increases in LDL, triglycerides, and cholesterol<sup>[22,23]</sup>.

The era of direct-acting antiviral (DAA) agents has increased SVR rates to over 90%, with dramatically improved side effect profiles<sup>[24-30]</sup>. IR and lipid alterations do not seem to affect treatment outcomes, and there is limited data on the effects of DAA therapy on metabolic and lipid profiles. A recent study evaluating the effects of sofosbuvir (SOF) and ribavirin (RBV) therapy in a mostly non-diabetic population demonstrated fluctuations in LDL levels throughout treatment, with elevations in LDL in patients achieving SVR as well as a small decrease in hemoglobin A1C (HbA1C) levels ( $5.58\% \pm 0.08\%$  to  $5.45\% \pm 0.91\%$ ;  $P = 0.0046$ )<sup>[31]</sup>. Additional data regarding metabolic alterations after therapy with the new DAA is scarce. In this retrospective study, the effects of HCV eradication on glucose and lipid metabolism in patients treated with SOF-based regimens at WRNMMC from 2014 to 2015 were assessed.

## MATERIALS AND METHODS

### Eligibility criteria

Patients aged 18 years or older with confirmed infections with HCV (by RNA) treated and cured at our institution with any combination of a NS5B inhibitor (SOF), NS5A inhibitor [ledipasvir (LDV)], protease inhibitor (Simeprevir), RBV and PegIFN from January 2014 to March 2015 were eligible for the study. Electronic records were reviewed to look for patients with a HbA1C and/or lipid panel drawn

before and after therapy. A total of 234 patient charts were reviewed.

### HbA1C

The HbA1C closest to starting day of HCV therapy (up to six months pre-therapy) and the closest HbA1C post-therapy (up to six months) were included in our analysis. RBV is known to cause hemolysis, with remarkable drops in hemoglobin. Since HbA1C is closely related to red blood cell lifespan and could be altered by RBC destructions and anemia, the HbA1C in this population was selected between three to six months post therapy. Hemoglobin levels were reviewed pre-therapy and post-therapy and added to the analysis.

In patients with the diagnosis of diabetes mellitus type 2, a review of concomitant hypoglycemic medications was performed. All clinic encounters up to a year prior to starting HCV therapy, during therapy, and up to six months post therapy were reviewed, looking for adjustments of medications that could have altered HbA1C values. Those patients who started a medication or had an adjustment of baseline medical management were removed from the analysis. Patients on stable doses of oral hypoglycemic medications or insulin regimens during the study period were included. Attempts to account for diet and exercise regimens were beyond the scope of this analysis.

### Lipids

Lipid panels closest to the starting and end dates of therapy (up to six months pre and post therapy) were included. All samples were drawn during the morning. However, due to the retrospective nature of the analysis, fasting could not be confirmed for all patients. Patients on stable doses of lipid-lowering agents were included, while patients started on new medications or with adjustments during the study period were removed from the analysis.

### Data collection

Basic demographic and clinical information was collected for all patients, including age, gender, race, body-mass index (BMI) pre-and post-HCV therapy, and specific HCV anti-viral therapy used. Pre-therapy aspartate aminotransferase (AST), alanine transaminase (ALT), alkaline phosphatase, total bilirubin, albumin, total protein, Hepatitis C RNA, Hepatitis C genotype, and liver biopsy staging were also included. Patients with other liver diseases, such as hemochromatosis, Wilson disease, and alcoholic liver disease, were excluded from the analysis. A total of 60 patients were included in the final analysis. The study protocol was approved by the Institutional Review Board of Walter Reed National Military Medical Center.

### Statistical analysis

Data were collated and analyzed using statistical software package IBM SPSS Statistics 21.0 (IBM, Armonk, New York). Continuous data was reported as means  $\pm$  SDs. Paired *t*-test was used to compare variables measured before and after HCV treatment.

Student's *t* test was used to analyze between group comparisons of continuous data including the change in HbA1C, HA1C, LDL, and high density lipoprotein (HDL) over the HCV treatment. A probability value of less than 0.05 was considered statistically significant. The statistical review of the study was performed by a biomedical statistic.

## RESULTS

A total of 234 patients were treated for HCV during the study period. Of these, 60 patients met the inclusion criteria. Their average age was  $60.6 \pm 6.7$  years; 26.7% were Caucasian, 41.7% were African American, and 63.3% were male. Clinical history in the cohort was significant for diabetes (38.3%) and hyperlipidemia (HLD) (33.3%). Patients had a mean viral load of  $4.7 \times 10^6 \pm 7.6 \times 10^6$ ; 50.0% were infected with genotype 1a, and 26.7% were infected with genotype 1b. The mean pre-treatment AST was  $61.0 \pm 49.3$  units/L, ALT  $72.1 \pm 56.2$  units/L, alkaline phosphatase  $102.3 \pm 71.3$  units/L, total bilirubin  $0.8 \pm 1.5$  mg/dL, albumin  $4.2 \pm 0.4$  g/dL, and total protein  $7.4 \pm 0.7$  g/dL.

All patients were treated with a SOF-based regimen. Of the 23 patients with diabetes, 15 were treated with a stable dose of anti-diabetic medications, most commonly metformin. Of the 20 patients with HLD, 12 were taking a statin, and only three had their statins held during therapy (Table 1).

A total of 39 patients had pre- and post-treatment HbA1C measured. Overall, there was a significant drop in HbA1C during treatment (Figure 1). This was not accompanied by a significant decrease in BMI (pre-treatment  $28.86 \pm 5.15$  kg/m<sup>2</sup>, post treatment  $28.48 \pm 4.72$  kg/m<sup>2</sup>,  $P = 0.683$ ). There was no significant difference in HbA1C effect between males and females ( $P = 0.793$ ). There was no significant difference in HbA1C drop between genotype 1a and 1b ( $P = 0.605$ ). Although not statically significant, patients with a history of diabetes tended to have a larger drop in HbA1C than those without diabetes, and Caucasians tended to have a larger drop in HA1C than African Americans. Patients aged 65 and older were less likely to have a drop in their HbA1C with treatment (younger than 65,  $0.68\% \pm 0.75\%$ , 65 and older,  $-0.01\% \pm 0.47\%$ ,  $P = 0.0187$ ). Sixteen of these patients were treated in conjunction with ribavirin; this did not have a significant effect on HbA1C change (drop in HbA1C with ribavirin  $0.44\% \pm 0.76\%$ ; without ribavirin  $0.68\% \pm 0.74\%$ ,  $P = 0.342$ ). Patients with a high viral load ( $> 6000000$  copies) tended to have a larger drop in HbA1C with treatment (high VL  $0.87\% \pm 0.97\%$ , low VL  $0.40\% \pm 0.62\%$ ,  $P = 0.080$ ).

Fifty-two patients had pre- and post-treatment lipid panels measured. Overall, there was a significant increase in LDL and total cholesterol (TC) with minimal change in HDL (pre  $52.8 \pm 18.3$  mg/dL, post  $51.4 \pm 18.5$  mg/dL,  $P = 0.699$ ) and triglycerides (pre  $132.1 \pm 99.7$  mg/dL, post  $129.8 \pm 80.8$  mg/dL,  $P = 0.853$ ) (Figure 2). Patients with a history of HLD did not have

significantly larger increase in LDL than those without a history of hyperlipidemia (HLD  $27.8 \pm 30.7$  mg/dL, non-HLD  $30.4 \pm 44.6$  mg/dL,  $P = 0.810$ ). Patient's age 65 or older did not have a significantly larger increase in LDL than younger patients (65 or older  $22.4 \pm 32.3$  mg/dL, younger  $30.4 \pm 37.1$  mg/dL,  $P = 0.511$ ). Caucasians and African Americans had similar increases in LDL (Caucasians  $35.7 \pm 36.0$  mg/dL, African Americans  $33.4 \pm 35.5$  mg/dL,  $P = 0.847$ ). Those treated with SOF + ledipasvir tended to have a larger increase in LDL than those treated with other regimens (SOF + LED  $36.7 \pm 39.3$  mg/dL, other therapy  $22.1 \pm 33.1$  mg/dL,  $P = 0.157$ ). Treatment regimen including interferon did not affect LDL increase ( $P = 0.755$ ). High VL ( $> 6000000$  copies) prior to treatment did not affect significantly impact the increase in LDL ( $P = 0.221$ ). Patients with hepatitis C genotype 3 ( $n = 3$ ) on average had an increase in LDL of 59 mg/dL (pre 87.3 mg/dL, post 146.3 mg/dL) and an increase in TC of 60 mg/dL (pre 148.7 mg/dL, post 208.7 mg/dL).

## DISCUSSION

The main finding of this retrospective study was a significant decrease in HbA1C up to six months post-HCV eradication. The mechanism responsible for this

**Figure 1 Effects of hepatitis C eradication on hemoglobin A1C.** Vertical axis represents HbA1C levels in mg/dL. HbA1C significantly decreased after eradication of hepatitis C virus (pretreatment  $6.66 \pm 0.95$  mg/dL vs post-treatment  $6.14 \pm 0.65$  mg/dL,  $P < 0.005$ ). HbA1C: Hemoglobin A1C.

improvement in glycemic control is unknown although likely multifactorial. It is well known that HCV alters glucose metabolism by inducing inflammatory cascades and promoting IR. Defects in pathways important in hepatic gluconeogenesis such as PI3K and AKT phosphorylation have been reported in patients infected with HCV. Insulin receptor substrates 1 and 2 are closely related to the PI3K/AKT pathways; these two receptors are key components in the development of IR in patients infected with HCV. The virus can degrade these two receptors, directly affecting the PI3K/AKT pathways<sup>[32-34]</sup>. Eradication of the virus restores homeostasis of these pathways, leading to an improvement in IR.

In the interferon/RBV era, several studies have demonstrated an improvement of IR with SVR. Early work by Thompson *et al.*<sup>[17]</sup> demonstrated a 10% decrease in IR in genotype 1 patients who achieved SVR, which was supported by the more recent results from Chien *et al.*<sup>[35]</sup> that showed a significant decrease in HOMA-IR at EOT after eradication of the virus with this combination. Similarly, a study by Meissner *et al.*<sup>[31]</sup> demonstrated a small but significant decrease in HbA1c in patients treated with SOF/RBV ( $5.58\% \pm 0.08\%$  to  $5.45\% \pm 0.91\%$ ;  $P = 0.0046$ ). While the majority of these patients were non-diabetic or pre-diabetics, the patients included in this analysis had a significantly higher rate of diabetes, at 56%. When compared to the non-diabetic patients, the diabetics had a greater improvement in HbA1C. Gender, race, HCV genotype, and HCV RNA did not affect HbA1C drop.

In a subgroup analysis, patients treated with the SOF/LDV had a lower drop in HbA1C when compared to SOF/RBV and SOF/SIM groups. One possible explanation is the relationship between the new DAA and its target. The non-structural proteins of the virus NS5A and NS5B are key components in the activation of inflammatory cascades promoting insulin resistance<sup>[34]</sup>. It is plausible that the interaction of the medication or the duration of therapy alters the effects of insulin resistance, although further study is required.

Although this study was not designed to identify the

**Figure 2 Effects of hepatitis C eradication on lipids.** Vertical axis represents lipid levels in mg/dL. LDL and total cholesterol were significantly higher post hepatitis C eradication (LDL:  $99.5 \pm 28.9$  mg/dL vs  $128.3 \pm 34.9$  mg/dL,  $P < 0.001$ ; total cholesterol  $171.6 \pm 32.5$  mg/dL vs  $199.7 \pm 40.0$  mg/dL,  $P < 0.001$ ). No significant changes were noted for HDL and triglycerides. LDL: Low-density lipoprotein; HDL: High-density lipoprotein.

long-term implications of hepatitis C eradication in glucose control, it is possible that these changes could have long-term implications regarding medical management. One of 16 patients on medical therapy for diabetes required a decrease in insulin therapy post viral eradication and another was taken off completely of therapy. The savings from a drop of even 0.5% of HbA1c are significant, and many oral hypoglycemics maximum efficacy is only a 1% improvement in HbA1c. Even more important than potential cost savings are the implications of better glucose control in the development of microvascular and macrovascular disease as small drops in HbA1c can alter the course of these complications. Primary care physician should monitor diabetic patients post HCV eradication to assess if changes in medical management are required and to prevent complications such as hypoglycemia.

The implications of insulin resistance, especially in diabetic patients infected with HCV, are well established. Huang *et al.*<sup>[36]</sup> showed an increased risk of liver disease progression to cirrhosis in HCV-infected patients with diabetes. Hui *et al.*<sup>[3]</sup> demonstrated that insulin resistance was an independent predictor for the degree of fibrosis and fibrosis progression in HCV-infected patients. Everhart *et al.*<sup>[37]</sup> showed that not only hepatic steatosis was associated with liver disease progression, but also the degree of insulin resistance. They suggested that addressing these two issues might modify disease progression<sup>[37]</sup>. Taking into account this information and the results of our study, we should consider adding diabetic HCV-infected patients to the high-risk group that would benefit from priority in treatment.

These results also correlate with previous studies evaluating the effects of HCV eradications and lipids. An increase in TC and LDL post therapy was demonstrated irrespective of anti-viral therapy or genotype. Chronic infection with HCV has been implicated in the development of hypolipidemia<sup>[38,39]</sup>. A reversal of these findings has been reported in patients treated with INF/RBV regimens, as well as SOF/RBV regimens that have

achieved SVR, suggesting this is most likely related to viral clearance rather than a medication effect<sup>[22,23,31]</sup>. The implications of these alterations in cardiovascular and cerebrovascular disease are beyond the scope of this retrospective study but should be further investigated.

The study does have several limitations including its retrospective nature and the small number of patients. Even though all lipids were drawn during the morning time, fasting was unable to be confirmed. Other parameters that could have altered the results, such as dietary changes and exercise, were not available. Medication reconciliation was not directly obtained, but an evaluation of several encounters from the electronic medical record from different providers was performed, looking for adequate medication reconciliation. The length of analysis was also limited to six months post-HCV therapy, so an analysis of the long-term implications of these results cannot be made.

This analysis did strengthen the knowledge pertaining to the metabolic effects of SOF-based regimens and confirmed that eradication of the virus could have extra-hepatic benefits. Even though HOMA-IR is a more direct measurement of IR, HbA1c is a more practical parameter that can be used to assess glucose control, and this study confirmed an improvement in HgA1c with SVR.

In conclusion, this study showed a significant drop in HbA1c up to six months after the eradication of HCV with SOF-based regimens. Future studies are needed to see if this change is sustainable. The effects of virus eradication on lipid panels were also determined, and they confirmed previous analyses that showed an increase in lipid panels, including LDL and TC, with SVR. This study suggests that physicians treating HCV patients should reassess preventive medicine measures after therapy, as the benefits of eradicating HCV may extend beyond eliminating the effects of chronic liver inflammation.

## COMMENTS

### Background

The hepatitis C virus (HCV) is a leading cause of chronic liver disease, with a prevalence of infection in the United States of approximately 1.6%. It is the leading cause of death from liver disease and is the leading indication for liver transplantation in the United States. Chronic hepatitis C infection (CHC) is known to induce systemic changes regarding glucose control and lipid metabolism. Glycemic balance can be affected by direct effect over insulin activation cascades and as a systemic response to inflammatory cytokines. Patients with CHC developed diabetes mellitus earlier than non-infected patients. Lipid metabolism is also affected due to known impaired lipid secretions associated with the infectious mechanism of the virus (possible use of lipid receptor to infect hepatocytes). Steatosis is another major finding in patients infected with CHC.

### Research frontiers

Hepatitis C therapy has changed drastically in the last four years. The authors are now able to achieve cure rates of over 90%, with minimal side effects. The long-term implications of these new agents are still unclear, and previous studies have shown mixed results regarding alterations in glucose and lipid control after eradication. There is limited data regarding the newer anti-viral agents and their effects on metabolic derangements. The study attempts to assess the metabolic changes associated with these new agents.

## Innovations and breakthroughs

Similar studies evaluating metabolic changes associated with hepatitis C eradication have used HOMA-IR as a surrogate of glucose homeostasis. Although this is a very accurate way of assessing glucose changes post hepatitis C eradication, its use on a daily clinic encounter is limited. In the study, the authors used HgA1c as a surrogate for glucose homeostasis. This laboratory test is easy to use and is well known by non-gastroenterology/hepatology providers. This laboratory test is more practical for daily clinic encounters. Previous studies on patients treated and cured with interferon and Ribavirin have shown alterations in lipid homeostasis, similar to the results. As the data on lipid alterations with the new direct antiviral agents is limited, the study adds to the knowledge on non-hepatic effects associated with a sustained virological response.

## Applications

As reported in the study, several patients required adjustments in their hyperglycemic regimens, and one patient was completely taken off medication. The study suggests that shortly after completing hepatitis C therapy, primary care doctors should monitor diabetic patients, under medical management, to assess if changes to their medications are needed. Although the study was not meant to assess long-term effects, changes in HbA1c, as seen in the study, can add benefits in cost savings, as well as prevent microvascular and macrovascular disease. The changes seen in lipid homeostasis are worrying and require further investigation. These patients are still at risk of developing other liver diseases, such as non-alcoholic fatty liver disease. Primary care doctors should implement close monitoring of lipids after hepatitis C eradication, and those who meet the criteria for therapy should be treated accordingly.

## Terminology

NS5A: Non-structural protein 5A. This protein plays a key role in HCV replication. It is one of the main targets for some of the new direct acting antiviral agents; NS5B: Non-structural protein 5B. Involved in Hepatitis C RNA replication. Main target for some of the new anti-viral agents, such as Sofosbuvir; Sustain virological response: Patients with undetectable hepatitis C viral load 12 wk after completing hepatitis C therapy.

## Peer-review

The manuscript is well presented and of interest and the results can contribute to increase the knowledge of this topic.

## Abstract

### AIM

To determine the association between cirrhosis and ischemic stroke in a large nationally representative sample.

### METHODS

A retrospective cross-sectional study of all hospitalized patients during 2012 and 2013 in the United States was performed using the National Inpatient Sample database. Hospitalizations with acute stroke, cirrhosis and other risk factors were identified using ICD-9-CM codes.

### RESULTS

There were a total of 72082638 hospitalizations in the United States during the years 2012 and 2013. After excluding hospitalizations with missing demographic variables, that there were a total of 1175210 (1.6%) out of these were for acute ischemic stroke. Cirrhosis was present among 5605 (0.4%) cases of ischemic stroke. Mean age among the cirrhotic and non-cirrhotic groups with ischemic stroke were 66.4 and 70.5 years, respectively. Prevalence of risk factors among the two groups was also calculated. After adjusting for various known risk factors the odds of having an ischemic stroke (OR = 0.28,  $P < 0.001$ ) were 72% lower in cirrhotics compared to non-cirrhotics.

### CONCLUSION

Our study suggests that in a large, nationally representative sample of the United States population, cirrhosis

is associated with a lower likelihood of stroke.

**Key words:** Cirrhosis; Ischemic stroke; Cerebrovascular accident; National Inpatient Sample

© **The Author(s)** 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Our study demonstrates that in a large, nationally representative sample, cirrhosis is associated with a lower likelihood of having an ischemic stroke, after adjusting for known risk factors. Although the odds of having a stroke are lower in cirrhotics, the mortality is significantly higher in them compared to non-cirrhotics.

## INTRODUCTION

Cirrhosis is among the top ten leading causes of death in the United States<sup>[1,2]</sup>. With recent advances in the management of various complications of cirrhosis, it has become one of the most prevalent chronic conditions, that patients live with for a considerable duration of time<sup>[3]</sup>. For instance, there were 633323 patients living with cirrhosis in 2010<sup>[4]</sup>.

Due to altered homeostasis and hemodynamics in cirrhosis it is reasonable to assume that the risk of an ischemic cerebrovascular event [acute ischemic stroke (AIS)] in cirrhotics would be different from that of the general population<sup>[5-8]</sup>. The question whether cirrhosis is associated with a reduced risk of stroke has been a source of controversy for a long time. There have been various studies reporting increased incidence of carotid plaques and atherosclerosis in patients with advanced liver disease, both known risk factors for ischemic stroke<sup>[9-11]</sup>. On the other hand, it is also well known that liver disease causes thrombocytopenia and coagulopathy which should in turn be protective against an ischemic cerebrovascular accident (CVA)<sup>[12]</sup>. Recently, Chen *et al.*<sup>[12]</sup> and Berzigotti *et al.*<sup>[13]</sup> showed that patients with liver cirrhosis may be at a lower risk of experiencing an ischemic CVA<sup>[12-14]</sup>. However, due to predominance of one ethnic group in the former and the relatively small sample size in the latter, the impact of cirrhosis on risk of stroke still remains inconclusive.

We therefore aim to define the impact of cirrhosis and extent of its association with ischemic stroke by using the largest national database for hospitalized patients in the United States.

## MATERIALS AND METHODS

### Data source

The National Inpatient Sample (NIS) formerly known as

Nationwide Inpatient Sample database is an administrative database developed by the Agency of Healthcare Research and Quality for Healthcare Cost and Utilization Project (HCUP). It is the largest all-payer database of hospitalized patients in the United States. NIS is a 20% stratified sample of all discharges from United States community hospitals<sup>[15]</sup>. Thus, manufacturer provided sampling weights were used to produce national estimates. We used NIS databases for the years 2012 and 2013 in this study. The NIS database provides de-identified information regarding the demographic characteristics (age, gender, race), mortality, principal and secondary diagnoses, *etc.*, for each hospitalization. It however does not contain any lab values, imaging or other advanced diagnostic information.

### Study design

This is a retrospective cross-sectional study using a national inpatient database. We used International Classification of Diseases, 9<sup>th</sup> Revision, Clinical Modification (ICD-9-CM) codes 571.2 (Alcoholic cirrhosis of liver), 571.5 (biliary cirrhosis) and 571.6 (cirrhosis without mention of alcohol) to identify the patients with cirrhosis<sup>[3,16]</sup>. ICD-9-CM codes 433.x1, 434.x1, 435 and 436 listed as principal diagnoses were used to identify hospitalizations for acute ischemic cerebrovascular events. These ICD-9-CM codes with modifiers have been previously validated and used to identify AIS in administrative databases with good accuracy<sup>[17-20]</sup>. All the patients with missing age, gender or race information were excluded. The patients with missing age and gender information constituted < 1% of the included population. The hospitalization with missing race were more prevalent, however they were due to non-participation of some states in reporting ethnic information and thus did not result in under-representation of any particular ethnic group. The basic demographic characteristics for different sub-groups have been described in Table 1. We used ICD-9-CM codes to identify the known risk factors for ischemic stroke<sup>[21-25]</sup>. Prevalence of these risk factors was also calculated for different subgroups (Table 1). Since, this study was conducted using a de-identified commercially available database Institutional Review Board approval was not required.

### Statistical analysis

Stata 13.1 (Stata Corp, College Station TX) and SPSS 23.0 (SPSS Inc., Chicago, Ill) were used for statistical analysis. National estimates were produced by using the sampling weights provided by HCUP.  $\chi^2$  test and Independent-samples *t*-test for means were used to determine statistical significance of differences in the prevalence of risk factors and demographic variables among the two groups. Due to the binary nature of the outcome/dependent variable, *i.e.*, presence of ischemic stroke, multivariate logistic regression model was used to assess the association between cirrhosis and ischemic stroke while controlling for known risk factors (as listed in Table 1) of ischemic stroke. Wald's

**Table 1** Demographic characteristics and prevalence of risk factors in patients with ischemic stroke among cirrhotic and non-cirrhotic groups

	Cirrhotic	Non-cirrhotic	P value
Mean age (SD)	66.4 (11.9)	70.5 (14.3)	< 0.001
Age categories			
Age < 40	0.8	2.3	< 0.001
Age 40-64	46.6	30.6	
Age > 65	52.6	67.1

Atrial fibrillation	23.8	21.9	0.001
Anticoagulation use	4.4	6.8	< 0.001
Dyslipidemia	34.4	56.5	< 0.001
Alcohol abuse	28.8	3.8	< 0.001
Family history of stroke	1.5	2.3	< 0.001

The numbers in each cell represent percentage of patients with particular characteristics/risk factor in each group. SD: Standard deviation; CAD: Coronary artery disease; CHF: Congestive heart failure.

test was used to determine statistical significance of association between the factors used in the regression model and the outcome, *i.e.*, stroke. *P*-value less than 0.05 was considered statistically significant. The coefficient obtained as a result of the regression model was converted to OR for ease of understanding and is being reported here along with 95%CI. Since the prevalence of our outcome (Stroke) was less than 10%, the OR provides a good estimate of the relative risk<sup>[26]</sup>. The biostatistical methods and tests used in this study were reviewed by a biomedical statistician.

## RESULTS

There were a total of 72082638 hospitalizations in the United States during the year 2012 and 2013. After excluding hospitalizations with missing demographic variables (age, gender, and race), a total of 1175210 (1.6%) hospitalizations were for AIS. Out of these, 5605 (0.4%) were identified to have co-existing cirrhosis of liver. Decompensated cirrhosis which was defined by

**Figure 1** Distribution of demographic characteristics and risk factors in cirrhotic and non-cirrhotic groups with ischemic stroke. CAD: Coronary artery disease; CHF: Congestive heart failure; Afib: Atrial fibrillation.

presence of variceal hemorrhage, ascites, spontaneous bacterial peritonitis or hepatic encephalopathy, constituted 14.3% of the cirrhotic group<sup>[27]</sup>. Mean age among cirrhotic and non-cirrhotic patients were 66.4 (SD = 11.9) and 70.5 (SD = 14.3) years, respectively. Proportion of males among the two groups was 55.1% and 46.5% respectively. The racial distribution was similar among the two groups with 66.6% and 70.8% Caucasians; and 14.9% and 15.9% African-Americans in cirrhotic and non-cirrhotics respectively. The prevalence of some risk factors (Figure 1) for AIS like - diabetes (45.1% vs 37.8%), hypertension (52.2% vs 62.5%), congestive heart failure (18.9% vs 13.1%), smoking (37.2% vs 28.8%), atrial fibrillation (23.8% vs 21.9%), alcohol use (28.8% vs 3.8%) and peripheral vascular disease (8.7% vs 6.9%), were all higher among cirrhotics compared to non-cirrhotics (Table 1). Whereas, others like Coronary atherosclerosis (25.3% vs 27.7%), previous history of stroke (13.1% vs 14.8%), hypercholesterolemia (34.4% vs 56.5%) were found to be higher among the non-cirrhotic group (Table 1). Anticoagulation use, which is considered to be associated with a lower risk of ischemic stroke was more prevalent among the non-cirrhotics at 6.8% compared to 4.4% in cirrhotics.

The overall *P*-value of the logistical regression model was statistically significant at < 0.001. The odds of having an AIS for patients with cirrhosis were 72% lower than patients without cirrhosis (OR = 0.28, 95%CI: 0.26 to 0.29) and was statistically significant with a *P*-value < 0.001. The all cause in-hospital mortality among the cirrhotic group (5%) with AIS was significantly higher than non-cirrhotic group (3.3%) (*P* < 0.001). Even after adjusting (using logistic regression) for various co-morbidities using Charlson comorbidity index (modified to exclude liver disease)<sup>[28,29]</sup>, patient demographics, and hospital characteristics; the mortality remained higher among cirrhotics with stroke (OR = 1.6, 95%CI: 1.22-2.10, *P* = 0.001).

## DISCUSSION

The impact of cirrhosis on stroke has been controversial

for a long time. Our study demonstrates that the odds of having an AIS for cirrhotics are significantly lower (72%) than non-cirrhotics. This is consistent with some of the other smaller non-United States based studies done previously. The magnitude of association however, is different<sup>[12,13]</sup>. The study by Chen *et al.*<sup>[12]</sup> showed that risk of having an AIS was lower in non-alcoholic cirrhosis. But, it was conducted in Taiwan, and has limited generalizability due to predominance of only one kind of ethnic population. Since, ethnicity is itself an independent risk factor of AIS, our results have a more generalized applicability. Our study also had a much larger sample size and adjusted for the most number of risk factors of stroke in any study so far. The reduced likelihood of AIS in patients with cirrhosis represents a very important clinical finding. It may aid a clinician in determining the optimal management of often complicated cirrhotic patients with co-morbidities, that put them at a higher than usual risk of AIS, such as atrial fibrillation. The mechanism of this “protective effect of cirrhosis” is unclear but could be related to the underlying coagulopathy, thrombocytopenia or the altered hemodynamic flow patterns<sup>[12,13]</sup>. This study demonstrates the need for a prospective study to further explore this “protective effect of cirrhosis” on AIS.

Our study is to date the largest of its kind, and likely represents the true association between cirrhosis and strokes after adjusting for several known risk factors. Despite patients with cirrhosis being less likely to have a stroke, the mortality was significantly higher in them compared to non-cirrhotics. This is likely due to complications arising from the cirrhosis which may interfere with the usual management of stroke, for example, the coagulopathy due to cirrhosis may pose problems for planned interventions, if needed.

Our study findings, although important, need to be interpreted in light of some limitations. Firstly, NIS being an administrative database is not free from coding errors, especially related to liver diseases and acute strokes. However, we have used either the previously validated or commonly used codes for cirrhosis and AIS which have been shown to have good accuracy<sup>[3,30-32]</sup>. Secondly, the OR provides a close estimate of Relative Risk due to relatively low prevalence of Stroke in our population, but its not a replacement for the true relative risk which can only be obtained from a prospective cohort study.

Our study demonstrates that in a large, nationally representative sample, cirrhosis is associated with a lower likelihood of having an ischemic stroke, after adjusting for known risk factors. Although the odds of having a stroke are lower in cirrhotics, the mortality is significantly higher in them compared to non-cirrhotics. Prospective studies are needed to establish the causal relationship and better define this association in future.

## COMMENTS

### Background

Cirrhosis is one of the leading causes of morbidity and mortality in the United States. Cirrhotic patients usually suffer from coagulopathy while simultaneously being at an increased risk of deep venous thrombosis. These problems

along with the usually encountered thrombocytopenia imply that the risk of an ischemic cerebrovascular accident (CVA) in a cirrhotic would be different from that of general population. This impact of cirrhosis on the risk of ischemic cerebrovascular events (ischemic stroke) has been controversial.

### Research frontiers

The relationship between cirrhosis and ischemic CVA has not been studied in detail.

### Innovations and breakthroughs

The study is the first study with such a large sample size that controls for so many known risk factors of stroke to explore the true relationship between ischemic stroke and cirrhosis.

### Applications

The reduced likelihood of acute ischemic stroke (AIS) in patients with cirrhosis represents a very important clinical finding. It may aid a clinician in determining the optimal management of often complicated cirrhotic patients with co-morbidities, that put them at a higher than usual risk of AIS, such as atrial fibrillation (Afib).

### Terminology

Charlson comorbidity index is a tool to adjust for the impact of co-morbidities developed for use with administrative databases utilizing ICD-9 codes.

### Peer-review

This paper is described in detail, which, as valuable information, could help the readers that have better understand the first-hand knowledge of this topic to start novel studies.

### Abstract

#### AIM

To investigate whether a novel immune function biomarker QuantiFERON-Monitor (QFM) can identify cirrhotic patients at greatest risk of infection.

#### METHODS

Adult cirrhotic patients on the liver transplant waiting list were recruited for this observational cohort study from a tertiary liver transplant referral unit. The immune function biomarker, QFM was performed using the same method as the widely available Quantiferon-gold assay, and measures output in interferon gamma in IU/mL after dual stimulation of the innate and adaptive immune systems. Ninety-one cirrhotic patients were recruited, with 47 (52%) transplanted on the day of their QFM. The remaining 44 (48%) were monitored for infections until transplant, death, or census date of 1<sup>st</sup> February 2014.

#### RESULTS

Cirrhotic patients express a median QFM significantly lower than healthy controls (94.5 IU/mL vs 423 IU/mL), demonstrating that they are severely immunosuppressed.

Several factors including model for end stage liver disease, presence of hepatocellular carcinoma, bilirubin, international normalized ratio and haemoglobin were associated with QFM on univariate analysis. Disease aetiology did not appear to impact QFM. On multivariate analysis, only Child-Pugh score and urea were significantly associated with a patient's immune function as objectively measured by QFM. In the 44 patients who were not transplanted immediately after their blood test and could be monitored for subsequent infection risk, 13 (29.5%) experienced a pre-transplant infection a median 20 d (range 2-182) post-test. QFM < 214 IU/mL was associated with HR = 4.1 ( $P = 0.01$ ) for infection. A very low QFM < 30 IU/mL was significantly associated ( $P = 0.003$ ) with death in three patients who died while awaiting transplantation (HR = 56.6).

### CONCLUSION

QFM is lower in cirrhotics, allowing objective determinations of an individual's unique level of immune dysfunction. Low QFM was associated with increased susceptibility to infection.

**Key words:** Infection; Biomarker; Immune dysfunction; Immune function; Immunosuppression; Liver; Immune system; Cirrhosis; Mortality

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** QuantiFERON-Monitor (QFM) is a net immune function biomarker that measures interferon- $\gamma$  after stimulation of the innate and adaptive immune systems and is based on a readily available pathology platform. Measuring QFM in cirrhotic patients provides an objective marker of their immune dysfunction, which has otherwise been difficult to quantify. Low QFM is significantly associated with the risk of pre-transplant infection, and very low QFM may be associated with increased risk of mortality.

Sood S, Yu L, Visvanathan K, Angus PW, Gow PJ, Testro AG. Immune function biomarker QuantiFERON-monitor is associated with infection risk in cirrhotic patients. *World J Hepatol* 2016; 8(35): 1569-1575 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i35/1569.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i35.1569>

### INTRODUCTION

QuantiFERON-Monitor (QFM, Qiagen Ltd, United States) was developed as an immune function monitoring tool in the post-transplant setting and provides a general biomarker of immune function based on stimulation of both the innate and adaptive immune systems<sup>[1]</sup>. It was developed based on the same diagnostic platform as the widely available QuantiFERON-Gold assay (QFN-gold, Qiagen Ltd, United States) and requires minimal

laboratory processing. A high QFM result suggests a robust immune response, whilst a low result implies impaired immunity. Initial pilot data showed low QFM compared with age-sex matched controls not just in patients on immunosuppression post-transplant, but also in cirrhotic patients on the waiting list prior to transplant<sup>[1]</sup>.

Patients with decompensated cirrhosis have inherently impaired immune responses, with bacterial infections occurring in 20%-60% of patients hospitalized for cirrhosis<sup>[2]</sup> and responsible for up to 25% of deaths in patients with liver disease<sup>[3]</sup>. The immune dysfunction in cirrhosis involves impairments of both quantity and quality of many immune cells that have been individually studied but are not always appreciated in clinical care.

In this study we present data that represents the first well described clinical cohort of patients to be evaluated with the QFM assay. We describe their immune function and investigate whether low QFM is associated with infection risk in this prospective cohort of pre-transplant cirrhotic patients.

### MATERIALS AND METHODS

We performed a prospective observational cohort study on 91 patients with cirrhosis awaiting liver transplantation at a single centre. Patients were recruited between November 2011 to December 2013 and followed until the census date of 1<sup>st</sup> February 2014. Approximately half the patients had blood taken immediately prior to their transplant surgery, while the remainder had a period of time in between their blood test and transplantation, death or the census date.

The QFM assay was performed on 1 mL of whole blood. As per manufacturer's guidelines, blood was stimulated with the QFM immune ligands anti-CD3 and R848 in the form of a single lyophilized ball within 8 h of being taken. Stimulated blood was incubated overnight at 37 °C. Following incubation, the blood underwent centrifugation and plasma harvested. An enzyme-linked immunosorbent assay (ELISA) was performed by a separate investigator who was blinded to clinical data. Clinicians caring for the cirrhotic patients were blinded from the QFM assay results. QFM output was measured as interferon- $\gamma$  (IFN- $\gamma$ ) production measured as IU/mL, in a process similar to that applied to perform a QFN-gold assay: Samples were brought to room temperature and given 60 min to equilibrate. The lyophilized IFN- $\gamma$  standard was reconstituted with deionized water. This was gently mixed to minimize frothing and ensure complete solubilisation. Dilutions were prepared to validate the standard curve.

The lyophilized conjugate was reconstituted with 0.3 mL of deionized water and mixed gently to minimize frothing and ensure complete solubilisation. Further dilutions were performed with addition of Green Diluent. Fifty microliters of prepared conjugate was added to each ELISA well, after which 50  $\mu$ L of each sample were added. Plates were covered and mixed using a microplate shaker for 1 min and then incubated at room

**Table 1** Baseline characteristics of cirrhotic patients

	Demographics	Median QFM (95%CI) IU/mL
Age (median, yr)	54 (20-72)	94.5 (37.3-158)
Male	62 (68.1%)	124.5 (37.3-223)
Female	29 (31.9%)	73.9 (7.50-158)
Child-Pugh score		
A	7	381 (12.9-1234)
B	29	224 (94.4-506)
C	55	37.3 (19.5-128)
MELD score		
0-10	10	319 (12.9-904)
11-20	42	155.5 (94.5-240)
21-30	34	30.0 (9.16-157)
≥ 30	5	8.81 (0.63-47.6)
Primary aetiology of cirrhosis, n (%)		
HCV	39 (42.9)	130 (47.6-223)
PSC	10 (11.0)	61.6 (1.19-279)

temperature for 120 min  $\pm$  5 min.

Wells were then washed with 400  $\mu$ L of working strength wash buffer for at least 6 cycles in a microplate washer. Plates were tapped, while facing down on absorbent, low-lint towels to remove residual wash buffer. One hundred microliters of enzyme substrate solution was then added to each well, and plates covered with a lid. These were mixed using a microplate shaker, and then incubated at room temperature for a further 30 min.

Following this further incubation, 50  $\mu$ L of enzyme stopping solution was added to each well and mixed thoroughly with the microplate shaker. The optical density was then measured within 5 min of stopping the reaction using a microplate reader fitted with a 450 nm filter, as well as a 620 nm-650 nm reference filter. The optical density values were used to calculate the output result of IFN- $\gamma$  in IU/mL. Low QFM was suggestive of an immunosuppressed state.

Basic clinical data was collected from participants who were recruited as part of a post-transplant research trial. Collected data included age, gender, disease aetiology and blood biochemistry. Patients were also evaluated for commonly used scoring systems for the severity of liver disease, the Child-Pugh Score and model for end stage liver disease (MELD) score. Patients were monitored prospectively for infection occurring after their QFM sample and up to either liver transplant, infection, death

**Figure 1** Median QuantiFERON ( $\pm$  IQR) by aetiology of liver disease. or the census date. Infections were per pre-defined criteria of "probable" or "definite" infection adjusted from The International Sepsis Forum Consensus Conference on Definitions of Infection in the Intensive Care Unit<sup>[4]</sup>. All patients were admitted to hospital for intravenous antimicrobial treatment.

Logistic regression, Mann-Whitney *U* test and Kaplan-Meier survival curves were analyzed with GraphPad Prism 6.0 for Mac (IBM, United States). All variables that showed potential predictive capacity of 15% ( $P < 0.15$ ) were entered into a multivariate logistic regression mode using STATA/SE version 12.0 for Mac (Statacorp, United States). *P* values under 0.05 were considered significant. The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki as reflected in a prior approval by the appropriate institutional review committee. All patients provided written informed consent.

## RESULTS

Ninety-one cirrhotic patients were recruited (Table 1). The majority ( $n = 62$ , 68.1%) were male. The mean age was 51 years (median 54, range 20-72 years). The most common aetiology of liver disease was hepatitis C virus infection (HCV, 43%), followed by Primary Sclerosing Cholangitis (PSC, 11%), alcoholic liver disease (ETOH, 11%), and non-alcoholic steatohepatitis (NASH, 10%) (Figure 1). ETOH was a significant co-factor in 14/24 (58.3%) of patients with HCV. QFM level did not vary significantly by aetiology ( $P = 0.08$ ).

The mean QFM in cirrhotics was 214.3 IU/mL, median 94.5 IU/mL compared to a historical cohort of healthy controls (mean 555.2 IU/mL, median 423 IU/mL)<sup>[11]</sup>. There was no significant difference between QFM in males and females ( $P = 0.11$ ). Of the patient group as a whole, the median MELD was 20 and Child-Pugh Score was 10. Hepatocellular carcinoma (HCC) was present in

**Table 2** Univariate analysis of QuantiFERON-Monitor in cirrhotic patients

31 patients (34.1%) and associated with a lower median MELD compared with non-HCC patients (15 vs 20,  $P < 0.0001$ ). Accordingly, HCC patients who expressed a more robust immune response with a median QFM more than double that of non-HCC patients (194 IU/mL vs 73.9 IU/mL,  $P = 0.03$ ).

Several other factors were associated with QFM on univariate analysis. Along with presence of HCC, haemoglobin level was positively associated with QFM. Alternatively, an inverse association was found with advancing MELD score, Child-Pugh score, urea and international normalized ratio (Table 2). On a multivariate regression model, only Child-Pugh score and urea were independently associated with QFM levels in cirrhotic patients (Table 3).

### Predicting pre-transplant infection

Of the 91 cirrhotic patients, approximately half ( $n = 47$ , 51.6%) were transplanted on the day of their QFM measurement. The remaining 44 (48.4%) had the QFM assay performed a median 46 d (range 2-591) prior to the date of censor. This sub-group were further investigated for rates of infection prior to transplantation. Most were receiving antibiotic prophylaxis (34/44, 77.3%).

At the census date, 33 patients (75%) had been transplanted, 3 patients had died (6.8%) and 8 (18.2%) were still awaiting transplantation. Advanced MELD ( $r^2 = 0.27$ ,  $P = 0.002$ ) and Child-Pugh score ( $r^2 = 0.15$ ,  $P = 0.03$ ) were associated with shorter time to transplant, while QFM was not ( $r^2 = 0.01$ ,  $P = 0.64$ ).

Thirteen of 44 patients (29.5%) experienced a pre-transplant infection at a median of 20 d (range 2-182) after their pre-transplant blood test. Three patients had spontaneous bacterial peritonitis (SBP), 4 pneumonia, 3 bacteraemia, 1 fungaemia, 1 urinary tract infection and 1 cholangitis. Most patients ( $n = 9$ , 69%) who experienced

**Table 3** Multivariate regression analysis

	Coefficient	P value	95%CI
Child-Pugh score	-51.9	0.013	-92.6:-11.3
MELD score	16.0	0.131	-4.88:36.9
HCC	62.9	0.366	-74.8:201
Bilirubin	-0.39	0.131	-0.91:0.120
Urea	-14.3	0.046	-28.3:-0.261
Haemoglobin	1.77	0.250	-1.27:4.82
Albumin	7.15	0.141	-2.43:16.7
INR	-114	0.168	-278:49.3

HCC: Hepatocellular carcinoma; MELD: Model for end stage liver disease; INR: International normalized ratio.

an infection had Child-Pugh C cirrhosis but Child-Pugh score was not associated with risk of infection (Figure 2A,  $P = 0.2$ ), whereas MELD score ( $\geq 20$ ) was (Figure 2B; HR = 4.7,  $P = 0.01$ ). Urea above the laboratory reference range of 6.7 mmol/L was not associated with infection risk ( $P = 0.15$ ).

A QFM under the cohort mean of 214 IU/mL was significantly associated with infection pre-transplant (HR = 4.1, Figure 2C,  $P = 0.01$ ) and the combined outcome of infection or death on the waiting list (Figure 2D, HR = 4.4,  $P = 0.006$ ).

Three patients died in this cohort while awaiting transplantation, two from bleeding (one intracranial, one variceal) and one from sepsis and multiorgan failure. The median MELD of these patients was 24 and Child-Pugh score of 12. Patients who died pre-transplant had a significantly lower QFM (AUROC 0.88,  $P = 0.03$ ), and on survival analysis, a very low QFM ( $< 30$  IU/mL) was most associated with a HR of 56.6 for death (Figure 2E,  $P = 0.003$ ).

## DISCUSSION

Infections are implicated in up to 25% of deaths of patients with cirrhosis<sup>[3]</sup>, and are the second leading cause of death in patients with end-stage liver disease awaiting liver transplantation<sup>[5,6]</sup>. Immune dysfunction in cirrhosis is likely multifactorial, with impaired function identified in neutrophils<sup>[7-10]</sup>, monocytes<sup>[11]</sup> and lymphocytes<sup>[12]</sup>. Many of which also show impaired numbers, partly as a result of portal hypertension and splenic sequestration. Advanced cirrhosis is also associated with deficiencies in both structure and function of the reticuloendothelial system<sup>[13,14]</sup>, complement production<sup>[15]</sup>, and a chronic immune activation that appears to result in a systemic immune paralysis<sup>[16-20]</sup>. Although each individual aspect of immune deficiency has been studied in isolation, estimating a patient's overall level of immune function has been unattainable.

QFM was designed as a net immune function biomarker to manage immunosuppression in the post-transplant setting. Unlike other immune function assays that are predominantly confined to research settings, it has potential clinical utility as it is based on QFN-gold, an assay already in widespread use, and requires

**Figure 2** Pretransplant survival based on very low QuantiFERON. A: Infection free survival by Child-Pugh; B: Infection free survival by MELD; C: Infection free survival by QFM; D: Infection and mortality free survival by QFM; E: Pretransplant survival based on very low QFM. QFM: QuantiFERON-Monitor; MELD: Model for end stage liver disease.

only minimal laboratory processing. QFM incorporates both an innate and adaptive stimulant which offers an objective, albeit non-specific overview of a patient's individual immune response. A perhaps not unexpected finding of the original pilot study was that low QFM was identified in patients awaiting, and not only after liver transplantation<sup>[1]</sup>. In this study, we confirm and are able to quantify the immunosuppressed status of cirrhotic patients, with a median QFM of 94.5 IU/mL less than 25% that of healthy controls (423 IU/mL)<sup>[1]</sup>. Most importantly, we not only demonstrate a low QFM in cirrhotic patients (indicative of inherent immunosuppression), but that the most severe immune dysfunction is associated with heightened infection risk. Low QFM in cirrhotic patients had a HR of 4.1 for pre-transplant infection risk. A simple blood test that could highlight a patient's individual risk of subsequent infection would be of value to treating clinicians.

There are some limitations when performing a study in a transplant-waitlisted population. Firstly, with the sickest patients (based on MELD) often receiving priority organ selection, there was risk of patients with greatest risk of infection (and lowest QFM) being transplanted earlier. This risks a type II error, which potentially underestimates the clinical value of the assay in predicting infections; Secondly, we may have underestimated the infection

rate as diagnosing infections in patients with cirrhosis can be difficult, and empirical antibiotics are often used on presentation to hospital with conditions such as variceal bleeding or hepatic encephalopathy; and thirdly, since this data represents the first clinical cohort of non-transplant recipients evaluated with the QFM assay, readily defined set-points for low and very low QFM have not previously been evaluated or described.

Conversely, studying a transplant wait-listed population does offer some advantages since transplant listed patients are more unwell and at greatest susceptibility to infections (reducing the potential sample size and necessary follow-up period). They are closely monitored, with all events being reported to the transplant centre even if occurring at peripheral hospitals, thus allowing all clinical events to be documented.

Early identification and treatment of infections is essential in the management of cirrhotic patients, particularly given the morbidity and mortality often attributed to infections in this vulnerable population. However, infections can be difficult to distinguish from other non-infectious causes of systemic inflammatory response syndrome and symptoms of liver deterioration<sup>[21]</sup>. Serum biomarkers are therefore being examined, although currently available tests such as C-reactive protein, ferritin and white blood cells lack specificity<sup>[21]</sup>.

To prevent infections, some cirrhotic patients are offered antibiotic prophylaxis, although mainly they have been used to prevent episodes of SBP. SBP has a recurrence rate of 70% within 12 mo<sup>[22]</sup>, and secondary prophylaxis is a part of internationally accepted guidelines<sup>[23]</sup>. Primary antibiotic prophylaxis has also been recommended in patients with low protein in ascitic fluid as there is an understanding that it improves incidence of infections and short-term survival<sup>[24,25]</sup>. However, adherence to these guidelines is low, and in part may be due to fears over antimicrobial resistance and reduced effectiveness over time<sup>[26,27]</sup>. An objective immune function biomarker that could highlight patients with the most severe immune-deficiency could enable the use of more targeted antibiotic prophylaxis to those most at risk of all infections, and not just SBP.

There was no significant difference in QFM based on aetiology of the underlying liver disease. Patients with hepatocellular carcinoma as their primary indication for transplant were often not as unwell as other cirrhotic patients, and therefore had significantly higher QFM results on univariate analysis. This was verified in multivariate analysis where HCC was not independently associated with high QFM. Only Child-Pugh score and urea were individually identified on a logistic multivariate regression model as being associated with low QFM. This suggests that commonly used disease scoring systems such as MELD or biochemical investigations such as white cell count are not truly indicative of a patient's underlying level of immune dysfunction and further highlights the possible value of an objective immune function biomarker. The significance of urea with QFM is interesting and would need further study. It could be a surrogate marker of renal function which is known to impact mortality in cirrhosis, although interestingly creatinine had no relationship to QFM. An alternate hypothesis may be that the urea level reflects an increased catabolic state associated with nutritional deficiencies that may impact immune function.

A very low QFM was significantly associated with pre-transplant mortality in this cohort. Although two patients subsequently died of bleeding rather than sepsis, this may highlight the severely immunosuppressed state of patients with critical illness, and offer QFM as an alternate overall prognostic marker. However, despite reaching statistical significance, it is difficult with low numbers to make any firm conclusions regarding QFM and mortality risk. Further studies in a non-transplant wait-listed cirrhotic population would be needed to further explore and confirm this association.

In conclusion, patients with cirrhosis are at high risk of infection, but quantification of immune dysfunction has been difficult in clinical practice. Immune functional assays are often isolated to one small component of immunity, associated with significant laboratory processing or confined to limited situations and medical research. This study describes the first clinical assessment of the QFM immune function assay in patients not receiving

immunosuppressant medications. We show that patients with cirrhosis are not only significantly immunosuppressed, but that a low level of QFM (suggestive of significant immune dysfunction) is associated with a four-fold increased risk for infection. The ability to employ a clinical assay that can objectively provide a biomarker of an individual's innate and adaptive immune function offers obvious benefits to patient care, even outside the transplantation setting. This study also serves as a proof of concept that immune function monitoring may be available and have clinical utility in other fields of medicine where patients are either inherently or iatrogenically immunosuppressed.

## COMMENTS

### Background

Patients with cirrhosis are known to be immunosuppressed and infections are a significant cause of morbidity and mortality. Predicting patients at greatest risk of infection is difficult. The QuantiFERON-Monitor assay (QFM) is a novel immune function biomarker designed to assess immune function in a transplant setting. In this first study to employ QFM in a non-transplant setting, the authors aim to identify whether QFM can objectively measure a patient's immune dysfunction and whether this correlates with the risk of infection.

### Research frontiers

Identifying cirrhotic patients at greatest risk of infection is difficult. Usual biochemical measures such as C-reactive protein and white cell count are not associated with infection in cirrhotic patients.

### Innovations and breakthroughs

QFM is a novel immune function biomarker that provides an objective measure of immune function. In particular, it benefits from measuring interferon gamma production after stimulation of both arms of the immune system (innate and adaptive). In this study, the assay is shown to objectively measure immune dysfunction in cirrhotic patients, and that the patients with lower values had the greatest risk of infection.

### Applications

QFM may have utility in measuring the level of immune function in patients with cirrhosis. This could then identify patients at greatest risk of infection, and who may benefit from either earlier transplantation or antibiotic prophylaxis. Furthermore, the assay may be useful in other medical conditions where patients are either inherently or iatrogenically immunosuppressed.

### Peer-review

This is an questionable topic. First of all, the material method section should be described in a detailed manner. More aspects should be enlightened. Moreover, discussion part should be enlarged properly and more recent studies should be mentioned and more recent studies should be added to references part.

### Abstract

#### AIM

To investigate and summarize the literature regarding the diagnosis and management of intrahepatic pancreatic pseudocysts (IHPP).

#### METHODS

A literature search was performed using PubMed (MEDLINE) and Google Scholar databases, followed by a manual review of reference lists to ensure that no articles were missed. All articles, case reports, systematic reviews, letters to editors, and abstracts were analyzed and tabulated. Bivariate analyses were performed, with significance accepted at  $P < 0.05$ . Articles included were primarily in the English language, and articles in other languages were reviewed with native speakers or, if none available, were translated with electronic software when possible.

#### RESULTS

We found 41 published articles describing 54 cases since the 1970s, with a fairly steady rate of publication. Patients were predominantly male, with a mean age of 49 years. In 42% of published cases, the IHPP was the only reported pseudocyst, but 58% also had concurrent pseudocysts in other extrapancreatic locations. Average IHPP size was 9.5 cm and they occurred most commonly (48%) in the left hemiliver. Nearly every reported case was managed with an intervention, most with a single intervention, but some required up to three interventions. Percutaneous treatment with either simple aspiration or with an indwelling drain were the most common interventions, frequently performed along with stenting of the pancreatic duct. The size of the IHPP correlated significantly with both the duration of treatment ( $P = 0.006$ ) and with the number of interventions required ( $P = 0.031$ ). The duration of therapy also correlated with the initial white blood cell (WBC) count ( $P = 0.048$ ).

**CONCLUSION**

Diagnosis of IHPP is difficult and often missed. Initial size and WBC are predictive of the treatment required. With appropriate intervention, most patients achieve resolution.

**Key words:** Pseudocyst; Intrahepatic; Percutaneous; Pancreatic; Drainage

**Core tip:** Intrahepatic pancreatic pseudocysts (IHPPs) are rare and the pathophysiology is not entirely clear, but they likely result from proteolytic pancreatic fluid tracking from the pancreas into the surrounding tissue. This fluid may then migrate along planes such as the hepatogastric or hepatoduodenal ligaments, to penetrate the hepatic parenchyma. The initial size of the IHPP and the initial white blood cell are predictive of the number of treatments required and the overall duration of treatment required. Percutaneous approaches have been successful and result in good clinical outcomes.

Demeusy A, Hosseini M, Sill AM, Cunningham SC. Intrahepatic pancreatic pseudocyst: A review of the world literature. *World J Hepatol* 2016; 8(35): 1576-1583 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i35/1576.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i35.1576>

**INTRODUCTION**

A pancreatic pseudocyst is an abnormal collection of pancreatic fluid generally due to pancreatitis, exists for at least 4 wk, have a well-defined wall, and contain essentially no solid material<sup>[1,2]</sup>. They are more commonly seen in patients with alcohol-associated pancreatitis (20%) than with gallstone pancreatitis (6.6%)<sup>[3]</sup>. Although most commonly immediately peripancreatic or intrapancreatic, they can occur in truly extrapancreatic locations throughout the peritoneal cavity as well as the mediastinum<sup>[4,5]</sup>.

Extrapancreatic pseudocysts are relatively uncommon, estimated to occur in up to 22% of patients with pancreatic pseudocysts<sup>[5]</sup>. The location depends on where the pancreatic enzymes are released and the path they travel. One of the least common locations for truly extrapancreatic pseudocysts is within the liver<sup>[4,5]</sup>. Here we describe such a case of an intrahepatic pancreatic pseudocyst (IHPP), and exhaustively review, and analyze, the world literature on IHPP.

A 56-year-old male with a history of acute alcoholic pancreatitis presented with intermittent chronic abdominal pain. Magnetic resonance imaging revealed a 1.3-cm lesion in the body of the pancreas consistent with a small pancreatic pseudocyst. Computed tomography (CT) 4 mo later revealed a new, 18-cm-long, bilobed fluid collection, wrapped about the hepatoduodenal ligament,

not only communicating with the original fluid collection but also insinuating itself deeply into the hepatic parenchyma (Figures 1A), with evidence of communication to the erstwhile intrapancreatic pseudocyst (Figure 1B). Given worsening right upper quadrant abdominal pain, fever, chills, anorexia and significant weight loss, and an unknown age of the new IHPP, percutaneous transhepatic drainage was performed of the more superficial, inferior lobe (Figure 2, fluid was high-amylase and culture-negative), as well as endoscopic pancreatic sphincterotomy, and pancreatic-duct stenting. Follow-up CT one week later revealed a significant reduction in the size of both lobes of the pseudocyst. Three weeks later, however, he developed worsening abdominal fullness, pain and fevers. Repeat CT showed the superficial, inferior lobe to be well drained with the pigtail in place (Figure 3A), but the deeper superior collection was found to be larger containing a small bubble of gas (Figure 3B), with the connecting bridge collapsed. The drain was therefore repositioned into this deeper lobe (Figure 4, culture-positive). Following this procedure, the patient improved clinically and was discharged on 4 more weeks of IV antibiotics. Two weeks later he required aspiration of a small liver abscess (low-amylase, culture-positive), although his pseudocysts remained collapsed. At this point the drain was removed. Interval imaging one month and three months (Figure 5) later revealed no residual fluid collections and he remains drain-free, off antibiotics, gaining weight, and productive at work.

**MATERIALS AND METHODS**

A PubMed and Google Scholar search using key words "pseudocyst", "pancreatic", and "intrahepatic" followed by extensive cross-reference review revealed 41 published articles on patients with IHPP. All articles, case reports, systematic reviews which also added a case, letters to editors, and abstracts were analyzed and the data tabulated for comprehensive review and statistical analysis. Bivariate analyses were performed in Statistical Package for the Social Sciences (IBM Corporation, New York, NY, United States). Statistical review of the study was performed by a biomedical statistician.

Articles included were primarily in the English language, but also included French, German, Portuguese, Czech, Korean, and Japanese. Foreign-language articles were reviewed with native speakers or, if native speakers were not available, then the articles were translated with electronic software when possible.

**RESULTS****Prevalence and patient characteristics**

We identified 41 articles containing 54 cases of IHPP in the literature, the earliest identified case being published in 1974 (Table 1). These are primarily single case reports and mini case series but included two relatively thorough review articles which reviewed 26 cases<sup>[6]</sup> and 23 cases<sup>[7]</sup>. Two of the cases were notable in that the IHPP formation

Figure 1 Abdominal computed tomography images showing bilobed intrahepatic pancreatic pseudocysts (A), including connection to main pancreatic duct (B, arrows).

Figure 2 Abdominal computed tomography image showing percutaneous transhepatic drainage of the more superficial, inferior lobe.

was thought to be secondary to ectopic pancreatic tissue and not an inflammatory pancreatic process<sup>[8,9]</sup>. In many of the cases (42%), the IHPP was the only reported pseudocyst, but a significant number also had other concurrent pseudocysts, the most common of which were intra- or peripancreatic pseudocysts (71%).

### Diagnosis

Diagnosis of an IHPP can be difficult as it is uncommon and it is not often part of the initial differential of a patient presenting with abdominal pain. Furthermore, if the presentation is delayed, imaging may reveal the IHPP but without inflammatory changes of the pancreas. Abdominal pain was the primary complaint in 91% of cases, but physical exam was generally nonspecific. Only 17% ( $n = 9$ ) of patients were noted to have a palpable abdominal mass or hepatomegaly, and 15% ( $n = 8$ ) had peritoneal signs. Initial diagnosis was often *via* CT (53%) or ultrasound (US) (33%) but nearly every patient in our database (91% of cases where imaging is mentioned) did get a CT scan at some point in the diagnostic or therapeutic process, and CT is generally considered to be the imaging modality of choice for these patients currently. Prior to the widespread availability of the CT scan, however, a significant workup was often done to identify the etiology of a patient's presentation

and in some cases would include a gastrointestinal transit studies, endoscopy, venogram, arteriogram, or exploratory laparotomy where the lesions were finally identified<sup>[10-12]</sup>. Endoscopy has been used effectively in several cases, not only including initial diagnosis<sup>[13]</sup>, but also with therapeutic intervention<sup>[14,15]</sup>, as discussed further below.

The diagnosis of an IHPP was often delayed with the lesions often initially being mistaken for intrahepatic biliary dilatation, hemangioma, hepatic cyst, pyogenic liver abscess, amebic abscess, biloma, malignancy, echinococcal cyst, or even peritoneal tuberculosis<sup>[10,13,16-19]</sup>. Although IHPP lesions may be clinically suspected in a patient based on the presentation and radiological imaging, definitive diagnosis was rarely made until analysis of the cystic fluid was performed demonstrating a high amylase content<sup>[6,7,17,20,21]</sup>.

### Management

Despite advancements in, and the increasing availability of, imaging modalities, especially the CT scan, the number of reported cases and the type of management techniques have not evolved significantly. There are no widely accepted management guidelines for IHPPs and therefore clinicians have tailored the treatment to the individual patient based on judgment, taking into account many factors, such as underlying etiology, location of the pseudocyst, concomitant lesions, and other patient comorbidities.

Most patients reviewed were symptomatic (91% of reported cases) and required either transcutaneous or surgical intervention. Prior to the development of advanced radiological imaging, more patients underwent a laparotomy and open drainage<sup>[10,12,22]</sup>.

In recent years, however, several less invasive methods have been used to manage IHPPs. Unlike the more commonplace peripancreatic or intrapancreatic pseudocysts, for IHPPs the most common method was percutaneous aspiration or drainage (Table 2) which provided a definitive diagnosis, and was usually well tolerated with minimal complications in these patients<sup>[6,7,23]</sup>. Simple needle aspiration alone with either US or CT

the literature requiring additional interventions.

In addition to either percutaneous drainage or aspiration, there were several other approaches or adjunctive procedures which have been utilized to manage an IHPP. Although most cases are managed percutaneously or operatively, there is an increasing experience with endoscopic approaches. These have included endoscopic retrograde pancreatography (ERCP) with pancreatic duct stenting, endoscopic transpapillary nasopancreatic drainage, pancreatic duct balloon dilatation, and ERCP-guided aspiration (Table 2)<sup>[13-15,24,25]</sup>. Bhasin *et al.*<sup>[24,25]</sup> for example, reviewed 11 patients with atypically located pseudocysts, treated with ERCP and transpapillary nasopancreatic drainage. Placement of a nasopancreatic drain across the disruption was successful in 10 of the 11 patients (90.9%), with resolution of the extrapancreatic pseudocysts in 4-8 wk, with a follow-up period of 3-70 mo.

Operative interventions on patients with IHPPs have been generally reserved for those refractory to, or inappropriate for, nonoperative treatment, such as cases of diagnostic uncertainty<sup>[26]</sup>, rupture<sup>[22]</sup>, or severe infection<sup>[27]</sup>. All 15 operative interventions (Table 2) to manage these IHPPs were open operations and included partial resection with drainage of the cavity into a Roux limb<sup>[8,9,22]</sup> and complete resection/excision of the lesion<sup>[26,28]</sup>. In 10 reports the operation was the first intervention, in 4 reports it was the second intervention, and in one report it was the third intervention (likely,

see below). The four second-intervention operations followed percutaneous aspiration in two cases<sup>[8,22]</sup> and percutaneous drainage in two cases<sup>[12,29]</sup>. The one third-intervention report<sup>[5]</sup>, however, included 19 extrapancreatic pseudocysts, eight of which were intrahepatic, but it is not clearly reported which if any of those eight IHPP patients underwent which operation. We found no report of postoperative pancreatic fistula development complicating operation.

### Outcomes/complications

Although spontaneous resolution of pseudocysts with conservative (noninterventional) management has been reported, complications in these cases included persistent nausea and vomiting, rupture, fistula tract formation, abscess formation if not sterile, or obstruction of the venous or biliary system due to mass effect.

Outcomes were generally very good for patients presenting with these IHPP, with 45% of patients achieved complete resolution of both the cyst and symptoms. In addition, 21% of patients experienced partial resolution of the cyst but total resolution of their symptoms by the time of the follow-up. In our analysis, we noted a statistically significant correlation between the size of the IHPP and both the duration of treatment ( $P = 0.006$ ) and the number of interventions required ( $P = 0.031$ ).

Infection of these pseudocysts was reported in

16% of the cases (Table 2), but an organism is not always reported and it is usually unknown whether organisms were part of the original process, or later infected the pseudocyst. Many cases were associated with leukocytosis [mean reported white blood cell (WBC) count of 15000] but without correlation to positive cultures on pseudocyst aspiration. Although there is no correlation between infection and final outcome, we did note a statistically significant positive correlation between the initial WBC count and the duration of treatment ( $P = 0.048$ ).

There are four reported deaths in the IHPP literature, three of which had undergone a percutaneous drainage procedure<sup>[7,16,20,30]</sup>. Of note, two of these cases had an infectious component either of the intrahepatic pseudocyst or another concomitant pseudocyst<sup>[20,30]</sup>.

## DISCUSSION

IHPPs frequently present with abdominal pain and are diagnosed with either US or CT imaging. Although the mechanism by which IHPPs develop is not entirely clear, the time to presentation varies tremendously with reports ranging from 6 d to 2 mo<sup>[26,29]</sup>. It is understood, however, that although a collection of pancreatic fluid is not called a "pseudocyst" until it has been present for at least 4 wk, according to the 2012 revision of the Atlanta classification and definitions by international consensus<sup>[1]</sup>, many of the IHPP reports reviewed here predate that nomenclature. Therefore, we have retained the term "pseudocyst" in these cases.

The process of IHPP formation begins of course with an inflammatory or traumatic episode during which pancreatic duct disruption occurs, resulting in the leakage of pancreatic fluid into the surrounding tissue. Then, once the pancreatic proteolytic enzymes are found outside the pancreatic parenchyma, they may migrate along planes (e.g., hepatogastric, hepatoduodenal) or, by digesting tissue, across planes into the hepatic parenchyma. The end result of this is often observable by imaging and on anatomical-pathological findings, evidencing rupture of the main pancreatic duct and active communication with the intrahepatic collection, as shown in several reported cases<sup>[5,21,31-34]</sup>, and in our case (Figure 1). However, communication does not always persist and in these select cases, may actually be more amenable to conservative management or observation.

The most common extrapancreatic location for pancreatic pseudocyst development is within the lesser sac and may be seen alone or along with an IHPP<sup>[4]</sup>. An IHPP may be either subcapsular or intraparenchymal with CT imaging of the former characterized by peripheral location and a biconvex appearance<sup>[20,29]</sup>. They are further characterized by their spatial location in either the right lobe, left lobe, or involving both lobes. It has been hypothesized that the location of the pancreatic inflammation (e.g., head vs tail) is correlated with the tract the fluid takes and eventual location in

the liver of the IHPP with several different paths described<sup>[4,5,13,15,16,19,33-37]</sup>. However, we did not find this to be a statistically significant correlation. The left lobe was by far the most common location for an IHPP (Table 2) with fluid that likely traveled through the hepatogastric ligament.

Although IHPPs may resolve spontaneously, this is uncommon. As in our case, symptoms, or occasionally diagnostic uncertainty, generally require intervention to prevent complications such as infection, fistula, rupture, and mass-effect obstruction of the biliary or portal systems. Our experience certainly echoes that in the literature, *viz.*, that percutaneous or surgical drainage is usually well tolerated and results in resolution of the pseudocyst and improvement in associated symptoms. Treatment of course depends on the location, size, and effects of the pseudocyst, patient stability, and whether or not the lesion remains in persistent communication with the pancreas. In addition to the primary drainage methods to address the IHPP, several adjunctive procedures have been done, some of which were reportedly novel for this indication. Examples include placement of pancreatic duct stent, endoscopic placement of a nasopancreatic drain, or FNA during endoscopy<sup>[13,24,25]</sup>. Recurrence of these pseudocysts has not been described in the literature although is certainly possible, and indeed likely, that there were recurrences, the absence of which may be due to lack of longitudinal follow-up, lack of publication, or the rarity of the condition.

Our case was particularly interesting in that the pseudocyst was very large and bilobed, originating around the hepatoduodenal ligament and extending into the liver. The interval presentation between his pancreatitis flare and initial presentation allowed the pancreas to return to fairly normal appearance. This supports the idea that the hepatoduodenal ligament may be a critical structure in the formation of IHPPs.

In conclusion, although IHPPs are often not included in the differential diagnosis of a patient presenting with an intrahepatic lesion, in the right setting and population of patients, it should be considered as an important differential diagnosis. Analysis of this sparse literature has been instructive in revealing a significant correlation between the size of the IHPP and both the duration of treatment and the number of interventions required. The duration of therapy was also correlated with the initial WBC count. These observations may help with prediction of the clinical course in future cases.

## COMMENTS

### Background

The authors have summarized and analyzed the literature on intrahepatic pancreatic pseudocysts (IHPP), to facilitate an appreciation for this study's relevance and to help understand its significance for the field as a whole.

### Research frontiers

Current important areas in the research field as related this study include the establishment of a registry.

## Innovations and breakthroughs

The key advances in the current study is the recognition that size of the IHPP correlates with both the duration of treatment and the number of interventions required. The duration of therapy was also correlated with the initial white blood cell count.

## Applications

These observations may help with prediction of the clinical course in future cases.

## Peer-review

This is an interesting paper on intrahepatic pseudocyst. Conclusions are interesting. Please elaborate if possible more on the role of endoscopic treatment in such cases.

### Abstract

#### AIM

To examine the association of *PNPLA3* polymorphisms in chronic hepatitis C patients and development of liver disease spectrum.

#### METHODS

Literature was searched systematically from PubMed/MEDLINE, EMBASE, and Cochrane search engines for full-length articles written in English that examined *PNPLA3* polymorphism in chronic hepatitis C (CHC) patients. Studies evaluating the association of *PNPLA3* polymorphism spectrum (fatty liver, steatohepatitis, cirrhosis, and hepatocellular carcinoma) of CHC were included. Pooled data are reported as OR with 95%CI. Our study endpoint was the risk of the entire liver disease spectrum including: Steatosis/fatty liver, cirrhosis, and hepatocellular carcinoma in CHC patients with *PNPLA3* polymorphisms.

#### RESULTS

Of 380 studies identified, a total of 53 studies were included for full-text review. Nineteen on chronic he-

patitis C were eligible for analysis. Pooled ORs for rs738409 GG compared to CC and CG among patients with fatty liver was 2.214 (95%CI: 1.719-2.853). ORs among advanced fibrosis/cirrhosis were 1.762 (95%CI: 1.258-2.468). Similar odds ratios among hepatocellular carcinoma patients were 2.002 (95%CI: 1.519-2.639). Pooled ORs for rs738409 GG and CG compared to CC among patients with fatty liver were 1.750 (95%CI: 1.542-1.986). Pooled ORs for advanced fibrosis/cirrhosis patients were 1.613 (95%CI: 1.211-2.147). All analyses were homogenous and without publication bias except one. The associations were maintained after adjusting for publication bias and heterogeneity.

## CONCLUSION

*PNPLA3* polymorphisms have strong association with increased risk and severity of the liver disease spectrum in CHC patients.

**Key words:** *PNPLA3* polymorphism; Cirrhosis; rs738409; Hepatitis C virus; Hepatocellular carcinoma

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** *PNPLA3* polymorphisms (rs738409 CG and GG) are associated with increased risk of steatosis, advanced fibrosis, cirrhosis, and hepatocellular carcinoma in chronic hepatitis C patients.

## INTRODUCTION

Hepatitis C virus (HCV) infection is one of the most important causes of chronic liver disease in the United States<sup>[1]</sup>. About 27% of cases of cirrhosis and 25% of hepatocellular carcinoma (HCC) worldwide are secondary to HCV infection<sup>[2]</sup>. Multiple genetic factors identified within the past few years have been shown to be associated with the predisposition to chronic liver disease and the progression to cirrhosis and HCC<sup>[3,4]</sup>. The single nucleotide polymorphism (SNP) rs738409 C>G (isoleucine to methionine substitution at position 148, I148M) in the *PNPLA3* gene has been strongly linked to progression of liver disease in multiple studies, and this association was confirmed in meta-analyses of the spectrum of alcoholic liver disease (ALD)<sup>[5]</sup> as well as non-alcoholic fatty liver disease (NAFLD)<sup>[6-9]</sup>.

The frequency of hepatic steatosis varies with ethnicity where it was reported as 45%, 33% and 24% in Hispanics, Whites and Blacks respectively<sup>[10]</sup>. At the

same time the frequencies of the *PNPLA3* rs738409[G] allele were 0.49, 0.23, and 0.17 in Hispanics, European Americans and African Americans<sup>[11]</sup>. In addition, the prevalence of the GG genotype in different races in fact correlates with the rate of NAFLD in each respective population, with nearly half of all Hispanics possessing the allele, who in turn are also most likely to have NAFLD. The same is true of the inverse, with less than one quarter of African Americans having the *PNPLA3* rs738409[G] allele, and they are least likely to develop NAFLD compared to Hispanics and Caucasians<sup>[10,11]</sup>.

Given that the association between *PNPLA3* polymorphism and liver disease spectrum in chronic hepatitis C (CHC) patients has not been consistent, especially for HCC<sup>[12,13]</sup> and cirrhosis<sup>[14,15]</sup>, we performed this meta-analysis to further examine the association of *PNPLA3* polymorphisms with the predisposition to the entire spectrum of liver disease among patients with CHC.

## MATERIALS AND METHODS

### Literature search

Utilizing the Meta-analysis of Observational Studies in Epidemiology guidelines, literature was searched from PubMed/Medline, Embase, and Cochrane search engines for full-length articles written in English that examined *PNPLA3* polymorphism in CHC patients<sup>[16]</sup>. The initial medical subject headings search terms were: "Hepatitis C, Chronic" and "adiponutrin, human". The search was then expanded using the terms: "rs738409" and "patatin-like phospholipase domain-containing 3 protein". All databases were searched from their inception date through March 2015. Meeting abstracts from major gastroenterology conferences over the past 3 years were also searched to identify studies that were potentially overlooked in our database search. Articles were selected for full text review based on title and abstract.

### Study selection

Three independent investigators (Masadeh M, Al Hanayneh M and Maslonka M) manually search the retrieved publications to ensure all appropriate articles were discovered and included. Two authors (HS and AKS) reviewed articles in question for possible inclusion. The following inclusion criteria were set for inclusion in this meta-analysis: (1) studies published as full-length articles which reported association of the *PNPLA3* variant (rs738409 C>G) among CHC patients; and (2) studies which analyzed patients with other liver diseases and reported separate data on *PNPLA3* polymorphisms for CHC.

The following exclusion criteria were set: (1) studies without available gene frequency data for analysis; and (2) studies including subjects with other liver diseases without separate data on CHC patients.

### Definitions

HCV infection was diagnosed with both positive serum

anti-HCV antibodies and serum HCV ribonucleic acid (RNA). The disease spectrum was defined as the following: steatosis = fatty liver (FL) on imaging without evidence of cirrhosis or HCC; advanced fibrosis and cirrhosis = biopsy-proven bridging fibrosis, or clinical evaluation supported by hematological, biochemical, and radiologic imaging findings; and HCC = diagnostic imaging findings on triple phase magnetic resonance imaging or computed tomography, or using histological confirmation from liver tissue. Healthy controls were defined as subjects without liver disease and without HCV infection.

### Data extraction

After determining eligibility for inclusion, two reviewers (Masadeh M and Al Hanayneh M) independently extracted data for (1) study characteristics: Author and year of publication, and study design (population based or not, using controls or not); (2) study population: Liver disease spectrum and sample size; (3) frequencies of *PNPLA3* polymorphism genotypes (rs738409 CC, CG, and GG); and (4) OR: For association of *PNPLA3* polymorphism and the spectrum of liver disease and for severity of liver disease. Any discrepancies amongst the reviewers were resolved by jointly reviewing the study in question. Among studies comparing diseased population with healthy controls, similar data were also extracted on healthy controls.

### Endpoints and outcomes

Our study endpoint was the risk of the entire liver disease spectrum including: Steatosis/fatty liver, cirrhosis, and HCC in CHC patients with *PNPLA3* polymorphisms.

### Quality assessment

The quality of included studies was assessed independently by three authors (Masadeh M, Al Hanayneh M and Maslonka M) using the Newcastle-Ottawa Quality Assessment Scale for case-control studies<sup>[17]</sup>. This scale has one instrument for assessing case-control studies and another one for cohort studies. Each of these instruments includes measures of quality in selection, comparability, and exposure domains. While one point is granted for each of the areas measured within the selection and exposure domains, a maximum of two points can be assigned within the comparability domain with highest possible total score of nine. Previous studies have reported that a score of seven or greater denotes a high-quality study<sup>[18]</sup>. Any discrepancies between the three coauthors were addressed by a joint reevaluation of the original article.

### Statistical analysis

The strength of the association between rs738409 and CHC liver disease spectrum prevalence was expressed by OR and their corresponding 95%CI. The Random effects model was used for analyzing pooled data for all the analyses<sup>[19]</sup>. Heterogeneity was measured using  $I^2$  statistics for inter-study variance, with the  $\chi^2$  test

used for statistical analysis. Heterogeneity was defined with  $I^2 \geq 50\%$  or  $\chi^2 P < 0.10$ <sup>[20]</sup>. At least two studies are needed to examine and report heterogeneity. To examine the heterogeneous data and source of heterogeneity, sensitivity analyses were performed in a stepwise fashion for (1) study quality; and (2) excluding studies with the highest and lowest OR. Publication bias was assessed using Egger regression and the Begg-Mazumdar rank correlation tests<sup>[21-23]</sup>. Egger test is a regression method checking for association between effect sizes and standard error and uses actual effect size for each study<sup>[23]</sup>. Begg-Mazumdar is a rank correlation test examining the potential association between effect estimates (taken as a rank and not exact effect size) and sampling variance (or standard error)<sup>[22]</sup>. At least three studies are needed for examining and reporting publication bias. For analyses with publication bias, the analyses were repeated either by performing sensitivity analysis or using the Duval and Tweedie Trim and Fill method, a nonparametric (rank-based) data augmentation technique<sup>[24]</sup>. The method can be used to estimate the number of studies missing from a meta-analysis resulting in a skew of the data due to the suppression of the most extreme results on one side of the funnel plot. The method then amplifies the observed data so that the funnel plot is more symmetric and re-computes the summary estimate based on the comprehensive data. The method should not be regarded as a way of yielding a more "valid" estimate of the overall effect or outcome, but as a means of examining the sensitivity of the results to one particular selection mechanism<sup>[25]</sup>. All statistical analyses were performed using R (Foundation for Statistical Computing) utilizing the metaphor package, or Comprehensive Meta-analysis (Biostat, Englewood, NJ). Singal AK from University of Alabama, Birmingham, reviewed the statistical methods of this study.

## RESULTS

### Baseline study characteristics

A total of 380 citations were retrieved on initial search. After reviewing article titles and abstracts, a total of 53 studies were included for full-text review (Figure 1). Of these, twenty articles were excluded because they did not have sufficient data for our analysis. Nine studies were excluded for including subjects with liver disease not caused by HCV<sup>[11,26-33]</sup>, and three studies were excluded for including subjects co-infected with human immunodeficiency virus and/or hepatitis B virus infection<sup>[34-36]</sup>. One duplicate study<sup>[37]</sup> and one study that looked at treatment response<sup>[38]</sup> were excluded. Nineteen studies evaluating 9093 patients (57.6% males, mean body mass index 25.1 kg/m<sup>2</sup>) on association of *PNPLA3* polymorphisms in CHC<sup>[12-15,39-53]</sup> were included for the analysis. Data on study design, ethnicity and genotype frequency are summarized in Table 1.

Summary		501	9093		57.6	52.7	25.1				

<sup>1</sup>C allele: G allele; <sup>2</sup>CC + CG: GG; <sup>3</sup>CC: CG + GG; <sup>4</sup>Genotype counts were reported as ratios (CC wild genotype: CG heterozygote genotype: GG homozygote genotype) unless indicated by star(s); <sup>5</sup>Calculated from percentages in the original article; <sup>6</sup>Population based studies. A: Asian; BMI: Body mass index; C: Caucasian; FL: Fatty liver; HCC: Hepatocellular carcinoma; M: Mixed (Caucasians and non-Caucasians<sup>[46]</sup> and White/Black/Hispanic<sup>[53]</sup>); P: Prospective; R: Retrospective; M%: Males percentage; N: Number of cases; NA: North African; NS: Not specified in the original manuscripts (although all 4 studies included European referral centers only).

**Figure 1** Attrition on literature search and study inclusion. HCV: Hepatitis C virus; HBV: Hepatitis B virus; HIV: Human immunodeficiency virus.

### Study quality assessment

Based on the Newcastle-Ottawa Scale, nine studies were of “high quality” with a score of seven or more, and the remaining ten studies had a score of six or below (Table 2).

### Association between *PNPLA3* polymorphism and liver disease spectrum (GG vs CG and CC analysis)

**Association of *PNPLA3* polymorphisms with FL in CHC patients:** Among six studies on 3310 patients, the pooled OR for rs738409 GG genotype compared to CC and CG genotypes in CHC was 2.214 (95%CI:

1.719-2.853) (Figure 2A). The data was homogeneous ( $I^2 = 9.4\%$ ,  $P = 0.36$ ) and without publication bias as assessed by Egger test ( $P = 0.08$ ) and Begg-Mazumdar test ( $P = 0.14$ ).

### Association of *PNPLA3* polymorphisms with advanced fibrosis and cirrhosis in CHC patients:

Among seven studies on 3377 patients, the pooled OR for rs738409 GG genotype compared to CC and CG genotypes in CHC was 1.762 (CI: 1.258-2.469) (Figure 2B). The data was heterogeneous ( $I^2 = 65.9\%$ ,  $P = 0.081$ ), with evidence of publication bias as assessed by Begg-Mazumdar test ( $P = 0.036$ ) and tendency for publication bias as assessed by Egger test ( $P = 0.059$ ). Sensitivity analysis after excluding studies with lowest<sup>[14]</sup> and highest<sup>[49]</sup> OR revealed similar effect size: 1.82 (95%CI: 1.41-2.34) with  $I^2 = 18.8\%$ ,  $P = 0.30$ . Additionally, when Dual and Tweedie trim and fall test was used to assess publication bias, 3 studies were trimmed with no change in effect size (OR = 1.39, 95%CI: 1.01-1.92).

### Association of *PNPLA3* polymorphisms and HCC in CHC patients:

Among seven studies on 2274 patients, the pooled OR for rs738409 GG genotype compared to CC and CG genotypes in CHC was 2.002 (95%CI: 1.519-2.639) (Figure 2C). The data was homogenous ( $I^2 = 30\%$ ,  $P = 0.19$ ), without publication bias as assessed by Egger test ( $P = 0.91$ ) and Begg-Mazumdar test ( $P = 0.99$ ).

**Table 2** Newcastle - Ottawa Scale on quality score of the included studies

**Figure 2** Forest plots for analysis of chronic hepatitis C studies on the association of *PNPLA3* polymorphisms GG vs CG and CC with fatty liver in (A), cirrhosis in (B), and hepatocellular carcinoma in (C). The effect size is reported as odds ratio with 95%CI. The bottom line in "the statistics for each study" heading is the pooled effect size analyzed using the random effects model. OR greater than 1 denotes risk for the respective outcome or positive association, and OR less than 1 indicates a protective effect or negative association. The 95%CI not crossing 1 indicates a significant association. Valenti 2012<sup>a</sup> in panel (A) refers to reference<sup>[43]</sup>, and in panel (B) refers to reference<sup>[14]</sup>.

### Association between *PNPLA3* polymorphism and liver disease spectrum (GG and CG vs CC analysis)

**Association of *PNPLA3* polymorphisms with FL in CHC patients:** Among three studies on 1794 patients, the pooled OR for rs738409 GG and CG genotypes compared to CC genotype in CHC was 1.750 (95%CI: 1.542-1.986) (Figure 3A). The data was homogeneous

( $I^2 = 0.0\%$ ,  $P = 0.84$ ), without publication bias as assessed by Egger test ( $P = 0.57$ ) and Begg-Mazumdar test ( $P = 0.99$ ).

### Association of *PNPLA3* polymorphisms with advanced fibrosis, and cirrhosis in CHC patients:

Among three studies on 2131 patients, the pooled OR

**Figure 3** Forest plots for analysis of chronic hepatitis C studies on the association of *PNPLA3* polymorphisms GG and CG vs CC with fatty liver in (A), and cirrhosis in (B). The effect size is reported as odds ratio with 95%CI. The bottom line in the "statistics for each study" heading is the pooled effect size analyzed using the random effects model. OR greater than 1 denotes risk for the respective outcome or positive association, and OR less than 1 indicates a protective effect or negative association. The 95%CI not crossing 1 indicates a significant association.

for rs738409 GG and CG genotypes compared to CC genotype in CHC was 1.613 (95%CI: 1.211-2.147) (Figure 3B). The data was homogeneous ( $I^2 = 41\%$ ,  $P = 0.18$ ), without publication bias as assessed by Egger test ( $P = 0.056$ ) and Begg-Mazumdar test ( $P = 0.99$ ).

## DISCUSSION

We have previously described that *PNPLA3* polymorphism is a modifier in the natural history of ALD<sup>[5]</sup> and NAFLD<sup>[6-8]</sup>. In this meta-analysis, we found a clear association between *PNPLA3* polymorphisms and the entire spectrum (steatosis/fatty liver, cirrhosis, and HCC) of liver disease in CHC patients.

It was previously reported that *PNPLA3* polymorphisms were an independent predictor of more rapid fibrosis progression in patients with chronic hepatitis C<sup>[50]</sup>. The mechanism whereby rs738409 influences the development of fatty liver likely involves a decreased ability of the 148M *PNPLA3* variant to regulate hepatic lipid metabolism<sup>[54]</sup>. It is not known whether the rs738409 SNP influences the steatogenic effect of HCV and the progression of CHC. However, if steatosis causes fibrosis progression in CHC, then it may be assumed the rs738409 SNP should also be associated with advanced fibrosis and HCC<sup>[40]</sup>.

Like any other meta-analysis, our study had to face the possibility of publication bias. In order to minimize this possibility, and the subsequent overestimation of the true effect size due to negative study identification failure<sup>[55]</sup>, we combined searches from PubMed/Medline, Embase and Cochrane with manual searches. Although we used procedures in agreement with current guidelines, we cannot formally rule out the possibility that we overlooked studies that were not accessible<sup>[55]</sup>. Another limitation of this meta-analysis is the inclusion of case-control studies in which the potential for biases (e.g., selection and reporting) is higher when compared to randomized trials, and they are more inherent to confounding factors. In contrary to the previous meta-analysis on *PNPLA3* polymorphisms in alcoholic and non-alcoholic liver diseases that compared different genotypes<sup>[5-8]</sup>, our current analysis used the recessive

model when comparing GG genotype vs CC and CG genotypes, and the dominant model when comparing GG and CG genotypes related to the CC genotype. Finally, no pooled data were provided on steatohepatitis in chronic HCV patients as only one study had reported such an association<sup>[14]</sup>, while the studies by Ezzikouri *et al.*<sup>[44]</sup> and Yasui *et al.*<sup>[48]</sup> either did not have biopsies performed or reported "necroinflammatory changes". Lack of standard definition amongst these studies prevented pooling them together.

The *PNPLA3* GG genotype was negatively associated with sustained virological response and early viral kinetics in patients receiving peginterferon and ribavirin<sup>[15]</sup>. Also, in patients with chronic hepatitis C who failed to achieve sustained virologic response following interferon-based therapy, IL28B and *PNPLA3* were independent predictors of rapid fibrosis progression<sup>[50]</sup>. Tamaki *et al.*<sup>[50]</sup> developed a fibrosis progression-score by combining IL28B and *PNPLA3* genotypes and ALT values, which stratified patients into low, intermediate, and high-risk groups for fibrosis progression. However, this fibrosis progression score needs external validation. In the era of direct-acting antiviral therapy, the question that remains unanswered is whether or not *PNPLA3* polymorphisms identify high-risk CHC patients that are responsive to new treatment regimens. In summary, this meta-analysis provides strong evidence for the association of *PNPLA3* polymorphisms and the spectrum of liver disease in patients with CHC, beginning with fatty liver disease and extending as far as cirrhosis and even HCC in patients with CHC. Further studies on treatment response are needed in this group of patients who carry a higher risk for more rapidly progressive liver disease.

## COMMENTS

### Background

Hepatitis C virus (HCV) infection is one of the most important causes of chronic liver disease in the United States. About 27% of cases of cirrhosis and 25% of hepatocellular carcinoma (HCC) worldwide are secondary to HCV infection.

### Research frontiers

Given that the association between *PNPLA3* polymorphism and liver disease

spectrum in chronic hepatitis C (CHC) patients has not been consistent, especially for HCC and cirrhosis, the authors performed this meta-analysis to further examine the association of *PNPLA3* polymorphisms with the predisposition to the entire spectrum of liver disease among patients with CHC.

### Innovations and breakthroughs

In this meta-analysis, they found a clear association between *PNPLA3* polymorphisms and the entire spectrum (steatosis/fatty liver, cirrhosis, and HCC) of liver disease in CHC patients.

### Peer-review

This manuscript is very well designed; the authors did a great effort in selecting the articles to be included in the meta-analysis with a proper quality scoring of selected articles.

# World Journal of *Hepatology*

*World J Hepatol* 2016 December 28; 8(36): 1593-1644

## Editorial Board

2014-2017

The *World Journal of Hepatology* Editorial Board consists of 474 members, representing a team of worldwide experts in hepatology. They are from 52 countries, including Algeria (1), Argentina (6), Armenia (1), Australia (2), Austria (4), Bangladesh (2), Belgium (3), Botswana (2), Brazil (13), Bulgaria (2), Canada (3), Chile (1), China (97), Czech Republic (1), Denmark (2), Egypt (12), France (6), Germany (20), Greece (11), Hungary (5), India (15), Indonesia (3), Iran (4), Israel (1), Italy (54), Japan (35), Jordan (1), Malaysia (2), Mexico (3), Moldova (1), Netherlands (3), Nigeria (1), Pakistan (1), Philippines (2), Poland (1), Portugal (2), Qatar (1), Romania (6), Russia (2), Saudi Arabia (4), Singapore (1), South Korea (12), Spain (20), Sri Lanka (1), Sudan (1), Sweden (1), Switzerland (1), Thailand (4), Turkey (21), Ukraine (3), United Kingdom (18), and United States (55).

### ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Mohammed Joutei Hassani Tahiri, MD, PhD, Associate Professor, Department of Gastroenterology and Hepatology, Ibn Rochd University Hospital Centre Casablanca, Casablanca 20170, Morocco

### AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### INDEXING/ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

The pathway from clinical suspicion to establishing the diagnosis of biliary atresia in a child with jaundice is a daunting task. However, investigations available help to point towards the correct diagnosis in reasonable time frame. Imaging by Sonography has identified several parameters which can be of utility in the diagnostic

work up. Comparison of Sonography with imaging by Nuclear medicine can bring out the significant differences and also help in appropriate imaging. The battery of Biochemical tests, available currently, enable better understanding of the line-up of investigations in a given child with neonatal cholestasis. Management protocols enable standardized care with optimal outcome. The place of surgical management in biliary atresia is undisputed, although Kasai procedure and primary liver transplantation have been pitted against each other. This article functions as a platform to bring forth the various dimensions of biliary atresia.

**Key words:** Biliary atresia; Neonatal cholestasis; Kasai procedure; Neonatal jaundice; Hyperbilirubinemia

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The etiology of biliary atresia is intriguing with a myriad of diagnostics available to work up a child with neonatal jaundice. This article attempts to review the pathogenesis, evaluation, management and outcome for current update of biliary atresia.

Govindarajan KK. Biliary atresia: Where do we stand now? *World J Hepatol* 2016; 8(36): 1593-1601 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i36/1593.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i36.1593>

### INTRODUCTION

Biliary atresia is the commonest surgical cause for neonatal cholestasis, although the diagnosis is one of exclusion of the various causes of neonatal cholestasis which require non-surgical management. Incidence of neonatal cholestasis is noted to be 1 in 2500 newborn children<sup>[1]</sup>. Among the group of children with neonatal cholestasis, about 34%-42% have been noted to have Biliary atresia<sup>[2,3]</sup>. The actual incidence is around 1 in

8000-18000 live births<sup>[4]</sup>. The etio-pathogenesis is not entirely convincing to point towards a particular offending agent, inspite of several studies describing the causal association of infective or autoimmune origin. The investigations for the establishment of the diagnosis are elaborate, and require extensive workup. As timely surgical intervention is essential, an appropriate and prompt work up is required.

## ETIOLOGY

For the purpose of better understanding, biliary atresia is categorized into 2 forms, the perinatal or the acquired form and the embryonic or the congenital form. The embryonic form is the less common variant of the two (20%), with a link to syndromic association such as Biliary atresia Splenic Malformation (BASM - polysplenia, intestinal malrotation, preduodenal portal vein, absent inferior vena cava, aberrant hepatic artery, abdominal heterotaxia), known to be due to gene mutations controlling the bile duct development. The commoner perinatal form (80%) is supposed to be the end result of viral trigger and complex interactions between innate and adaptive immune responses<sup>[5]</sup>.

The complete deletion of inversin gene in mice was shown to produce laterality defects in the abdominal organs along with malformations of the hepatobiliary system, similar to that of the fetal form<sup>[6]</sup>. However, the role of the inversin gene in humans is unlikely in the fetal form of Biliary atresia, as established by Schön *et al*<sup>[7]</sup>.

Several viral agents such as human papilloma virus, cytomegalo virus, respiratory syncytial virus, reovirus, rotavirus<sup>[8-12]</sup>, epstein barr virus, herpes virus, hepatitis B virus<sup>[13-15]</sup> have been implicated in the past, but none have been consistently and convincingly shown to be associated with the pathogenesis of Biliary atresia in humans.

The cystic biliary atresia is believed to be an exclusive subtype, based on the following observations: (1) jaundice noticed at birth; (2) diagnosed antenatally by the identification of a cystic lesion at the porta on sonography; and (3) intra-operatively a cystic lesion seen, not communicating with intrahepatic ductal system or duodenum.

Reports on cystic type biliary atresia declare that the entity has a better outcome<sup>[16]</sup>.

## PATHOGENESIS

To explain the pathogenesis of Biliary atresia, the concept of an initial viral infection damaging the biliary duct, followed by exaggerated autoimmune directed inflammation of biliary ducts and secondary biliary cirrhosis as a result of progressive ductal injury and obstruction has been mooted<sup>[17,18]</sup>.

Interestingly, studies have noted the ability of Rota virus to target cholangiocytes and cause tissue specific inflammation and pathogenic effects in mouse models. The theory of viral mediated damage and progressive

obliterative inflammation of bile ductules has been put forward, on the basis of this murine model. The virus is found to be tropic to cholangiocytes, leaving behind gamma interferon producing CD4 and 8 lymphocytes which target the hepatobiliary system, culminating in fibrosis of the injured ductal elements, bearing the striking resemblance to Biliary atresia<sup>[19]</sup>.

Furthermore, it was concluded that the gamma interferon triggered the inflammatory changes responsible for progressive bile duct obstruction and obliteration<sup>[19]</sup>. It is believed that DNA hypomethylation changes in CD4 lymphocytes leads onto uncontrolled gamma interferon expression<sup>[20]</sup>. Gamma interferon through release from T lymphocytes, has been projected as the pivotal player, orchestrating the sequence of events, specifically the later occurrence of intraductal inflammation, ductal fibrosis and loss of epithelial integrity. However, the initial response of neutrophilic inflammation to the provoking viral agent was not altered, lending to the surmise that the gamma interferon is responsible for the ultimate damage and loss of extrahepatic bile ducts<sup>[21]</sup>. It is noteworthy that, in their attempt to achieve viral clearance, the CD8 lymphocytes secondarily cause ductular damage resulting in the experimental type of Biliary atresia<sup>[19]</sup>. Alpha2 beta1 integrin has been identified to be the medium of interaction responsible for predisposition of the cholangiocytes to Rhesus Rota virus infection<sup>[22]</sup>.

Regulatory T lymphocyte defects in the presence of viral infection, has also found to be contributory to the unchecked bile ductal inflammation and destruction<sup>[23]</sup>.

## ANIMAL MODELS

The use of intrahepatic injection of chemicals like carbon tetrachloride, ethanol, formalin have been found to simulate inflammation similar to biliary atresia in adult rat<sup>[24,25]</sup>. Other animals like lamb fetus has also been studied<sup>[26]</sup>. Attempted *in vivo* replication of biliary atresia includes bile duct excision or ligation. Sea Lamprey as a model has been propagated with the advantage of seamless progress into biliary atresia without the need for intervention with injection of chemicals or surgical bile duct ligation<sup>[27]</sup>.

## CLINICAL PRESENTATION

The consistent passage of clay coloured stools, dark coloured urine, icterus at about 2 wk of age in a neonate should prompt the complete work up for cholestasis, especially biliary atresia.

## INVESTIGATIONS

Simple macroscopic examination showing clay coloured acholic stool raises a strong suspicion of biliary atresia. When the stools are not acholic, additional features such as fecal fat and consistency can provide more information. Soil like consistency of stool with massive fat droplets on Sudan III stain is a finding which has

high sensitivity, although not specific for biliary atresia detection<sup>[28]</sup>.

### Blood biochemistry

Gamma glutamyl transpeptidase (GGT) has been found to be an important parameter in the differential diagnosis of neonatal cholestasis. Children with Biliary atresia consistently had higher GGT levels than those without Biliary atresia (902.7 mmol/L vs 263.2 mmol/L)<sup>[29]</sup>. Tang *et al*<sup>[30]</sup> demonstrated that an elevated GGT more than 300 IU/L had a specificity of 98% and sensitivity of 38% to differentiate biliary atresia from Neonatal Hepatitis. In addition, the association between GGT and Alanine transferase ALT (GGT/ALT ratio more than 2) was put forth as a useful adjunct in the differential diagnosis of biliary atresia<sup>[30]</sup>.

It is to be noted that, more relevance is placed on the correlation of GGT with age, than an absolute GGT value. To elaborate further, GGT is best diagnostic when evaluating cholestasis in children aged less than 120 d. Among infants aged 31-60 d, GGT levels more than 268 IU/L had a sensitivity of 80.5% and specificity of 75.6%, respectively, with an accuracy of 79.1% in the diagnostic evaluation of Biliary atresia. Recommended cut-off values of GGT for various age groups include 303 IU/L for age 61-90 d, 298 IU/L for age 91-120 d, 252 IU/L for age more than 121 d<sup>[31]</sup>. Another study brought out the optimal threshold for GGT for various ages, 150 IU/L for age less than 4 wk, 250 IU/L for age between 4-8 wk and 300 IU/L for age more than 8 wk<sup>[32]</sup>.

On the contrary, alkaline phosphatase levels were noted to be higher in those children without biliary atresia<sup>[31]</sup>.

The Apolipoprotein E has been found to be useful in the diagnostic workup as the serum levels have been consistently elevated in biliary atresia<sup>[33]</sup>. Rafeey *et al*<sup>[34]</sup> in a recent study showed Apolipoprotein E to have positive predictive value of 71% and negative predictive value of 67% in differentiating biliary atresia from other neonatal cholestatic disorders, indicating that its utility as a stand-alone diagnostic test is limited. Similar results have been seen with procalcitonin, which is an inflammatory marker, synthesized in the liver. Hence it could be used possibly in combination with other tests to improve the diagnostic accuracy<sup>[34]</sup>.

Recently, microRNA assay has been pointed to be a novel method of quick diagnosis of biliary atresia. Injury to liver tissue in biliary atresia is supposed to release certain microRNAs, which are non-coding RNAs regulating target genes. High levels of these micro RNAs are found in the intrahepatic bile ducts confirming the source of release and their specificity. The study by Zahm *et al*<sup>[35]</sup> has established the high levels of serum miR220b/429 in Biliary atresia patients in comparison to other cholestatic disorders, implying the potential and promising utility of these in aiding in the early diagnosis.

### Imaging

Sonography has distinct advantages of being non-

invasive, repeatable, less expensive, readily available bedside and non-ionising, although limited by operator dependancy. Hence, this is used as the initial screening modality in the work up of neonatal cholestasis.

The usefulness of sonography, as an initial diagnostic tool is well brought out in several studies. Presence of a triangular cord sign which is the visualization of the fibrotic cord in the portal hilum is one of the hallmarks of sonographic imaging with a positive predictive value of 95%<sup>[36]</sup>. Triangular or tubular structure with echogenic density cranial to portal vein bifurcation at the liver hilum is indicative of triangular cord sign<sup>[37]</sup>. Gall bladder (GB) morphology is looked into as the primary diagnostic factor on sonography. If the GB morphology is normal on sonography, the next step of measuring the triangular cord thickness is undertaken, which if more than 3.4 mm, the sonographic diagnosis of Biliary atresia is very likely<sup>[38]</sup>.

In addition, the GB contractility, size and dimension, regular mucosal contour all go together in the diagnostic imaging. Findings pertaining to GB on sonography can be absent/non visualized GB, irregular contour of GB, small shrunken GB, non contractile GB despite 4 h of fasting, cystic structure replacing GB and absent echogenic mucosal lining of GB. The liver echotexture signifying the presence of cirrhosis is another finding useful on sonography for prognostication<sup>[39]</sup>. At a cut off GB length of 1.5 cm, high index of suspicion for biliary atresia to be kept while evaluating a baby with neonatal cholestasis<sup>[40]</sup>. In the early stage of the disease, the triangular cord sign may be not prominent, leading to missed diagnosis. Triangular cord sign combined with GB length can act as twin hallmarks in the sonographic diagnosis of biliary atresia. In the setting of periportal inflammation or cirrhosis, sonographic diagnosis may be difficult as triangular cord sign may not be apparent. Utility of the GB ghost triad, including GB length less than 1.9 cm, irregular contour of GB and lack of smooth, regular mucosal echogenicity of GB may be helpful in the above scenario. With an accuracy of 97%, it appears to be an invaluable diagnostic feature on sonography<sup>[41]</sup>.

As adjuncts to the above sonographic parameters, the right hepatic artery diameter more than 1.5 mm and ratio of the right hepatic artery to that of the portal vein more than 0.45 were of use in the sonographic evaluation<sup>[42]</sup>.

The visualisation of hepatic subcapsular flow due to hepatic arteriopathy and fibrosis in biliary atresia is another sonographic feature on colour Doppler study<sup>[43]</sup>. El-Guindi *et al*<sup>[44]</sup> in a recent study reported the superiority of demonstration of hepatic subcapsular flow over the other sonographic parameters such as triangular cord sign, GB contractility, GB size and dimensions of hepatic artery. Even when the sonographic hallmark of triangular cord sign could not be satisfactorily demonstrated, presence of hepatic sub capsular flow can be of significant value in sonographic examination<sup>[45]</sup>.

The measurement of liver span below the costal margin by sonography can help in the workup, as consistently "small" livers are seen in non-biliary atresia

children<sup>[29]</sup>.

Using a special transducer sonography probe, it is now possible to measure liver fibrosis, based on the technique of transient elastography. Consequently, prognostication of the state of the advanced liver disease can be predicted in a non-invasive manner. It is predicted to be useful as a follow up tool, without the need to resort to performing a liver biopsy. However, the sensitivity of this test in identifying early stages of liver fibrosis is limited<sup>[46]</sup>.

It is recommended that a confident demonstration of the triangular cord sign can route the algorithm towards operative cholangiography, rather than subjecting to liver biopsy, in view of the accuracy of the sonographic sign<sup>[29]</sup>.

### **Antenatal diagnosis**

The presence of a cystic structure at the porta hepatis without intrahepatic biliary ductular dilatation goes towards the diagnosis of biliary atresia, in the antenatal period. This is also known to be associated with additional anomalies<sup>[47,48]</sup>.

### **Sonography vs scintigraphy**

Compared to nuclear scintigraphy, sonography has better discriminatory value in the differential diagnosis. This is evidenced by the higher specificity of the triangular cord sign (95.8%) against scintigraphy (72.9%). Also, the positive predictive value of the triangular cord sign scoring twice higher than scintigraphy (77.8% vs 38.1%) puts sonography ahead, in the correct detection of biliary atresia<sup>[49]</sup>.

### **Magnetic resonance cholangiopancreatography**

The utility of Magnetic resonance cholangiopancreatography (MRCP) has not been encouraging in view of the cost, varying results and the need for immobilisation. Negative and positive predictive value have been reported as 91%-100%, 75%-96% respectively<sup>[50,51]</sup>. The requirement of sedation, preferably general anesthesia is a significant concern in addition to long image acquisition time. In a recent study, the image acquisition time using three dimensional MRCP has been reported to be around 180 s. The sensitivity 99.08% and negative predictive value 96.88% were high but the specificity 36.05% and positive predictive value 65.19% were low<sup>[52]</sup>.

### **Nuclear scintigraphy**

Nuclear scintigraphy is non-invasive, simple and is supposed to have practical utility in view of the logical assumption of the functional ability of liver to take up the tagged agent and subsequent excretion in the intestine, enabling visualization of gut activity. Studies caution regarding excessive reliance of scintigraphy, as it may contribute to misdiagnosis in infants with jaundice<sup>[29]</sup>. However, in the background of elevated bilirubin levels and likely deranged liver function, ability to take up the agent

may be compromised. To overcome this, cholegogues such as Ursodeoxy cholic acid, Phenobarbitone, Phenytoin are used as pre-treatment agents, to ensure adequate "priming"<sup>[53]</sup>.

The value of delayed or 24 h imaging has been pointed out to decrease the false positive results as nearly 50% of the bowel visualization was seen in the delayed image<sup>[54]</sup>. As an adjunct, SPECT has been put forth in dealing with poor bowel visualization. More studies are required before concluding in favor of its usage<sup>[55]</sup>. However, arguments against, have discouraged the same citing the poor image resolution with consequent difficult interpretation. Excretion is expected to be less due to reduced uptake primarily, given the background of deranged liver function and high bilirubin levels, competing with the tagged agent effectively to decrease the uptake. Furthermore, it has been proposed that this would be time consuming and lead to more delay in the work up<sup>[56]</sup>.

A recent meta-analysis places the scintigraphy in the correct perspective, at a low specificity of 70.4%, although pooled sensitivity was high at 98.7%. This would mean that almost every case of biliary atresia gets detected, but when the scintigraphy shows no excretion, it does not necessarily diagnose biliary atresia amongst the other causes of neonatal cholestasis<sup>[53]</sup>.

### **Histology**

Liver biopsy is considered as gold standard in the diagnosis of biliary atresia, with an accuracy of 88.2%-96.9%<sup>[57,58]</sup>. To cope with the delayed referrals and the negative laparotomy rate, histology of liver biopsy is proposed as the best alternative. Also, histology has a definitive role, where the various imaging modalities may not be able to suggest the suitable diagnosis, especially in younger neonatal cholestatic children. Among the several findings in histology, ductular proliferation, bile plugs in the ducts and the ductules and portal fibrosis were found to be statistically significant in the diagnostic workup of biliary atresia. On further multivariate analysis, the ductular proliferation emerged as the sole parameter of paramount importance. Of note, age was not found to be a factor in altering the diagnostic histological features in biliary atresia. Multinucleate giant cell formation and myeloid metaplasia were noted to be seen more commonly in neonatal hepatitis<sup>[58]</sup>. Utility of the liver biopsy in the work up of neonatal cholestasis has been recommended as a guideline<sup>[59]</sup>.

Histology can also prognosticate in addition to providing a diagnosis, by cirrhosis assessment and ductal plate malformation. Ductal plate malformation which refers to presence of fetal type intrahepatic duct, is identified to be a poor prognostic factor as it is known to be associated with poor bile flow after Portoenterostomy<sup>[60]</sup>.

Ductal diameter less than 100 microns was a feature identified with children requiring liver transplantation<sup>[61]</sup>. Whereas, when ductal size was more than 150 microns, in combination with a columnar lined epithelium, it was predictive of good prognosis after surgical mana-

gement<sup>[62]</sup>.

Fibrosis as an independent prognostic marker in histological evaluation is established by various studies<sup>[63-65]</sup>. Also, it has been utilized to predict the long term outcome in post-operative biliary atresia patients<sup>[66]</sup>.

Ductopenia and secondary biliary cirrhosis were consistently found to be late histological features<sup>[67]</sup>.

### Endoscopy

Use of endoscopy in biliary atresia is mainly for dealing with the sequelae of portal hypertension and varices. However, endoscopy can be of use in aiding diagnostic workup, in addition to duodenal intubation for bile detection. Sampling of Duodenal contents to improve the accuracy of scintigraphy, as gamma camera may not pick up minimal activity, is a step towards improvisation by means of non-imaging method<sup>[68]</sup>.

### Scoring system

Based on the variable nature of the diagnostic tests and their overlapping tendency, it would be best to rely on a combination of investigations with correlation to the clinical condition, to reach a prompt and confident diagnosis in the individual child with neonatal cholestasis. Most investigations by themselves do not point to a clear cut differentiation between biliary atresia and other causes of neonatal cholestasis. Hence this has led to a strategy of mix and match of modalities to evolve a meaningful scoring system to attempt to objectively categorize the children with biliary atresia from the group of Neonatal cholestasis. The proposal of El-Guindi *et al*<sup>[69]</sup> consists of a twelve-point scoring system, according to clinical, laboratory, ultrasonographic, and histopathological parameters, with a reported accuracy of 98.3% in pin pointing biliary atresia. Strikingly, scintigraphy was not included in their scoring, referring to its low specificity and time lost to prime the patient. Confining to histology, Chen *et al*<sup>[70]</sup> have evolved a 8-feature (liver fibrosis, portal ductal proliferation, bile plugs in portal ductules, cholestasis, hepatocellular changes inflammatory cells infiltration in portal region, extramedullary hematopoiesis, and ductal plate malformation), 21-point (0 to 21) scoring system declaring an accuracy of 91.9% in correctly identifying biliary atresia<sup>[70]</sup>.

## OPERATIVE MANAGEMENT

Surgery is the main stay of treatment in biliary atresia to effectively establish bile drainage and jaundice clearance. Left untreated, there is an incessant progression towards Biliary cirrhosis, end stage liver failure and death by 3 years of age<sup>[4]</sup>. The hallmark of biliary atresia is the difficulty in prediction of the natural course and outcome, given that it should not be considered a single disease entity with a predictable natural history and stereotypical response to surgery<sup>[71]</sup>.

Kasai portoenterostomy relies on the realization that the microscopic structures in the porta hepatis will act as micro-conduits of bile as an internal biliary fistula is

created with a segment of bowel. Use of gall bladder, appendix has been tried earlier as conduits instead of the bowel segment, but none were successful like the bowel. In view of higher revision rates, other conduits except bowel have been abandoned<sup>[72]</sup>.

The extended Kasai procedure attempts at utilising more anastomotic area for achieving effective bile drainage by extending the dissection into the Rex recess (the space between segments III and IV under the liver bridge) and around the bifurcation of the right vascular pedicle of portal hilum<sup>[73,74]</sup>.

Laparoscopic portoenterostomy has not been shown to have better outcome than the open portoenterostomy<sup>[75]</sup>. Although proponents have defended the minimal access approach with the claim that the risk for damage to small bile ductules around the porta hepatis is minimal, due to avoidance of deep suturing and extensive dissection<sup>[76]</sup>. The advantage of minimal adhesions after laparoscopic intervention, enabling future liver transplantation has also been negated<sup>[77]</sup>. Hence, the open portoenterostomy continues to be the gold standard for biliary atresia<sup>[78]</sup>.

The recommendation to perform per op cholangiography directly without a liver biopsy where clinical suspicion is high, reflects the equivocal state of the liver biopsy<sup>[3]</sup>.

### Post-operative management

The role of corticosteroids is hotly debated and controversial, as there is no conclusive evidence in terms of long term improved outcome<sup>[79]</sup>. However, there does seem to be a positive impact of improved clearance of jaundice when steroids are used for a short course in the post-operative period. Thus the lack of translation of beneficial effect with usage of steroids has generally discouraged its prescription in the long term management, although there is a strong link between continuing inflammation, altered immunity and ongoing fibrosis in biliary atresia after Kasai procedure<sup>[80]</sup>. Unlike steroids, Urso deoxycholic acid does play a positive and significant role in the bile flow and finds a place in the post-operative protocol of Biliary atresia management<sup>[81]</sup>.

## OUTCOME

Lower degree of biliary fibrosis, bile ductular proliferation, absence of ductal plate malformation, large ducts more than 150 µm and younger age were found to be associated with better long term outcome<sup>[66]</sup>.

The cystic dilatation of the intrahepatic biliary system on sonography following Kasai during long term follow-up, is considered as a poor prognostic feature lowering the survival rate with native liver<sup>[82]</sup>.

The children with BASM tend to have a poorer prognosis<sup>[83,84]</sup>. Younger age at Kasai was linked with better outcome in those with the cystic type biliary atresia and BASM. Whereas younger age at surgery was not a determining factor in isolated biliary atresia<sup>[83]</sup>.

The long term survival with native liver is significantly lower, establishing the dictum that liver transplant is the

ultimate recipe for biliary atresia management. Adult outcome studies in Biliary atresia patients quote the survival with native liver at 20% in the adults 20 years post Kasai and 10% among those who are 30 years post Kasai<sup>[85,86]</sup>.

Centralisation of services, such that biliary atresia surgery is managed at select centres, has been shown to remarkably increase surgical outcome and overall survival. Standardisation of protocolised management with uniform pre operative work up, surgical technique, post operative management and follow-up seem to be the cohesive factors towards achieving a better outcome. To quote the Finnish study, jaundice clearance rate improved from 27% to 75% and overall survival from 64% to 92% with all the above measures<sup>[87]</sup>.

Kasai portoenterostomy effectively acts as a bridging procedure, enabling retention of native liver in about a quarter of patients and maintaining the rest till an organ is available for transplant in the long term<sup>[88]</sup>. The importance of surveillance is underlined by the fact that majority of the patients (58.3%) after Kasai procedure develop features of chronic liver disease such as Cirrhosis and Portal hypertension<sup>[89]</sup>.

Early neonatal screening with stool charts has a beneficial effect as evidenced by the fact that 5 year survival with native liver increased from 27.3% to 64.3%<sup>[90]</sup>.

Nutritional management for optimal outcome would include feeding regime with a medium chain triglyceride formula. Also, the follow-up of these children should monitor the regular vitamin supplementation of fat soluble vitamins. However, the question of nutritional resuscitation is relevant from the point of view of those awaiting liver transplant<sup>[4]</sup>.

## SCREENING

Various screening methods other than stool charts have been studied, but none are effective as a simple, cost effective and useful tool in screening general population. Serum bile acid, direct bilirubin, Apo C II/CIII proteins, urine sulfated bile acid, fecal bilirubin and fat<sup>[91-95]</sup> were some of the biomarkers used in the literature for screening of Biliary atresia.

## CONCLUSION

Biliary atresia is a multifactorial disorder with varied outcome depending upon the time of surgical treatment and histology. Strict adherence to protocols in the form of investigations would lead to seamless progression from diagnosis to management. Post operative management with appropriate medications is required to ensure an optimal outcome. Long term follow-up is essential as the native liver can fail over a period of time requiring the need for liver transplantation. Although advances regarding understanding of progressive inflammation after portoenterostomy have been made, translation into significant treatment has not evolved yet.

### Abstract

In recent years, defined progress has been made in

understanding the mechanisms of hemodynamic disturbances occurring in liver cirrhosis, which are based on portal hypertension. In addition to pathophysiological disorders related to endothelial dysfunction, it was revealed: There is the restructuring of the vasculature, which includes vascular remodeling and angiogenesis. In spite of the fact that these changes are the compensatory-adaptive response to the deteriorating conditions of blood circulation, taken together, they contribute to the development and progression of portal hypertension causing severe complications such as bleeding from esophageal varices. Disruption of systemic and organ hemodynamics and the formation of portosystemic collaterals in portal hypertension commence with neovascularization and splanchnic vasodilation due to the hypoxia of the small intestine mucosa. In this regard, the goal of comprehensive treatment may be to influence on the chemokines, proinflammatory cytokines, and angiogenic factors (vascular endothelial growth factor, placental growth factor, platelet-derived growth factor and others) that lead to the development of these disorders. This review is to describe the mechanisms of restructuring of the vascular bed in response to hemodynamic disturbances in portal hypertension. Development of pathogenetic methods, which allow correcting portal hypertension, will improve the efficiency of conservative therapy aimed at prevention and treatment of its inherent complications.

**Key words:** Portal hypertension; Vascular remodeling; Angiogenesis; Pathogenesis; Liver cirrhosis

## INTRODUCTION

The majority of severe complications of liver cirrhosis are directly related to its characteristic hemodynamic disturbances, and portal hypertension is at their core<sup>[1]</sup>. Due to various anatomical and functional factors, the increase in hepatic vascular resistance causes the development of portal hypertension. The synthesis of extracellular matrix components leads to serious changes in the liver cytoarchitectonics. Accompanying this process, hypoxia with the participation of vascular endothelial growth factor (VEGF) induce pathological angiogenesis. In addition, sinusoidal endothelial dysfunction in liver cirrhosis disturbs the balance between vasoconstrictors and vasodilators produced by the endothelium. There are endothelin-1 (ET-1) and nitrogen oxide (NO), the most studied at present<sup>[2]</sup>.

In spite of the formation of portosystemic shunts, the subsequent development of hyperdynamic circulatory syndrome contributes to the progression of portal hypertension. Appearing in this case circulatory disorders are caused by endothelial dysfunction and restructuring of the vascular bed that includes vascular remodeling and angiogenesis<sup>[3]</sup> (Figure 1).

The purpose of the review is to describe the mechanisms of restructuring of the vascular bed in response to hemodynamic disturbances in portal hypertension.

## CURRENT CONCEPT OF VASCULAR REMODELING

The term "remodeling" started to be used in the 1980s of the last century, mainly in cardiology. In the strict interpretation, it means the process of reorganization of the existing structure, during which it joins a new material or it is entirely changed. Vascular remodeling is an adaptive response to long-term hemodynamic disturbances. This process includes several stages<sup>[4]</sup>: (1) perception of signals about modified conditions of blood circulation and circulating humoral factors; (2) signal transmission within a cell and between adjacent cells; (3) synthesis, activation, or release of substances affecting cell growth, death, migration, or extracellular matrix

construction; and (4) structural changes of the vascular wall (both cellular and extracellular components), its mechanics, and function.

Endothelial cells are the main sensors perceiving changes in blood flow and the impact of various humoral factors. They are constantly activated by mechanical stimuli, such as shear stress and intravascular pressure, which are transformed into intracellular and extracellular chemical signals within endothelial cells. These changes occur in the early stage of the mechanotransduction process<sup>[5]</sup>. It involves a variety of physiological elements including ion channels, molecules of cell-matrix and cell-cell interactions [integrins, platelet-endothelial cell adhesion molecule-1 (PECAM-1) or CD31, adherent compounds], tyrosine kinase receptors, caveolae, G protein-coupled receptors and G-proteins, glycocalyx, endothelial cell cytoskeletal components, and others. In response to mechanotransduction, there are formation and secretion of biologically active substances produced by the endothelium. They regulate the development of extracellular matrix, proliferation, migration, and organization of endothelial and smooth muscle cells, as well as sensitivity to growth factors - the key events in the vascular remodeling. Currently, the most studied ones are the vasodilators NO and prostacyclin (PGI<sub>2</sub>), and the vasoconstrictor ET-1<sup>[6]</sup>.

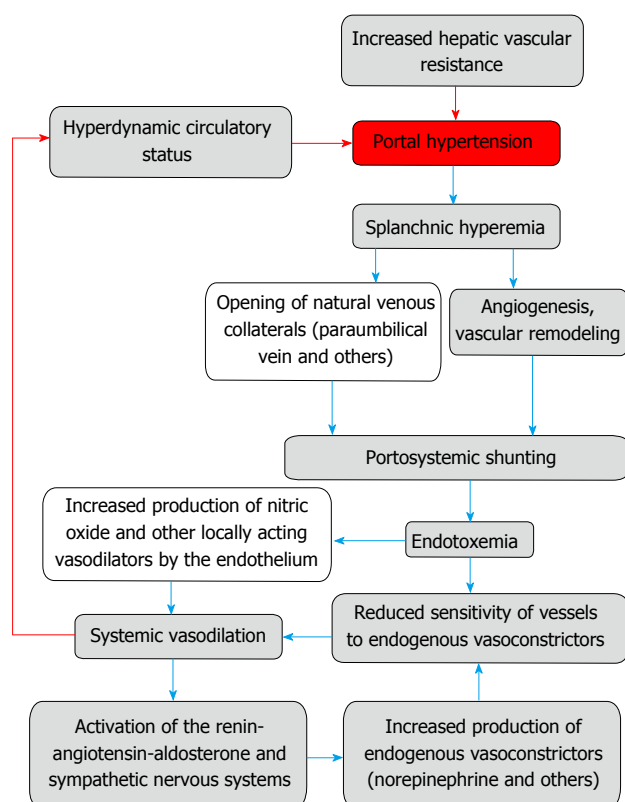

Structural changes of blood vessels consist in eutrophic, hypertrophic, and hypotrophic remodeling. In inward eutrophic remodeling, outer and lumen diameters are reduced, and media cross-sectional area is unaltered. Inward hypertrophic remodeling is characterized by an increase in media/lumen ratio owing to media cross-sectional area increasing. Outward hypotrophic remodeling refers to an increase in lumen diameter and a decrease in cross-sectional area<sup>[7]</sup>.

Distensibility is an important mechanical characteristic of the blood vessels defined as the percentage of change of their volume for each 1 mmHg change in intraluminal pressure. It depends primarily on the stiffness of the vascular wall, which mainly consists of collagen, elastin, and smooth muscles. It has been shown on the experimental model of spontaneously hypertensive rats that reduced distensibility of major arteries is related to increased quantity and changing structure of elastin, whereas its reduction in mesenteric resistance vessels mainly results from the modification of the elastin structure and possibly collagen accumulation<sup>[8]</sup>.

## MOLECULAR MECHANISMS OF THE ANGIOGENIC PROCESS

Angiogenesis is the complicated physiological process of creating new blood vessels. It occurs *via* activation of endothelial cells, expression of proteases in them, extracellular matrix destruction, proliferation, migration of endothelial cells, and creation of the highly permeable primary vascular structures, which is reconstructed into the three-dimensional vascular network after stabilization

**Figure 1** Potential mechanisms of the pathogenesis of portal hypertension in liver cirrhosis.

and “maturation” by attracting pericytes and smooth muscle cells<sup>[9]</sup>.

The major inducer of angiogenesis in both pathological and physiological conditions is hypoxia. The cells react to lack of oxygen by several mechanisms including accumulation of hypoxia-inducible factors (HIFs). They are activated in the physiologically important sites of regulation of the oxygen pathways to provide quick and adequate responses to hypoxic stress and activate genes that regulate the angiogenesis process, vaso-motor control, energy metabolism, erythropoiesis, and apoptosis<sup>[10]</sup>.

The HIFs family include three  $\alpha$ -subunits, which are connected with a  $\beta$ -subunit (HIF-1 $\beta$ ). HIF-1 $\alpha$  is ubiquitously expressed, whereas HIF-2 $\alpha$  is found in a more limited set of cell types, particularly in vascular ECs, type II pneumocytes, hepatocytes, and macrophages. The role of HIF-3 $\alpha$  is less well understood in hypoxic responses<sup>[11]</sup>.

HIFs are considered to be the major transcriptional regulators of genes involved in response to the lack of oxygen, whereas miRNAs regulate gene expression post-transcriptionally<sup>[12]</sup>.

The most investigated angiogenic growth factors are the family of VEGF. It consists of five homologs: VEGF-A, B, C, D and placental growth factor (PlGF). All VEGFs binds to various related receptors: VEGFR-1, VEGFR-2, VEGFR-3. Only the first two of them are responsible for transmission of angiogenic signals. What is more, the binding of VEGF-A to VEGFR-2 and the increase of

vascular permeability under the influence of nitric oxide are the mechanisms triggering vasculogenesis and angiogenesis<sup>[13]</sup>.

Members of the fibroblast growth factor (FGF) family are also capable of stimulating angiogenesis. Cellular response to the impact of FGFs develops *via* specific binding to FGF-receptors (FGFR), which have internal tyrosine kinase activity. Dimerization of FGFR is a precondition for activation and phosphorylation of signaling molecules occurring with the participation of heparin-binding proteins. The process stimulates cell differentiation, proliferation, migration, and destruction of the extracellular matrix. It is important to note that while members of the VEGF family are involved mostly in the capillary formation, the FGF mainly involved in arteriogenesis<sup>[14]</sup>.

Although the platelet-derived growth factor (PDGF) influence on angiogenesis is not so explicit in contrast with VEGF and FGF, studies *in vivo* have shown that it is capable of causing the formation of blood vessels and regulating their tone<sup>[15]</sup>.

Tie-2 (Tek), a tyrosine kinase receptor expressed by endothelial cells, and its ligands, the angiopoietins (Ang), play an important role in the coordination of the angiogenesis process. Angiopoietin-1 (Ang-1) promotes stabilization of vessels *via* inhibiting endothelial cells apoptosis and stimulating its formation. In contrast, Ang-2, an antagonist of Ang-1, results in destabilization of vessels by converting the endothelial cells to the proliferative phenotype from the stable state. However, Ang-2 is also able to stimulate angiogenesis with the participation of VEGF<sup>[16]</sup>.

Integrin  $\alpha$  v  $\beta$  3 ( $\alpha$ v $\beta$ 3) and  $\alpha$  v  $\beta$  5 ( $\alpha$ v $\beta$ 5) were regarded as positive regulators of angiogenesis for a long time. Nevertheless, the recent studies have shown their inhibitory role in this process<sup>[17]</sup>.

Vascular endothelial (VE)-cadherin, an endothelial-specific adhesion molecule, promotes cell-cell junctions during neovascularization and manages the transport of molecules through the endothelial lining<sup>[18]</sup>.

Thrombospondin-1, an antiangiogenic protein, has a direct impact on migration and apoptosis of endothelial cells. Furthermore, it prevents the release of VEGF from the extracellular matrix by suppressing the activation of matrix metalloproteinases (MMPs)<sup>[19]</sup>. Endostatin, a fragment of the C-terminal part of the collagen XVIII  $\alpha$ 1-chain, and angiostatin, a plasminogen degradation product, are also inhibitors of angiogenesis<sup>[20]</sup>.

The first step in the formation of new blood vessels is vasodilatation. Ang-2 and VEGF affect the formation of endothelial fenestrae. Increased vascular permeability causes extravasation of plasma proteins, which will further serve as a scaffold for migrating endothelial cells. Meanwhile, integrins provide them information about the presence of the angiogenic sites. The next step is the destruction of the basement membrane and the extracellular matrix by activated MMPs. This induces the subsequent migration and proliferation of endothelial cells with the participation of angiogenic growth factors such

as VEGF, FGF, and epidermal growth factor (EGF). One of the regulators of this process is a transmembrane protein ESDN - endothelial and smooth muscle cell-derived neuropilin-like protein<sup>[21]</sup>.

Endothelial progenitor cells differentiate into endothelial cells. VE-cadherin and integrins coordinate their binding, and tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), FGF, and PDGF create conditions for the formation of new capillaries. Endothelial cells form the new basement membrane and the extracellular matrix with the participation of surrounding pericytes. Ang-1 provides final vascular stabilization<sup>[9]</sup>.

## MECHANISM OF PORTAL-SYSTEMIC COLLATERALS FORMATION

In the early stages of the development of portal hypertension, a moderate increase in the portal pressure leads to a redistribution of blood flow toward the muscle layer of the small intestine. The appearance of mucosal hypoxia causes a significant increase in NAD(P)H oxidase activity, the main source of reactive oxygen species (ROS) in the mucous membrane, and also leads to increased production of VEGF and NO by arterioles, contributing splanchnic vasodilation<sup>[22]</sup>. In addition, multiple signaling pathways are stimulated, such as mitogen-activated protein kinases, tyrosine kinases, and transcription factors that are involved in VEGF-induced neovascularization<sup>[23]</sup>. It was shown that overexpression of Kruppel-like factor 2 in duodenal tissue with the assistance of microRNAs causes hemodynamic stimuli integration and VEGF-driven angiogenesis in patients with liver cirrhosis<sup>[24]</sup>. Besides the wall of the small intestine<sup>[25]</sup>, the elevated levels of VEGF, VEGFR-2, and CD31 (PECAM-1) is observed in the mesentery<sup>[26]</sup>.

These pathophysiological disturbances may be the initial step in the development of portosystemic collateral circulation in portal hypertension<sup>[27]</sup>. Monocytes adhere to the surface of activated endothelial cells and produce growth factors and proteases, such as urokinase plasminogen activator and MMPs, promoting the division and migration of smooth muscle cells. Proinflammatory cytokines [macrophage chemotactic protein-1, granulocyte-macrophage colony-stimulating factor, transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1), TNF- $\alpha$ ] also promote the growth of blood vessels, as well as growth factors such as PIGF, which stimulates the growth of endothelial and smooth muscle cells, FGF - through upregulated expression of PDGF receptor, and VEGF by reaction with Ang-1. At the same time, anti-inflammatory cytokines (e.g., interleukin-10) inhibit the process<sup>[28]</sup>.

It was shown in animal model of prehepatic portal hypertension induced by partial portal vein ligation, that the blockade of VEGFR-2 with anti-VEGFR-2 monoclonal antibody for 5-7 d and inhibition of VEGF/VEGFR-2 signaling using autophosphorylation inhibitor VEGFR-2 for 5 d after the operation resulted in 50% reduction of portosystemic collateral vessel formation<sup>[29,30]</sup>. Blockade

of NAD(P)H also contributed to this owing to the reduced splanchnic expression of VEGF, VEGFR-2 and CD31<sup>[31]</sup>.

It should be noted that the emerging shunts are very dynamic vascular bed because of the expression of various receptor types on the surface of the endothelial lining, for example,  $\alpha$  and  $\beta$  adrenoreceptors, 5-HT<sub>2</sub> receptors. Furthermore, vasoactive substances such as NO, ET-1, prostaglandins can affect their tonus<sup>[32]</sup>. In particular, it was noted that excessive discharge of blood through portosystemic collaterals because of postprandial splanchnic hyperemia promotes their dilation due to shear stress, which in turn induces the overproduction of NO by endothelial cells<sup>[33]</sup>. Although natural portosystemic anastomoses are found in all patients with portal hypertension, they acquire the highest clinical significance in the development of gastroesophageal varices, because their rupture leads to life-threatening bleeding. The determining factor in their formation is the type of hepatofugal blood flow, and a gastroesophageal drainage path is the most important in this situation. The left gastric vein plays the main role in this path. It drains blood from both surfaces of the stomach, ascends from right to left along the lesser curvature into the lesser omentum, to the esophageal opening of the diaphragm, where it receives esophageal veins. It then turns backward and passes from left to right behind the omental bursa and drains into the portal vein. Anastomoses between the left and right gastric veins and the left and short gastric veins, respectively indicated by terms "coronary vein" and "posterior gastric vein", have clinical significance only in portal hypertension, because they are involved in the formation of esophageal and related with them paraesophageal varices<sup>[34]</sup>.

Immunohistochemical studies, which was conducted in patients with portal hypertension, revealed the existence of the pronounced expression of PDGF, basic FGF-2, EGF and TGF- $\alpha$  in the wall of the coronary vein of the stomach. This fact shows that the increase in pressure in this vein activates smooth muscle cells and induces the release of growth factors that stimulate their proliferation, differentiation, and migration, as well as contribute to the disruption of the metabolism of collagen and elastin fibers. Phenotypic changes of smooth muscle cells is a response to chronic mechanical stimuli. They are lead to thickening of the venous wall and reduce its elasticity<sup>[35]</sup>.

## VASCULAR STRUCTURE OF THE LOWER ESOPHAGUS IN CLINICAL PORTAL HYPERTENSION

The venous system of the distal portion of the esophagus includes intraepithelial, subepithelial superficial, deep submucosal and adventitial veins. The largest varices are generally localized 2-3 cm above and 2 cm below the cardia, mainly in the lamina propria of the mucous membrane. They have two types of vascular structure: Palisading type and bar type. The palisading type has

dilated intraepithelial channels and numerous small superficial collateral veins. The bar type has triply dilated subepithelial superficial veins and deep submucosal veins which erode the epithelium<sup>[36]</sup>. Structural changes in the veins of the distal portion of the esophagus in portal hypertension are characterized by thickening of the medial layer because of hyperplasia of elastic and collagen fibers. Elastic fibers become fragmented and sharply tortuous directly in the varicose veins of the esophagus in the background of increasing sclerosis of the vascular wall<sup>[37]</sup>.

Four distinct intramural vascular zones of the gastroesophageal junction were defined as follows: Gastric zone, palisade zone, perforating zone, and truncal zone. Portacaval shunts in this area are formed because of increased pressure in the portal venous system<sup>[38]</sup>.

### **Gastric zone**

The longitudinal veins of the gastric area are located in the submucosa and the lamina propria of the proximal portion of the stomach. They are more abundant near the esophagus, have a small diameter, and form a group of several longitudinal vessels. The veins merge in the submucosa of the distal part of the gastric zone and form large tortuous trunks draining blood into the portal vein system.

### **Palisade zone**

The palisade zone is an extension of the gastric zone. It begins in the projection of the gastroesophageal junction and ends 2-3 cm above it. Veins in that zone are located randomly, close to each other, and are arranged longitudinally and in parallel as a palisade.

Numerous anastomoses are identified between vessels of both gastric and palisade zones. They are localized in the submucosa of the gastroesophageal junction, penetrate the muscularis mucosa, and pass into the lamina propria mainly in a longitudinal direction.

Veins of a proximal portion of the palisade zone simultaneously converge at one point and, perforating the muscularis mucosa, pass into the submucosa again as four or five big trunks. There are arched transverse anastomoses between them. Veins perforating the muscular layer of the esophagus were not detected in this zone.

### **Perforating zone**

Veins of the perforating zone, which is located 3-5 cm above the gastroesophageal junction, are not so homogeneous and constant. Vessels form five polygonal networks in the lamina propria of the esophageal mucosa (as a continuation of the veins of the palisade zone) and perforate the muscular layer, communicating with adventitial veins located on the outer esophageal surface. They were referred to as (treble clef) veins because of their similarity with music symbols.

The perforating zone is the "critical area" for variceal rupture in portal hypertension. This is due to increased

resistance to blood flow in this anatomical area, as well as increased fragility and superficial location of perforating veins<sup>[39]</sup>.

### **Truncal zone**

The truncal zone is a region from 8 to 10 cm in length with the bottom edge 5 cm above the gastroesophageal junction. Large longitudinal venous trunks, discovered here in the lamina propria, constitute a continuation of the polygonal vascular networks of the perforating zone. They have a small diameter in the proximal portion. Between them, there are several transversely oriented anastomoses. Perforating veins, locating randomly along the zone, pass from the submucosa of the esophagus to its outer surface and communicate with adventitial veins.

In physiological terms, palisade zone is the most important part of the vascular structure of the gastroesophageal junction. Veins are located there mainly in the lamina propria. Their superficial location decreases venous blood flow resistance to a minimum, which would otherwise arise in the high-pressure zone in the area of the lower esophageal sphincter.

A large number of small caliber vessels in the palisade zone with a longitudinal stroke and parallel to each other perfectly adapted to the physiological pressure variations that leads to a bi-directional flow during breathing. When the venous outflow is carried out in the caudal direction, the gastric zone collects and drains the blood into the portal vein system.

Deep submucosal veins are enlarged because of the blood outflow in the cranial direction in portal hypertension. They drain the blood into the enlarged adventitial veins (periesophageal collateral veins) through the numerous veins perforating the esophageal smooth muscle layer in the perforating zone. Adventitial veins, in turn, communicate with paraesophageal collateral veins, which are located in the posterior mediastinum. The blood flows from them usually into the azygos vein<sup>[40]</sup>, which structural changes in response to increased blood flow are characterized by focal destruction, hyperplasia and chaotic arrangement of elastic fibers<sup>[37]</sup>.

---

## **THE SYSTEMIC AND SPLANCHNIC ADAPTIVE RESPONSE OF VASCULAR BED TO HEMODYNAMIC DISTURBANCES IN PORTAL HYPERTENSION**

---

The development of portosystemic collateral circulation is a compensatory mechanism, which purpose is decompression of increased portal pressure. However, this does not happen. Conversely, there is a hyperdynamic circulatory state accompanied by increased cardiac output, decreased peripheral vascular resistance, and the opening of arteriovenous communications, which exacerbates portal hypertension. The cause of these disorders may be the flow of vasodilator substances (e.g., glucagon, endocannabinoid, atrial natriuretic

peptide, bacterial endotoxin) through the network of portosystemic shunts, as well as increased production of topical vasodilators by endothelium, such as NO, carbon monoxide, PGI<sub>2</sub>, endothelium-derived hyperpolarizing factor, adrenomedullin, hydrogen sulfide. Furthermore, in spite of increased circulating levels of endogenous vasoconstrictors (noradrenaline, ET-1, angiotensin II), vascular sensitivity to them is significantly reduced<sup>[41]</sup>.

### **Abdominal aorta**

Adaptive response of the abdominal aorta to shear stress, induced by the blood flow in the conditions of the hyperdynamic circulation, may be associated with oxidative stress. Production of ROS, such as superoxide and hydrogen peroxide, which are toxic metabolic products of the cells, leads to non-specific damage of nucleic acids, proteins, lipids, and its other components. ROS regulate vascular tone, endothelial cells sensitivity to oxygen, their growth, proliferation, and apoptosis. Furthermore, they promote the expression of inducible genes by transcription factors, including NF- $\kappa$ B. These genes contribute to the synthesis of chemokines, chemokine receptors, proinflammatory cytokines, and adhesion molecules, inducing an inflammatory response. Potential sources of ROS are various enzyme systems: NAD(P)H oxidase, xanthine oxidase, enzymes of arachidonic acid metabolism (cyclooxygenase and lipoxygenase), and the mitochondrial respiratory chain<sup>[42]</sup>.

Increased levels of TNF- $\alpha$ , IL-1 $\beta$ , and IL-6 in the aorta, as a result of oxidative stress, plays an important role in the induction of immune-mediated systemic vascular process in portal hypertension. Particularly, TNF- $\alpha$  induces activation and translocation of NF- $\kappa$ B to the nucleus with activation of NF- $\kappa$ B-dependent target genes. The subsequent increase in expression of connective tissue growth factor may enhance the synthesis of extracellular matrix proteins, particularly, collagen I type, whereas the decrease of the level of MMP-2/TIMP-2 complex (tissue inhibitor of metalloproteinase-2) will contribute to reducing the degradation of extracellular matrix proteins. These processes lead to significant histological changes in the aorta. Its wall thickness decreases, as well as the ratio of medial layer thickness to lumen diameter. Elastic fibers lose their ordered arrangement, and well-marked collagen fibers become more narrow and separated because of the increase of the extracellular matrix in the interstitium of media with a significant decrease in the number of smooth muscle cells<sup>[43,44]</sup>.

The left gastric artery is the first branch of the celiac artery. It is assumed that the hemodynamics in the left gastric artery in portal hypertension may act as the initiator of variceal formation, showing close linkage with variceal recurrence<sup>[45]</sup>.

### **Mesenteric resistance arteries**

Similar infringements also occur in mesenteric resistance arteries. The mechanical stimuli, generated by shear stress, activate endothelial cells and induce hyperproduction of NO and prostaglandins, causing vasodila-

tion<sup>[46]</sup>. The significantly reduced isometric stiffness of blood vessels and their increased elongation may cause structural changes in the internal elastic membrane and increase fenestrations in it<sup>[47]</sup>. This contributes to excessive NO-mediated vascular permeability and angiogenic processes in the mesentery of the small intestine because of the high VEGF and eNOS expression in microvessels located there<sup>[48]</sup>.

### **Portal vein and hepatic artery**

Splanchnic hyperemia leads to increased portal venous inflow. The portal vein becomes dilated under the influence of shear stress. Its intima and media are thickened due to the high content of collagen fibers here, hypertrophy, and hyperplasia of smooth muscle cells, which significantly reduce the vascular wall elasticity<sup>[49]</sup>. At the same time, portal blood flow, supplying the liver, decreases because of collateral circulation, and so-called hepatic arterial buffer response maintains hepatic perfusion constancy. This phenomenon, first described by Lautt<sup>[50]</sup>, was identified in physiological conditions and in various pathological conditions. In liver cirrhosis, it is caused by intrahepatic hypoxia. Oxidative stress contributes to hepatic artery remodeling, which is accompanied by its dilation, decreased elasticity and thinning of the wall, as well as increased expression of adenosine and NO<sup>[51]</sup>. This reduces hepatic arterial vascular resistance and allows to maintain oxygen supply to the liver, providing protection of the organ structure and function<sup>[52]</sup>.

### **Splenic artery and vein**

Significant histopathological changes also occur in the blood vessels of the spleen. Damaged splenic artery intima becomes thicker, and smooth muscle cells grow into it. The internal elastic lamina is stratified, that is accompanied by the destruction of both included in its structure and localized in media elastic fibers.

Smooth muscle cells, randomly located in media, have a different size and morphology, and the content of separating them collagen fibers, as well as the extracellular matrix, increases significantly, causing the "collagenization" of the vascular wall, thickening, and rigidity<sup>[53]</sup>. The splenic vein expanding and its intima and media thickening is due to high content of collagen fibers, hypertrophy, and hyperplasia of smooth muscle cells<sup>[54]</sup>. These pathologic changes in the blood vessels of the spleen lead to a significant reduction of their flexibility.

## **CONCLUSION**

In recent years, defined progress has been made in understanding the mechanisms of hemodynamic disturbances occurring in liver cirrhosis, which are based on portal hypertension. In addition to pathophysiological disorders related to endothelial dysfunction, it was revealed: There is the restructuring of the vasculature, which includes vascular remodeling and angiogenesis. In spite of the fact that these changes are the compensatory-adaptive response to the violated conditions

of blood circulation, taken together, they promote the development and progression of portal hypertension causing severe complications such as bleeding from esophageal varices. Disruption of systemic and organ hemodynamics and the formation of portosystemic collaterals in portal hypertension commence with neovascularization and splanchnic vasodilation due to the hypoxia of the small intestine mucosa. In this regard, the goal of comprehensive treatment may be to influence on the chemokines, proinflammatory cytokines, and angiogenic factors (VEGF, PIGF, PDGF and others) that lead to the development of these disorders. Although pathogenetically reasonable methods of correction of portal hypertension are studied mainly at the molecular, cellular level, and in animal experiments, it can be expected that their clinical implementation will improve the efficiency of conservative therapy aimed at prevention and treatment of its inherent complications.

## Abstract

### AIM

To assess how serum gamma-glutamyltransferase (GGT) fractions vary in patients with alcoholic liver disease (ALD) and non-alcoholic fatty liver disease (NAFLD).

### METHODS

Serum samples were obtained from 14 patients with biopsy-proven alcoholic liver diseases and 9 patients with biopsy proven non-alcoholic fatty liver disease. In addition to these biopsy-proven cases, 16 obese (body mass index > 25) patients without any history of alcohol consumption but with a fatty liver on ultrasound examination and with elevated GGT were included for an additional analysis. Serum GGT fractionation was conducted by high-performance gel filtration liquid chromatography and was separated into the four fractions, big-GGT, medium-GGT, small-GGT (s-GGT), and free-GGT (f-GGT).

### RESULTS

The results were expressed as a ratio of each fraction including the total GGT (t-GGT). The s-GGT/t-GGT ratios

were lowest for the control group and highest for the ALD group. The differences between the control and NAFLD groups and also between the NAFLD and ALD groups were statistically significant. In contrast, the f-GGT/t-GGT ratios were highest in the control group and lowest in the ALD group, with the differences being statistically significant. As a result, the s-GGT/f-GGT ratios were markedly increased in the NAFLD group as compared with the control group. The increase of the s-GGT/t-GGT ratios, the decrease of the f-GGT/t-GGT ratios, and the increase of s-GGT/f-GGT ratios as compared with the control group subjects were also found in obese patients with clinically diagnosed fatty change of the liver.

## CONCLUSION

Serum GGT fractionation by high-performance gel filtration liquid chromatography is potentially useful for the differential diagnosis of ALD and NAFLD.

**Key words:** Gamma-glutamyltransferase; f-GGT/t-GGT ratios; Alcoholic liver disease; Non-alcoholic fatty liver disease; Gel filtration liquid chromatography

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The aim of this study was to assess whether fractionation of serum gamma-glutamyltransferase (GGT) into four fractions by high-performance gel filtration chromatography is useful for the differential diagnosis of alcoholic liver disease (ALD) and non-alcoholic fatty liver disease (NAFLD). In patients with ALD, small-GGT (s-GGT)/total GGT (t-GGT) ratios were significantly higher and free-GGT (f-GGT)/t-GGT ratios were lower than in those in NAFLD. Consequently, there were marked differences in the s-GGT/f-GGT ratio between ALD and NAFLD. These preliminary results indicate that a large-scale study to clarify the diagnostic values of serum GGT fractionation in the differential diagnosis of ALD and NAFLD is warranted.

Fractionation of gamma-glutamyltransferase in patients with nonalcoholic fatty liver disease and alcoholic liver disease. *World J Hepatol* 2016; 8(36): 1610-1616 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i36/1610.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i36.1610>

## INTRODUCTION

Gamma-glutamyltransferase (GGT) [(5-glutamyl)-peptide: Amino acid 5-glutamyltransferase, EC 2.3.2.2] is present in many tissues, including the kidneys, pancreas, and liver<sup>[1]</sup>. GGT in serum is mainly derived from the liver and this enzyme is often used as a marker of hepatobiliary diseases. Although sensitive, GGT elevation is not specific enough for the differential diagnosis of hepatobiliary disorders. GGT is present in serum in multiple forms in molecular complexes that vary in size, charge, and density<sup>[2]</sup>. These forms were evaluated in the past by

electrophoretic methods to enhance the diagnostic value of GGT measurements<sup>[3]</sup>. These methods, however, were not sensitive enough to facilitate the differential diagnosis of liver diseases. To overcome this limitation, Franzini *et al.*<sup>[4]</sup> developed a high-performance liquid chromatography method to quantify four plasma GGT fractions on the basis of molecular size exclusion chromatography, followed by a GGT-specific post-column reaction.

GGT is widely used as a marker of excessive alcohol intake in patients with alcoholic liver disease (ALD)<sup>[5]</sup>. Induction of hepatic microsomal GGT by chronic alcohol consumption may account, at least in part, for GGT elevation in alcoholics<sup>[6]</sup>. In addition, serum GGT levels are often increased in patients with non-alcoholic fatty liver disease (NAFLD)<sup>[7]</sup>.

Distinguishing ALD from NAFLD is difficult because self-reported history of alcohol consumption is unreliable. Detection of patients with high alcohol intake by general practitioners is not necessarily easy<sup>[8,9]</sup>. Accurate diagnosis of NAFLD relies on a liver biopsy; hence, a less-invasive evaluation strategy is desirable<sup>[10]</sup>.

The aim of this preliminary study was to assess how serum GGT fraction patterns, obtained by a high-performance liquid chromatography method, vary in patients with ALD and NAFLD.

## MATERIALS AND METHODS

### Patients and blood sample preparation

Serum samples were obtained from 23 patients with biopsy-proven NAFLD or ALD at the Department of Hepatology, Kanazawa Medical University. Fourteen patients (11 males and 3 females, age  $53.0 \pm 10.6$  years) with biopsy-proven ALD (3 patients with fatty liver, 2 alcoholic fibrosis, 5 alcoholic hepatitis, 3 alcoholic hepatitis, and 3 liver cirrhosis) and 9 patients (6 males and 3 females, age  $57.2 \pm 9.86$  years) with biopsy-proven NAFLD (6 patients with non-alcoholic steatohepatitis and 3 with simple steatosis) were included in the study. In addition to these biopsy-proven cases, 16 obese (body mass index  $> 25$ ) patients (16 males, age  $48.3 \pm 6.97$  years) without any history of alcohol consumption but with a fatty liver on ultrasound examination and with elevated GGT were included for an additional analysis. Subjects suspected to have autoimmune hepatitis, primary biliary cirrhosis, hemochromatosis, Wilson's disease and alpha 1 anti-trypsin deficiency were excluded from this study. Serum samples were also obtained from 10 apparently healthy and age-matched subjects for a control group. The clinical data for these 49 patients are presented in Table 1. All samples were frozen by liquid nitrogen and were stored at  $-80^\circ\text{C}$  until analysis. Written informed consent was obtained from all the patients. The ethics committees of each institute approved the protocol.

### GGT fractionation by high-performance gel filtration chromatography

Serum GGT fractionation by high-performance liquid chromatography was conducted on the basis of the

Data are presented as median (25<sup>th</sup>-75<sup>th</sup> percentile). Statistical analysis: Wilcoxon-Mann-Whitney *U* test. AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: Gamma-glutamyltransferase; ALD: Alcoholic liver disease; NAFLD: Non-alcoholic fatty liver disease; NS: Not significant; HDL: High density lipoprotein; LDL: Low density lipoprotein; b-GGT: Big-GGT; m-GGT: Medium-GGT; s-GGT: Small-GGT; f-GGT: Free-GGT.

methods described by Franzini *et al.*<sup>[4]</sup>. A 100- $\mu$ L aliquot of serum was injected into a Superose 6 HR 10/300 GL column (diameter 10 mm, length 300-310 mm; GE Healthcare, Parsippany, NJ, United States) attached to a LC-10AD high-performance liquid chromatography system (Shimadzu Co., Kyoto, Japan). Gel filtration chromatography was performed using the isocratic mode with a binary mobile phase composed of 0.1 mol/L sodium phosphate buffer (pH 7.4), containing 0.2 mol/L NaCl, 0.1 mmol/L EDTA, and 5.4 mmol/L Gly-Gly to support the GGT reaction<sup>[11,12]</sup>. The flow rate of the mobile phase was 0.5 mL/min. Total run time was 60 min, and fractions were collected every 30 s. Serum containing high GGT (> 150 U/L) levels was difficult to separate into small-GGT (s-GGT) and free-GGT (f-GGT) fractions. To make an appropriate comparison of elution profiles of GGT fractions, serum samples with high-GGT-level sera were diluted to approximate 30-50 U/L with the mobile phase solvent prior to analysis. All results were expressed as compared with total GGT activity subjected to the high-performance liquid chromatography analysis.

#### Measurement of serum total and fractionated GGT activities

Serum total GGT (t-GGT) activities were determined using an enzymatic assay (Serotec Co. Ltd., Sapporo, Japan) with an autoanalyzer (JCA-2250; JEOL Ltd., Tokyo, Japan). This measurement conformed to the International Federation of Clinical Chemistry reference mode for GGT, implemented at a serum volume of 1.2  $\mu$ L and a reagent volume of 75  $\mu$ L<sup>[4]</sup>. Moreover, GGT activity in each fraction improved in the sensitometer mode, which was implemented at a serum volume of 25  $\mu$ L and a reagent volume of 40  $\mu$ L. The limit of quantitation at a 10% coefficient of variation was 0.102 U/L.

#### Statistical analysis

Total GGT activity and those in each high-performance liquid chromatography fraction in the NAFLD and ALD groups were analyzed using the non-parametric Wilcoxon-Mann-Whitney *U* test. Between-group comparisons of the laboratory data were made with Spearman's rank correlation coefficient. *P* values of < 0.05 were considered significant.

## RESULTS

#### Elution pattern of the GGT fractions

Figure 1A-E shows the GGT-specific elution profiles of representative serum samples obtained from the control group (Figure 1A and B), and patients with ALD (Figure 1C and D) and NAFLD (Figure 1E and F). Three distinct peaks and a low one were found by fractionation every 30 s. The area of the peaks was calculated using a blank for the average GGT eluted with elution volumes of 5.00-6.25 mL. Each GGT fraction was calculated by dividing the area of each single peak. As indicated in Figure 2, it was confirmed that the area under the chromatogram curve was proportional to the GGT enzyme activities.

On the basis of the molecular weight calibration curve (data not shown), these four peaks are equivalent to big-GGT (b-GGT) (MW > 2000 kDa, eluted between 6.25-9.50 mL), medium GGT (m-GGT) (MW 940 Da, eluted between 9.5-12.25 mL), s-GGT (MW 140 kDa, eluted between 12.25-15.5 mL) and f-GGT (MW 70 kDa, eluted between 15.5-20 mL), respectively.

#### GGT fraction profiles in four patient groups and the control group

The s-GGT/t-GGT ratios were lowest for the control group

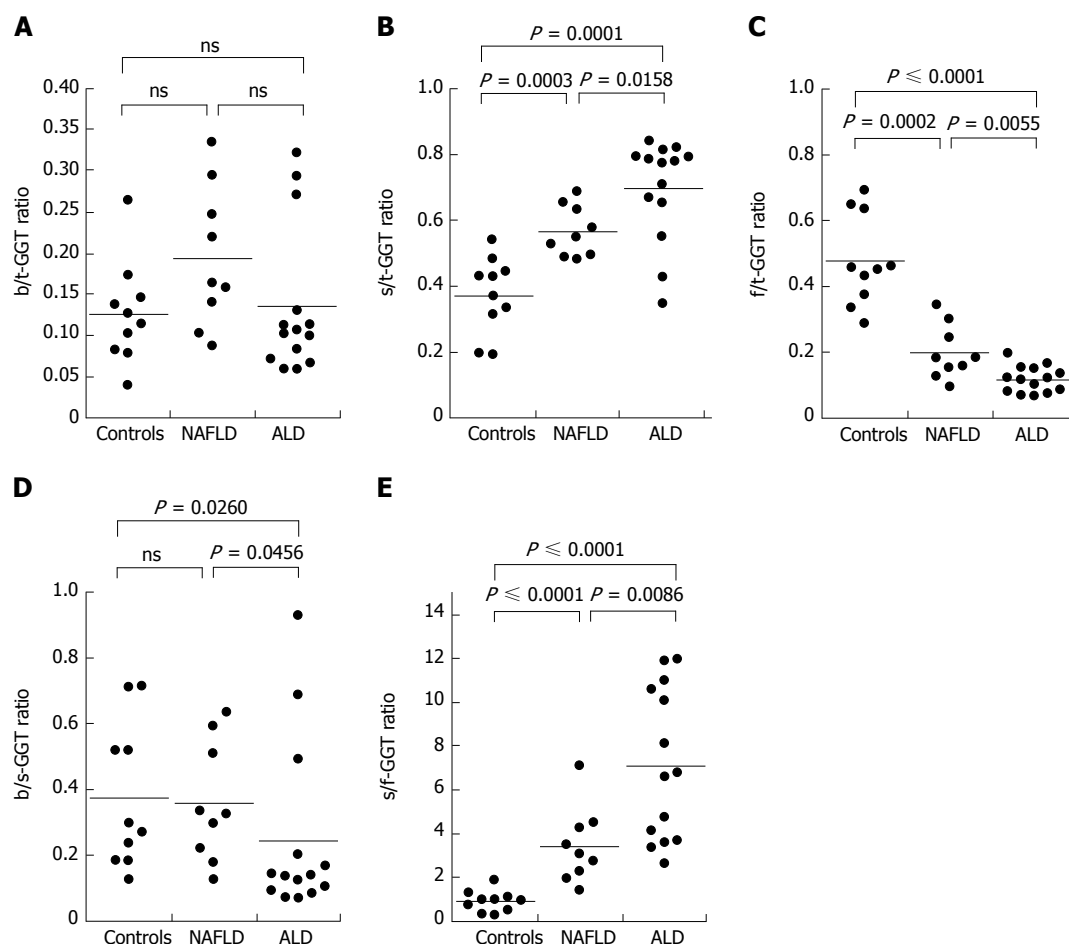

**Figure 1** Gamma-glutamyltransferase-specific elution profiles of representative serum samples (two of each) obtained from the control group subjects (A and B), patients with alcoholic liver disease (C and D), and patients with non-alcoholic fatty liver disease (E and F). On the basis of the molecular weight calibration curve (data not shown), these four peaks are equivalent to big-GGT (MW > 2000 kDa, eluted between 6.25-9.50 mL), medium GGT (MW 940 kDa, eluted between 9.5-12.25 mL), small GGT (MW 140 kDa, eluted between 12.25-15.5 mL) and free-GGT (MW 70 kDa, eluted between 15.5-20 mL), respectively. GGT: Gamma-glutamyltransferase.

**Figure 2** Linear correlation between the total area under the chromatograph curve multiplied by serum dilution factors and total serum gamma-glutamyltransferase activity. Elution volume (between 12-38 mL).  $y = 5.9667x + 15.303$ ;  $r = 0.988$ ;  $P < 0.001$ ;  $n = 49$ . GGT: Gamma-glutamyltransferase.

and highest for the ALD group. The differences between the control and NAFLD groups and also between the NAFLD and ALD groups were statistically significant, as indicated in Figure 3B. In contrast, the f-GGT/t-GGT ratios were highest in the control group and lowest in the ALD group, with the differences being statistically significant (Figure 3C). As a result, the s-GGT/f-GGT ratios were markedly increased in the NAFLD group as compared with the control group (Figure 3E). The increase of the s-GGT/t-GGT ratios, the decrease of the f-GGT/t-GGT ratios, and the increase of s-GGT/f-GGT ratios as compared with the control group subjects were also found in obese patients with clinically diagnosed fatty change of the liver (Figure 4C-E). There was also a positive correlation between b-GGT activity and levels of low-density lipoprotein and apolipoprotein B in the NAFLD group, but not in the ALD

**Figure 3** Serum b-GGT/t-GGT, s-GGT/t-GGT, f-GGT/t-GGT, b-GGT/s-GGT and s-GGT/f-GGT ratios in patients with biopsy-proven non-alcoholic fatty liver disease, biopsy-proven alcoholic liver disease and the controls group. ALD: Alcoholic liver disease; NAFLD: Non-alcoholic fatty liver disease; GGT: Gamma-glutamyltransferase; b-GGT: Big-GGT; t-GGT: Total-GGT; s-GGT: Small-GGT; f-GGT: Free-GGT; ns: No significant differences.

group, in the present study (data not shown).

## DISCUSSION

Franzini *et al*<sup>[4]</sup> described a high-performance gel filtration chromatography method for plasma GGT fraction analysis. This method permitted the quantification of four GGT fractions; b-GGT, m-GGT, s-GGT (likely lipoprotein-bound, molecular masses > 2000, 940 and 140 kDa, respectively) and a f-GGT fraction.

It is common for serum GGT levels to be elevated in patients with ALD<sup>[5]</sup> or obesity-related NAFLD<sup>[7]</sup>. Patients with elevated serum GGT levels who are obese and are also excessive, habitual alcohol drinkers are frequently encountered in clinical practice. It is necessary to have non-invasive measures to assess the relative contribution of overweight and excessive alcohol consumption on GGT elevations. We wondered how serum GGT fraction patterns obtained by the high-performance liquid chromatography method vary in patients with ALD and NAFLD.

The results of this preliminary study indicate that in patients with ALD, s-GGT/t-GGT ratios were significantly increased and f-GGT/t-GGT ratios were lower, compared with those in NAFLD patients. As a result, there was a

marked difference in the s-GGT/f-GGT ratios between patients with ALD and NAFLD. These results indicate that a large-scale study to clarify the diagnostic value of serum GGT fractionation in the differential diagnosis of ALD and NAFLD is warranted.

High-sensitivity GGT fraction patterns of various liver diseases were evaluated by Franzini *et al*<sup>[13-17]</sup>, Elawdi *et al*<sup>[18]</sup>, Fornaciari *et al*<sup>[19]</sup> and Corti *et al*<sup>[20,21]</sup>. They reported that the b-GGT/s-GGT ratio was significantly lower in both alcoholics and abstainers than in the control group, consistent with our study<sup>[13]</sup>. Patients with NAFLD and chronic hepatitis C have different GGT fraction patterns: b-GGT is increased in NAFLD, but not in chronic hepatitis C<sup>[14]</sup>. More recently, GGT fractions were measured in cirrhosis patients, revealing that, irrespective of etiology, s-GGT showed the greatest increase in cirrhotic patients and the b-GGT/s-GGT ratio was even lower than that in patients with chronic hepatitis C<sup>[18]</sup>.

To the best of our knowledge, the present study is the first direct comparison of serum GGT fraction profiles between patients with ALD and NAFLD. However, there are several limitations to the present study. The numbers of the biopsy-proven cases was small. In addition, how serum GGT profiles change with disease progression

**Figure 4** Serum b-GGT/t-GGT, s-GGT/t-GGT, f-GGT/t-GGT, b-GGT/s-GGT, and s-GGT/f-GGT ratios in patients with non-alcoholic fatty liver disease clinically diagnosed by ultrasonography. GGT: Gamma-glutamyltransferase; b-GGT: Big-GGT; t-GGT: Total-GGT; s-GGT: Small-GGT; f-GGT: Free-GGT; ns: No significant differences.

from fatty liver to liver cirrhosis in patients with NAFLD and ALD remains unclear. Also, the diagnostic value of GGT profiles remains to be compared with other markers including cytochrome C<sup>[22]</sup>.

In addition to the well-known alterations in hepatobiliary disorders, GGT is associated with cardiovascular disease (CVD)<sup>[23]</sup>. In a recent review article, the predictive value of GGT for assessing CVD and cancer mortality was described, including assessment at the physiological level of the enzyme activity<sup>[24]</sup>. Taking advantage of the high-performance gel filtration chromatography method for plasma GGT fraction analysis, Franzini *et al*<sup>[15]</sup> demonstrated that CVD risk factors were associated with b-GGT.

In conclusion, the serum GGT fraction patterns in patients with NAFLD are significantly different from those in patients with ALD. In patients with ALD, s-GGT/t-GGT ratios were significantly higher and f-GGT/t-GGT ratios were lower than in those in NAFLD. Consequently, there were marked differences in the s-GGT/f-GGT ratio between ALD and NAFLD. A large-scale study is needed to further evaluate the diagnostic value of serum GGT fractionation in the differential diagnosis of ALD and

NAFLD.

## COMMENTS

### Background

Distinguishing alcoholic liver disease (ALD) from non-alcoholic fatty liver disease (NAFLD) is difficult because self-reported history of alcohol consumption is unreliable. Detection of patients with high alcohol intake by general practitioners is not necessarily easy. Accurate diagnosis of NAFLD relies on a liver biopsy; hence, a less-invasive evaluation strategy is desirable.

### Research frontiers

Gamma-glutamyltransferase (GGT) in serum is mainly derived from the liver and this enzyme is often used as a marker of hepatobiliary diseases. Although sensitive, GGT elevation is not specific enough for the differential diagnosis of hepatobiliary disorders. GGT is present in serum in multiple forms in molecular complexes that vary in size, charge, and density. These methods, however, were not sensitive enough to facilitate the differential diagnosis of liver diseases. To overcome this limitation, Franzini *et al* developed a high-performance liquid chromatography method to quantify four plasma GGT fractions on the basis of molecular size exclusion chromatography, followed by a GGT-specific post-column reaction.

### Innovations and breakthroughs

To the best of our knowledge, the present study is the first direct comparison of

serum GGT fraction profiles between patients with ALD and NAFLD.

## Applications

Although preliminary, determination of serum GGT profiles may serve for differential diagnosis of ALD and NAFLD.

## Terminology

High-performance liquid chromatography (previously called high-pressure liquid chromatography), is a useful analytical tool which is able to separate various compounds based on their size, electrical charge and biochemical affinity.

## Peer-review

The research presents a screening for future investigations about AFLD and NAFLD diagnosis differentiation. It is an interesting approach of ALD and AFLD diagnosis which was not executed in the best possible way.

## Abstract

### AIM

To investigate the incidence of spontaneous bacterial peritonitis (SBP) in pre-transplant patients and its effect on post transplant mortality and graft failure.

### METHODS

We conducted a retrospective cohort study of patient records from the organ procurement and transplant network data set. Patients were identified by the presence of SBP pre-transplant. Univariate post-transplant survival models were constructed using the Kaplan-Meier technique and multivariate models were constructed using the Cox proportional hazards model. Variables that affected post-transplant graft survival were identified in the SBP population.

### RESULTS

Forty-seven thousand eight hundred and eighty patient records were included in the analysis for both groups, and 1966 (4.11%) patients were identified in the data set as having pre-transplant SBP. Patients that had pre-transplant SBP had higher rates of graft loss from recurrent hepatitis C virus (HCV) (3.6% vs 2.0%,  $P < 0.0001$ ), infections leading to graft loss (1.9% vs 1.3%,  $P = 0.02$ ), primary non-function (4.3% vs 3.0%,  $P < 0.0001$ ) and chronic rejection (1.1% vs 0.7%,  $P = 0.04$ ). Kaplan-Meier survival analysis showed a statistically significant difference in all-cause survival in patients with a history of SBP vs those without ( $P < 0.0001$ ). Pre-transplant history of SBP was independently predictive

of mortality due to recurrent HCV (HR = 1.11, 95%CI: 1.02-1.21,  $P < 0.017$ ) after liver transplantation.

## CONCLUSION

HCV patients prior to the advent of direct acting anti-viral agents had a higher incidence of pre-transplant SBP than other patients on the liver transplant wait list. SBP history pre-transplant resulted in a higher rate of graft loss due to recurrent HCV infection and chronic rejection.

**Key words:** Spontaneous bacterial peritonitis; Liver transplant; Graft failure; Hepatitis C

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Prevention of spontaneous bacterial peritonitis (SBP) pre-transplant may affect graft outcomes and ultimately patient survival post-transplant. Patients with hepatitis C virus (HCV) in whom therapy is deferred until the time of transplant due to hepatic decompensation, may benefit from expedited treatment if they possess a history of SBP to avoid complications related to HCV recurrence.

## INTRODUCTION

According to the Scientific Registry of Transplant Recipients database, since 2005 over 6000 liver transplants have been performed on an annual basis. Hepatitis C virus (HCV) has consistently been the most common indication for liver transplantation and challenging due to the possibility of viral recurrence post-transplant. Recurrent HCV had been a major problem for patients post liver transplantation, but with the new direct acting anti-viral (DAA) therapies, this problem is steadily declining. Even with resolution of this challenge, identifying factors that may accelerate graft loss or damage is still essential.

Originally established for mortality post transjugular intrahepatic portosystemic shunts, the laboratory based Model for End Stage Liver Disease (MELD and MELD-Na) is now the primary measure for liver organ allocation in the United States<sup>[1]</sup>. Since the use of MELD began in 2002, wait list mortality has significantly decreased as patients are prioritized effectively, however patients on the wait list still suffer from complications of end stage liver disease and portal hypertension such as gastrointestinal bleeding, encephalopathy, ascites, renal failure, and infection<sup>[2]</sup>.

Liver disease patients, with decreased levels of com-

plement proteins and decreased opsonization, live in a relatively immunocompromised state and are at high risk of developing bacterial, viral, or fungal infections<sup>[3]</sup>. Ascites reportedly occurs in 7% to 23% of hospitalized end stage liver disease patients<sup>[4]</sup>. An initial episode of spontaneous bacterial peritonitis (SBP) occurs in about 10% of these patients<sup>[5]</sup>. Infection related to SBP can have severe ramifications in the development of renal failure and mortality of patients while on the transplant wait list.

The utility of MELD in organ allocation is well established, but its extrapolation to post-transplant survival or graft outcomes is still unclear. Further, in the post MELD era, limited studies have investigated the role of SBP on post-transplant outcomes<sup>[6]</sup>. Therefore, in order to understand the role of infections on post-transplant outcomes, we aimed to investigate the incidence of SBP in pre-transplant patients and its effect on post transplant mortality and graft failure in the era prior to DAA therapy.

## MATERIALS AND METHODS

We investigated the United States organ procurement and transplant network (OPTN) dataset for liver transplants from February 2002 until November 2009 for liver graft recipients with a reported history of pre-transplant SBP. All patients who eventually underwent liver transplantation were included in the analysis. If the patient did not have a history of SBP or if the question was left blank (or "unknown" was selected) on the Adult Liver Transplant Recipient Registration Worksheet submitted to the United Network for Organ Sharing, the recipient was assumed to not have pre-transplant SBP. The population with a history of SBP was compared to those without the history of SBP for multiple pre- and post-transplant characteristics. Recipient etiology of disease was categorized as HCV, hepatitis B, non-alcoholic steatohepatitis or cryptogenic, alcohol alone, cholestatic liver disease, autoimmune, liver malignancy, or other. Etiologies of graft failure included biliary, *de novo* autoimmune hepatitis, recurrent (non-viral) disease, infection, primary non-function, recurrent viral hepatitis, acute rejection, chronic rejection, and vascular thrombosis. Laboratory (non-exception) MELD scores were used for all recipients.

Demographics, recipient, donor, and surgical characteristics were compared between groups using the  $\chi^2$  test for categorical variables and the Student *t*-test for continuous variables. Univariate post-transplant survival models were constructed using the Kaplan-Meier technique and multivariate models were constructed using the Cox proportional hazards model. Variables known to influence post-transplant survival from previous studies or those variables found to be significant in the univariate analysis to a level of less than 0.20 were included in multivariate models using a whole model (non-stepwise) analysis. Because of the finding of a relationship between SBP and graft failure due to recurrent HCV, a multivariate logistic regression model was developed to determine

**Table 1** Population characteristics

Population characteristic	History of pre-transplant SBP ( <i>n</i> = 1966)	No history of SBP ( <i>n</i> = 45914)	<i>P</i> -value
Recipient age, yr	50.51 (49.96-51.07)	47.97 (47.81-48.13)	< 0.0001
Donor age, yr	38.08 (38.84-39.61)	38.29 (38.12-38.46)	0.165
MELD score at transplant	25.28 (24.83-25.74)	20.34 (20.25-20.44)	< 0.0001

Liver retransplantation	145 (7.38)	3711 (8.08)	0.259

Categorical variables are expressed as number and column percent. Continuous variables are expressed as mean and 95% CIs unless otherwise specified. SBP: Spontaneous bacterial peritonitis; MELD: Model for End Stage Liver Disease; NASH: Nonalcoholic steatohepatitis.

those variables independently predictive of recurrent HCV. No data imputation was used. All statistical testing was two sided and the level of type one error deemed to be statistically significant was assumed to be less than or equal to 0.05. All dataset manipulation and analysis was performed using SAS (version 9.2, Cary, NC, United States). Local institutional review board approval was not required for analysis of this de-identified dataset.

## RESULTS

The OPTN data set contained information on 47880 patients transplanted during the study period. The characteristics of the study population are outlined in Table 1. Of this population, 1966 (4.11%) patients were reported to have a history of pre-transplant SBP. Patients with a history of SBP tended to be older (50.5 mean years in the SBP population vs 48.0 in the non-SBP population,  $P < 0.0001$ ), male (72.7% vs 65.2%,  $P < 0.0001$ ), and have a higher MELD score at the time of liver transplantation (25.3 vs 20.3,  $P < 0.0001$ ). The etiology of liver disease was significantly different between those recipients who had pretransplant SBP compared to those that did not. HCV was significantly more prevalent in the SBP population (41.1% vs 29.5%,  $P < 0.0001$ ).

Table 2 shows the distribution and causes of graft failure in the post-transplant time period. While overall graft loss was uncommon, compared to those without a history of SBP, patients that had pre-transplant SBP had higher rates of graft loss from recurrent HCV (3.6% vs 2.0%,  $P < 0.0001$ ), infections leading to graft loss (1.9% vs 1.3%,  $P = 0.02$ ), primary non-function (4.3% vs 3.0%,  $P < 0.0001$ ) and chronic rejection (1.1% vs 0.7%,  $P = 0.04$ ). In regards to all-cause survival, patients having pre-transplant SBP had worse unadjusted one year post-transplant survival (82.8% vs 86.5%,  $P < 0.0001$ ) and this difference widened at two years (76.5% vs 81.6%,  $P < 0.0001$ ). Figure 1 shows the Kaplan-Meier survival analysis. There was a statistically significant difference

in all-cause survival in patients with a history of SBP vs those without ( $P < 0.0001$ ).

In order to account for multiple factors influencing graft loss in this population, we developed a multivariable logistic regression model including factors known to affect survival rates: Age of recipient, age of donor, MELD score, history of previous transplant, and history of HCV. Table 3 shows the results of this analysis. A pre-transplant history of SBP was found to be an independent risk factor for post-transplant graft failure imparting a 57% increased risk of graft failure (OR = 1.57, 95%CI: 1.22-2.02,  $P < 0.001$ ). Table 4 shows the results of a multivariate proportional hazards survival model predicting death due to recurrent HCV. Once again, a pre-transplant history of SBP was independently predictive of mortality due to recurrent HCV (HR = 1.11, 95%CI: 1.02-1.21,  $P < 0.017$ ) after liver transplantation.

## DISCUSSION

We have shown that HCV patients prior to the advent of DAA agents had a higher incidence of pre-transplant SBP than other patients on the liver transplant wait list. Further, SBP history resulted in a higher rate of graft loss due to recurrent HCV infection and chronic rejection. This group also had an 11.2% greater risk of post-transplant mortality. In a multivariate Cox regression model, SBP was found to be an independent risk factor for post-transplant mortality.

Patients with a diagnosis of active HCV infection at the time of transplant have a known predisposition to graft failure due to HCV recurrence. However, the rate of progression to cirrhosis and graft failure is unpredictable. Certain known risk factors such as the donor's age, post-transplant CMV infection, HIV co-infection, the use of T cell depleting therapies, pulsed steroids, and other donor risk factors have all been associated with poorer outcomes<sup>[7]</sup>. SBP has not been studied in this regard. Our results show that a history of pre-transplant SBP may

**Table 2 Cause of graft failure in patients with and without a history of spontaneous bacterial peritonitis**

Cause of graft failure	History of pre-transplant SBP ( <i>n</i> = 1966)	No history of SBP ( <i>n</i> = 45914)	<i>P</i> -value
Biliary	24 (1.22)	423 (0.92)	0.176
<i>De novo</i> autoimmune hepatitis	2 (0.10)	17 (0.04)	0.182

**Figure 1 Kaplan-Meier post-transplant survival analysis of patients with a history of pre-transplant spontaneous bacterial peritonitis.** SBP: Spontaneous bacterial peritonitis.

contribute to worse survival and an increased risk of graft failure. As our study shows, 40% of pre-transplant SBP patients in this cohort suffered from HCV, whereas only 30% of a control, non-SBP pre-transplant group suffered from HCV.

Prior treatment regimens, which included interferon, to decrease HCV levels in pre-transplant candidates possessed their own risks and had shown an increase the rate of bacterial infections in these patients<sup>[8]</sup>. The rate of infection, especially the incidence of SBP in patients not receiving prophylaxis therapy, in Child Pugh B/C patients was higher than matched controls<sup>[8]</sup>. Several etiologies had been proposed, including the neutropenic and granulo-toxic effect of interferon causing an increase susceptibility to bacterial infections. These studies show

an increased risk of infection, including SBP, in HCV patients with poor liver function. With our data showing the deleterious effect of SBP on transplant outcomes, it supports the careful choice of HCV patients that were selected in the past to undergo interferon based therapies pre-transplant and the importance of SBP prophylaxis in this group with proper indications<sup>[8,9]</sup>.

Limited studies from the pre-MELD era did not show that pre-transplant SBP influenced post-transplant outcomes. A study following 100 patients, showed that 32% of patients developed a pre-transplant infection. The infections ranged from SBP (35.6%), blood stream infections (28.9%), cellulitis (13.3%), pneumonia (8.9%), urinary tract infections (6.7%), and other infections (6.7%)<sup>[10]</sup>. After following this group, the study found that patients with pre-transplant infections were less likely to be transplanted from home and required longer hospital stays, but the mortality at 90 and 180 d post-transplant did not differ significantly compared to individuals without pre-transplant infections. As shown by our Kaplan Meier survival curves in Figure 1, the survival of the two groups from our analysis of the OPTN database seems to be similar, but then diverges significantly starting at day 250. Therefore, even though the previously mentioned study did not find differences in survival, we feel that with longer follow-up this difference could have been statistically significant.

Another single center study, reported that patients with a history of SBP had more severe liver disease as measured by MELD and CTP score, but had similar

post-transplant mortality to those without a history of SBP<sup>[11]</sup>. The patients who developed SBP most commonly suffered from liver disease related to HCV or alcohol. The mean follow-up time period for this study was 3 years. While mortality or infection rates were not affected, these patients were more likely to require abdominal surgery 1 year post transplant for hernia repairs, bleeding, and vascular complications<sup>[11]</sup>. This study reinforces our findings of the large burden of SBP on pre-transplant cirrhosis patients and the higher rate of SBP in HCV patients. However, the relatively small sample size and inclusion of patients transplanted in the pre-MELD era may not be as applicable to the general population. Our cohort studies the transplants occurring after 2002, and includes a multi-center analysis with almost 48000 patient records.

There are several limitations to our study. One of the major limitations is the incomplete reporting of SBP in the OPTN database. We believe it is safe to assume that reported instances of SBP are accurate and have a clear documented episode recognized by the listing health care provider, which prompted this designation. However, the low rates of patients with SBP pre-transplant as compared to other studies in the literature, raises the speculation of recall bias from reporting centers on patient's history of SBP. The exact determination of SBP may not be uniform across all centers, and without full accessibility to numbers of SBP episodes, exact cell counts, or ascites fluid analysis we are dependent solely on information from the database. Further, those patients with severe infection due to SBP were likely excluded from transplant listing. Finally, while we may assume that survival statistics and graft loss are accurate in the OPTN database, other post-transplant variables are often incomplete including immunosuppression data and other details regarding HCV recurrence<sup>[12]</sup>. By using a worst case scenario analysis, if we assume that all patients in the OPTN database without data entered for SBP are included in the control group. Any mortality registered in these patients would only reduce the differences between our groups.

It has been shown that HCV patients being treated with interferon based therapies were at an increased risk of developing SBP<sup>[8]</sup>. It is unclear if this association is due to the underlying viral hepatitis disease process or related to the treatment regimen that were used. Regardless, stronger surveillance measures and antibiotic prophylaxis pre-transplant SBP may be necessary to improve post-transplant outcomes. Also, the new issue as we transition fully to DAA regimens is the decision to treat cirrhosis patients pre vs post-transplant<sup>[13,14]</sup>. If patients live in a region with a relatively high average MELD at time of transplant, treating HCV infection pre-transplant may put these patients into MELD "purgatory" - stable MELD that will not increase transplant prioritization, but continued low quality of life<sup>[15]</sup>. Due to the low rates of drug interactions between the DAAs and immunosuppression, some patients at higher MELD are deferred for therapy until after transplant. From these

results and our experience prior to the advent of DAAs, in those HCV patients we deem necessary to treat post-transplant, we should consider prioritizing therapy in those with a history of SBP. Further, we should strive to reduce donor risk factors, minimize pulsed steroids or T cell depleting immunosuppression to prevent post-transplant HCV recurrence and graft failure<sup>[16,17]</sup>. Over time, we predict the number of transplants performed in the United States stemming from HCV infection to decrease, but the decision to treat these patients around the time of transplant and avoiding SBP will continue to be a challenge.

## COMMENTS

### Background

This study examines the effect of spontaneous bacterial peritonitis in cirrhosis patients on the wait list for liver transplantation. Using the patients identified in the organ procurement and transplant network (OPTN)/United Network for Organ Sharing (UNOS) database, in the era prior to direct acting anti-viral agents, we investigated the effect of spontaneous bacterial peritonitis (SBP) on liver transplant graft loss and post-transplant mortality.

### Research frontiers

Future studies focused on the prevention of pre-transplant infections, like SBP, and the effect of direct acting anti-viral (DAA) therapies on graft loss and mortality is a potential area to study. Further, as the treatment paradigm for pre vs post-transplant hepatitis C virus (HCV) therapy changes, it may be worthwhile to examine the change it produces in graft loss from HCV complications.

### Innovations and breakthroughs

From our knowledge, this is the first article to assess the effect of SBP on post transplant outcomes from the OPTN dataset. Further it provides a collective experience of our outcomes from the pre-DAA therapy era which can be used as a basis for future comparison.

### Applications

This article has shown the importance of avoiding SBP infections in the pre-transplant population. Aggressive prophylaxis and treatment of this infection may have long term implications with regards to graft survival and mortality.

### Terminology

SBP: Spontaneous bacterial peritonitis - infection found in the ascites fluid in the peritoneum; DAA: Direct acting anti-viral therapies - the new class of HCV medications which directly inhibits replication; OPTN/UNOS: The national organization responsible for managing organ allocation, obtaining individual center's data on transplantation, and reporting collective outcomes.

### Peer-review

This is a good paper.

## Abstract

### AIM

To identify significant liver disease [including nodular regenerative hyperplasia (NRH)] in asymptomatic Didanosine (DDI) exposed human immunodeficiency virus (HIV) positive patients.

### METHODS

Patients without known liver disease and with > 6 mo previous DDI use had liver stiffness assessed by transient elastography (TE). Those with alanine transaminase (ALT) above upper limit normal and/or TE > 7.65 kPa underwent ultrasound scan (U/S). Patients with: (1) abnormal U/S; or (2) elevated ALT plus TE > 7.65 kPa;

or (3) TE > 9.4 kPa were offered trans-jugular liver biopsy (TJLB) with hepatic venous pressure gradient (HVPG) assessment.

## RESULTS

Ninety-nine patients were recruited, median age 50 years (range 31-70), 81% male and 70% men who have sex with men. Ninety-five percent with VL < 50 copies on antiretroviral therapy with median CD4 count 639 IU/L. Median DDI exposure was 3.4 years (range 0.5-14.6). Eighty-one had a valid TE readings (interquartile range/score ratio < 0.3): 71 (88%) < 7.65 kPa, 6 (7%) 7.65-9.4 kPa and 4 (6%) > 9.4 kPa. Seventeen (17%) met criteria for TJLB, of whom 12 accepted. All had HVPG < 6 mmHg. Commonest histological findings were steatosis ( $n = 6$ ), normal architecture ( $n = 4$ ) and NRH ( $n = 2$ ), giving a prevalence of previously undiagnosed NRH of 2% (95%CI: 0.55%, 7.0%).

## CONCLUSION

A screening strategy based on TE, liver enzymes and U/S scan found a low prevalence of previously undiagnosed NRH in DDI exposed, asymptomatic HIV positive patients. Patients were more likely to have steatosis highlighting the increased risk of multifactorial liver disease in this population.

**Key words:** Nodular regenerative hyperplasia; Human immunodeficiency virus; Steatosis; Non-cirrhotic portal hypertension; Didanosine

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Human immunodeficiency virus positive patients are at increased risk of liver disease. The aetiology is often multifactorial and includes exposure to antiretroviral therapy. We used a simple screening strategy based on transient elastography, liver enzymes and ultrasound scan to identify that 2% of asymptomatic patients exposed to Didanosine in a clinical cohort had undiagnosed nodular regenerative hyperplasia. A further 6% had undiagnosed steatosis. Implementation of a screening strategy enables identification of liver disease and initiation of earlier targeted interventions in this high-risk group.

Prevalence of significant liver disease in human immunodeficiency virus-infected patients exposed to Didanosine: A cross sectional study. *World J Hepatol* 2016; 8(36): 1623-1628 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i36/1623.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i36.1623>

## INTRODUCTION

Nodular regenerative hyperplasia (NRH) - the develop-

ment of micronodules in liver parenchyma without intervening fibrosis<sup>[1]</sup> - has been reported in human immunodeficiency virus (HIV) positive patients who often present late in the course of the condition with complications associated with non-cirrhotic portal hypertension (NCPH). A strong association with NRH is current or previous use of Didanosine (DDI)<sup>[1-6]</sup>. Although DDI is no longer used as first line antiretroviral therapy (ART), many HIV positive patients have significant previous exposure with a reported prevalence of NRH of between 0.5%-35%<sup>[1,2,6]</sup>. This wide range is indicative of the unreliability of screening strategies and the fact that studies largely included individuals diagnosed with NRH or NCPH as a result of liver biopsy for other conditions or as a result of late presentation with complications of portal hypertension<sup>[1-6]</sup>. However prior to this the disease is largely sub clinical and a screening strategy may be useful to identify patients with DDI associated liver disease earlier in the disease process.

Other studies have reported raised transaminases in NRH, but in many cases transaminases are only mildly elevated or not at all this indicating the unreliability of this alone as a screening tool<sup>[1]</sup>. Hepatic transient elastography (TE) is a validated non-invasive tool with good correlation for identifying hepatic and peri-portal fibrosis<sup>[2,7]</sup>. TE is also associated with hepatic venous pressure gradients (HVPG) in cirrhosis<sup>[8]</sup>. The co-relation with NRH is less well delineated, however increased liver stiffness readings have been reported in patients with both NRH and NCPH<sup>[9-14]</sup>, although one study found that liver stiffness readings did not predict the presence of portal hypertension in NRH<sup>[10]</sup>. Many studies also report reduced platelet levels and the presence of splenomegaly in individuals with NRH<sup>[1]</sup>.

Our aim was to develop and implement a screening strategy incorporating 3 separate measures; TE, platelet and alanine transaminase (ALT) levels, with subsequent ultrasound and trans-jugular liver biopsy (TJLB) in those who met criteria to identify DDI related liver disease in HIV positive patients with previous significant DDI exposure, but who were currently asymptomatic.

## MATERIALS AND METHODS

This study is a cross-sectional study in HIV outpatients at The Royal Free London NHS Foundation Trust from 2010 to 2011. Ethical approval was obtained (REC 10 /H0720/54). Study subjects were identified from the HIV clinical database. HIV positive patients currently under active follow-up and previously exposed to DDI therapy for longer than 6 mo were eligible to take part. Exclusions were viral hepatitis co-infection, age < 18 years, a body mass index (BMI) > 40, pregnancy or ascites. Patients were sequentially recruited as they attended for routine clinic follow-up. Statistical review of the study was performed by a biomedical statistician (Dr. Colette Smith).

Patients completed a study specific questionnaire on sociodemographic factors, medical history, lifestyle

including smoking, alcohol [Michigan Alcoholism Screening test (MAST)] and drug use. Clinical data (HIV viral load, CD4 count, whether on/off treatment, date of diagnosis, date of ART start, lipids, liver panel bloods, blood glucose, BMI) were also collected.

Liver TE was measured using FibroScan (FS) (Echosens, Paris). A median stiffness reading was measured using at least ten readings with a valid reading recording 60% accuracy and an interquartile range (IQR) of less than 30% of the median. Subjects were offered further evaluation with ultrasound of liver and spleen with doppler waveforms of the hepatic vasculature if they had either: (1) an ALT level above 19 IU/mL for women and 31 IU/mL for men; or (2) a platelet count (PLT) less than  $120 \times 10^9/L$ ; or (3) TE reading of  $> 7.65$  kPa (IQR  $< 0.3$ ).

Individuals with evidence on ultrasound of splenomegaly or fatty liver or coarse echotexture or abnormalities of hepatic doppler waveforms in conjunction with a raised ALT or TE reading as above were offered a TJLB with HVPG measurements. Patients with a raised ALT or platelets  $< 120 \times 10^9/L$  for whom an elastography score was unobtainable (centripetal obesity) or uninterpretable (less than 10 valid readings or IQR/LSM  $> 30\%$ ) were offered ultrasound and TJLB.

All TJLB procedures were performed in the interventional radiology suite by an experienced operator (O'Beirne J) after a 6-h fast, under local anaesthesia. Biopsies were taken using a 19G Tru-cut type biopsy needle (Quick core; Cook, William Cook Europe, Denmark). Three or 4 passes were performed through the same hepatic vein wall (right or middle) to ensure that sufficient liver tissue was obtained. Wedge hepatic vein pressures (WHVP) were measured using a 5-F Berenstein balloon catheter (Boston Scientific, Natick, MA) using the technique described by Groszmann and Wongcharatrawee<sup>[15]</sup>. Three sets of measurements were taken. WHVP was measured for at least 1 min each time. HVPG was calculated as the mean of the 3 gradients (the difference between WHVP minus free hepatic pressure). Groups were compared using the Mann Whitney *U* test for non-parametric continuous variables and using the  $\chi^2$  test for categorical variables.

## RESULTS

Four hundred and fifty-nine patients exposed to DDI for longer than 6 mo were identified from the clinic database. Eighty-four patients known to have co-infection with hepatitis B or C were excluded. No patients were excluded due to BMI  $> 40$  or presence of ascites. Of the remaining 376 patients, 99 patients were recruited sequentially as they attended HIV clinic during the study time period and response rates in those approached to take part in the study were  $> 95\%$ .

Characteristics of patients recruited ( $n = 99$ ) were compared to those not approached to take part ( $n = 274$ ) to assess potential for recruitment bias. There were no differences in those recruited by sex: 80.8% (80/99 recruited) vs 78.5% (215/274) not recruited were male;  $P = 0.41$ , total length of DDI exposure (mean 4.1

years recruited vs 4.1 years not recruited;  $P = 0.89$ ), most recent median ALT (34  $\mu/L$  recruited vs 35  $\mu/L$  not recruited;  $P = 0.85$ ) or most recent median platelets (210 recruited vs 210 not recruited;  $P = 0.09$ ). However a larger proportion of those of white ethnicity were recruited (77% vs 64%  $P = 0.02$ ) and of those they had a slightly older mean age (50 years vs 48 years;  $P = 0.001$ ).

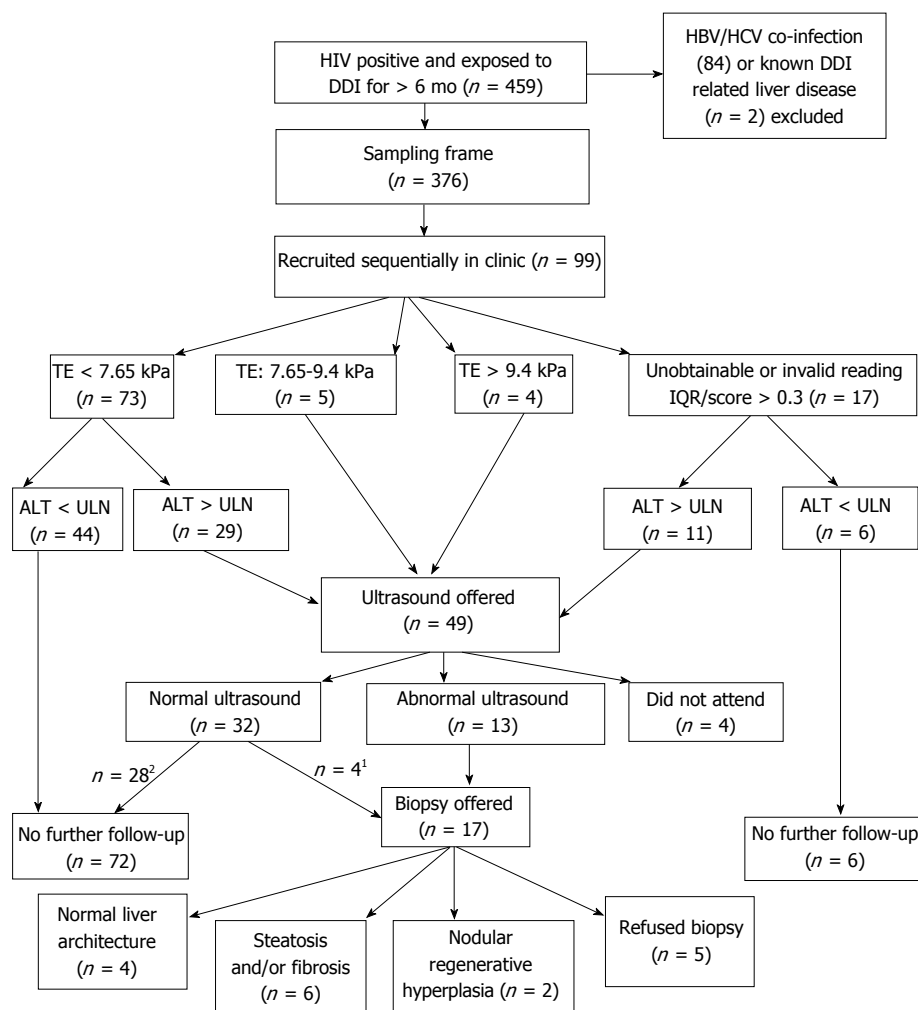

Of the 99 who took part in the study, 75 (75%) were men who have sex with men (MSM). Mean age was 50 years (range: 30 to 70), 76% were White, 19% Black and 5% were of another ethnicity. The majority had well-controlled HIV infection with a median CD4 count of 637  $mm^3$  (IQR: 254 to 1378) and 92% had a suppressed HIV VL at  $< 40$  copies. All were on ART and had been for a median of 15 years (IQR: 13 to 16 years). None were currently on a DDI containing ART regime. Median cumulative time previously on DDI was 43 mo (IQR: 22 mo to 68 mo). Overall, 43 (43%) patients reported never drinking alcohol or consuming less than 2 units monthly. Only 2 patients scored  $> 6$  on the MAST score indicating hazardous drinking.

The screening algorithm is shown in Figure 1. ALT above the upper limit normal (ULN) (19 IU/mL in women and 31 IU/mL in men) was found in 37% ( $n = 7/19$ ) of women and 50% of men ( $n = 40/80$ ). Median ALT in men was 32  $\mu/L$  (IQR 23-44) and 18  $\mu/L$  in women (IQR 15-22). Eight-two (82%) had a valid TE reading (IQR/score ratio  $< 0.3$  and success rate  $> 60\%$ ). Of these, 73 (73%) were  $< 7.65$  kPa, 5 (6%) between 7.65-9.4 kPa and 4 (4%)  $> 9.4$  kPa (Figure 1). Only one subject had platelets  $< 120$  and they were known to have cirrhosis of the liver at study entry.

Ultrasound assessment was offered to 49 patients (49%) based on TE reading and/or ALT result. All those that met the criteria for ultrasound were screened for autoimmune liver disease and thrombophilia with a coagulation screen. Four patients did not attend for ultrasound. The most common abnormality was increased reflectivity indicating fatty filtration in 8 patients (18%). A further 4 patients had a normal liver ultrasound but were offered a TJLB on the basis of their ALT and TE score. In total 17 met criteria for TJLB of whom 12 accepted. The characteristics of these patients are described in Table 1. There were no complications observed from the TJB procedures. In the 5 who did not accept liver biopsy, ultrasound appearances were normal in 2 subjects, indicative of fatty infiltration of the liver in 2 and demonstrated splenomegaly in one. Two had abnormal FS readings  $> 7.76$  kPa.

Overall, the commonest histological finding on liver biopsy was steatosis ( $n = 5$ ) or normal architecture ( $n = 4$ ). All subjects had HVPG  $< 6$  mmHg ( $n = 11$ ) including the 2 patients with previously undiagnosed NRH on biopsy in-keeping with a pre-sinusoidal component. This gives a prevalence of previously undiagnosed NRH in our cohort of 2% (95%CI: 0.55%, 6.8%).

As a sensitivity analyses we applied our study algorithm to two other patients attending the HIV clinic with previously identified DDI related liver disease. One

**Figure 1** Screening algorithm to detect Didanosine related liver disease in human immunodeficiency virus positive patients previously exposed to Didanosine for > 6 mo. <sup>1</sup>ALT > upper limit normal (ULN) or platelets < lower limit normal (LLN) or TE > 7.65 kPa; <sup>2</sup>ALT < ULN and platelets > LLN and TE < 7.65 kPa. TE: Transient elastography; HIV: Human immunodeficiency virus; DDI: Didanosine; ALT: Alanine transaminase; HBV: Hepatitis B virus; HCV: Hepatitis C virus; IQR: Interquartile range.

case had been identified due to complications of portal hypertension and the other from liver biopsy undertaken due to abnormal ultrasound scan (U/S) appearances. Both cases met our study screening criteria to proceed to TJLB indicating they would have been detected using our screening process.

## DISCUSSION

NRH largely presents with complications associated with NCPH after a prolonged asymptomatic period<sup>[1-6,9,12]</sup>. Although the aetiology may be multi-factorial, an overriding association is use of DDI. A recent study also identified an association between single-nucleotide polymorphisms in the 5'-nucleotidase and xanthine oxidase genes and development of NCPH after DDI exposure<sup>[13]</sup> suggesting an element of genetic predisposition *via* the purine metabolism pathway.

Our study is the first to use a screening strategy to identify asymptomatic individuals with a previous DDI exposure but with no known liver disease at study entry. Such a strategy is important to identify liver disease

at an earlier stage so that preventative measures and risk minimisation strategies may be instituted. Using our screening strategy we found 2 cases of previously undiagnosed NRH, but no cases of NCPH. Our strategy was based on TE, platelets and ALT levels, with ultrasound and subsequent TJLB in those who met criteria. We used a combination of methods to improve sensitivity of the screening strategy. Elevated transaminases, low platelets and moderate elevations in TE readings have all been described in known cases of NRH or NCPH. We chose a low TE cut off of 7.65 kPa as one study reported a median FS value of 7.9 kPa in subjects with biopsy confirmed NRH<sup>[10]</sup>. In addition in order to identify individuals with very low-level transaminase elevations we used a ULN cut off of 19 IU/mL in women and 31 IU/mL in men, contrasting with the ULN of 41  $\mu$ L/L used in previous studies<sup>[2]</sup>.

A recent multi-centre cohort of DDI-associated NCPH in HIV-infected adults identified thrombocytopenia, splenomegaly and elevated aminotransferases and alkaline phosphatase as significantly associated with NCPH<sup>[14]</sup>. The authors suggest a screening algorithm for NCPH consisting of DDI exposure or splenomegaly plus either

**Table 1** Characteristics of those with liver disease identified as a result of study screening

DDI: Didanosine; BMI: Body mass index; MAST: Michigan Alcoholism Screening test; ALT: Alanine transaminase; PLT: Platelet count; FS: FibroScan; TJLB: Trans-jugular liver biopsy.

a raised serum aminotransferase or thrombocytopenia or raised alkaline phosphatase as a trigger for further assessment. Using this study's algorithm only one third of our cohort would have been offered further investigation and one of the two cases of NRH identified in this study prior to development of NCPH would have been missed. Furthermore, splenomegaly is not uncommon in HIV positive patients<sup>[16]</sup>.

We opted to use TE together with ALT and platelet counts on the basis of ready availability of blood tests and the ease of use of FS in the outpatient ambulatory setting. The most common histological abnormality we found on liver biopsy was steatosis, in association with fibrosis in 2 cases. We are unlikely to have missed cases though cannot exclude NRH in those who declined biopsy, but is unlikely that they had underlying NRH in a greater frequency that that seen in patients who did agree to

undergo biopsy. Whilst DDI-associated NRH and NCPH is a serious condition with potentially life-threatening complications, this prospective study suggests a relatively low prevalence in treated cohorts. A previous study has identified non-alcoholic steatohepatitis (NAFLD) as a significant cause of unexplained serum aminotransferase elevation<sup>[12]</sup> in HIV positive people on ART and we also showed a significant rate of hepatic steatosis in association with hepatic fibrosis in our patients.

In this cross sectional study, we found a low prevalence of previously undiagnosed DDI-associated NRH using a screening strategy that combines TE, serum aminotransferase and platelet measurements followed by an U/S. We did, however, demonstrate a higher prevalence of NAFLD, which requires active management to address risk factors and prevent progression to fibrosis in HIV-positive patients.

## COMMENTS

### Background

Human immunodeficiency virus positive patients are at increased risk of liver disease. This is multifactorial and includes co-infection with hepatitis viruses, prescribed and recreational drug use and alcohol. The anti-retroviral drug Didanosine (DDI) has been implicated in the aetiology in some patients, particularly if the type of liver damage is nodular regenerative hyperplasia (NRH) or a patient has non-cirrhotic portal hypertension.

### Research frontiers

The authors used a combination of liver enzyme level (with a lower upper limit of normal) and transient elastography (TE) (which measures the liver stiffness) as an initial screen of patients exposed to DDI. This highly sensitive approach identified 42% who required further investigation with an ultrasound scan and 17% who subsequently were offered a transjugular liver biopsy. The authors, therefore, believe that the prevalence rate of 2% NRH in this DDI exposed asymptomatic cohort is accurate.

### Innovations and breakthroughs

The prevalence study is the first to systematically screen asymptomatic patients exposed to DDI. Other groups have looked at the association between the drug and liver disease but have not screened a large cohort of exposed but asymptomatic patients to establish a prevalence of disease.

### Applications

Use of a simple screening strategy in patients previously exposed to DDI will allow clinicians to identify liver disease which if left undiagnosed may present with the complications of portal hypertension such as variceal bleeding.

### Terminology

TE: A technique combining ultrasound waves and a pressure transducer to assess the stiffness of the liver. This has been validated as a tool to measure liver fibrosis and steatosis; NRH is characterized by small (less than 3 mm) regenerative nodules in the absence of fibrous septa on biopsy. The nodules cause obliteration of the portal veins which leads to portal hypertension.

### Peer-review

It is an interesting study.

## Abstract

### AIM

To evaluate the diagnostic value of serial biochemical blood tests in the diagnosis of biliary colic.

### METHODS

Files were reviewed of 1039 patients who were admitted to the Share'e Zedek Medical Center emergency department between the years 2012-2013, and received the coding of acute biliary disease. Of these, the first 100 cases were selected that met the following criteria: (1) a diagnosis of biliary colic or symptomatic cholelithiasis; (2) at least two biochemical blood tests performed; and (3) 18 years of age or older. Patients with other acute biliary diseases were excluded. The biochemical profile of the patients was analyzed as were their clinical and radiological findings.

## RESULTS

Three-quarters of the patients were women, whose average age of 37 years was younger than the average of the men, at 50 years. According to their histories, 47% of the patients had previously known cholelithiasis. Pain in either the right upper quadrant or the epigastrium was the presenting symptom in 93% cases. The greatest change in serum biochemical results was seen during the first day of the patients' admissions. Alanine aminotransferase (ALT) showed the highest initial rise above the reference range, followed by aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), bilirubin and alkaline phosphatase (ALKP) - all these increases were statistically significant ( $P < 0.05$ ). AST showed the sharpest decline followed by bilirubin and ALT. GGT and ALKP did not fall. A sharp rise and fall in liver enzymes, especially during the first day, most prominently in AST and ALT, was seen in 70% percent of cases. In 65% of cases trans-abdominal sonography did not give diagnostic findings.

## CONCLUSION

Serial serum liver enzyme measurements are helpful in the initial diagnosis of acute biliary colic.

**Key words:** Biliary colic; Symptomatic cholelithiasis; Gallstones; Liver enzymes; Aspartate aminotransferase; Alanine aminotransferase; Enzyme pattern; Diagnostic tool; Emergency department

**Core tip:** Gallstones are prevalent in affluent countries, more so in women than in men, and their prevalence increases with age. A large proportion of patients presenting to the emergency department with epigastric or right upper quadrant (RUQ) pain present a diagnostic challenge, especially when they belong to the older age group. We found that serial liver and biliary enzyme measurements reveal a characteristic pattern that helps the clinician determine quickly, cheaply and safely that the cause of RUQ/epigastric pain is biliary colic, in 71% of the patients. Serial enzyme testing is a useful adjunct to other diagnostic tools, for the diagnosis of acute upper abdominal pain.

## INTRODUCTION

Gallstones are prevalent in affluent countries, more so in women than in men, and their prevalence increases with age<sup>[1]</sup>. Gallstones usually produce symptoms when they migrate into the cystic duct or common bile duct

(CBD), causing obstruction that increases intraluminal pressure and distends the viscus. The most characteristic symptom of gallstone disease is biliary colic<sup>[2]</sup>, i.e., pain arising from the cystic duct or CBD.

A patient presenting to the emergency department (ED) complaining of epigastric or right upper quadrant (RUQ) pain, with a classic history and physical examination compatible with biliary colic does not present a great diagnostic challenge. A large proportion of patients presenting to the ED with epigastric or RUQ pain do present a diagnostic challenge, especially when they belong to the older age group (in which both a wide array of underlying diseases and polypharmacy are prevalent) which has become more common in Western society over recent decades<sup>[1]</sup>. Unfortunately, "classic" cases are the exception rather than the rule<sup>[3,4]</sup>. The differential diagnosis in an older patient with many co-morbidities includes: An acute coronary syndrome, pericarditis, an aortic dissection, peptic ulcer disease including a perforated ulcer, pulmonary embolism, lower lobe pneumonia, renal colic, pyelonephritis, partial colonic obstruction, diverticulitis, appendicitis, pancreatitis, acute cholecystitis, cholangitis, diabetic ketoacidosis, porphyria and biliary colic<sup>[2]</sup>. The diagnostic pathways are not straightforward, consume time and resources and are subject to pitfalls and misleading findings.

The confirmatory diagnostic test for biliary colic in the ED is the demonstration of gallstones in the cystic duct or CBD by trans-abdominal sonography<sup>[4-6]</sup>. However the demonstration of cholelithiasis alone is not diagnostic<sup>[1]</sup>, and unfortunately, the demonstration of gallstones in the cystic duct or CBD is very difficult even for an experienced radiologist under optimal conditions, namely in a lean, cooperative and fasted patient, when time is not limited. In practice, it is often very difficult to demonstrate gallstones in the cystic duct or CBD<sup>[7]</sup>. Due to these limitations, and in the majority of cases, ultrasonography is usually not diagnostic in the first hours or days of the patient's admission, and a negative ultrasound scan may be misleading<sup>[1,5,7-9]</sup>. A simple, rapid, cheap, non-invasive, reproducible and reliable test is needed to diagnose biliary colic quickly and efficiently.

Laboratory testing of serum "hepatocellular" and cholestatic liver enzymes [namely: Aspartate aminotransferase (AST) and alanine aminotransferase (ALT), and alkaline phosphatase (ALKP) and gamma-glutamyl transferase (GGT), respectively] is performed almost routinely in patients presenting with epigastric or RUQ pain, as the clinician searches for diagnostic patterns. For example: A patient with or without pain who has elevated "cholestatic" enzymes, ALKP and GGT, is considered a potentially "surgical" patient who is suffering from a chronic mechanical obstruction of the biliary tract. And indeed, it is rare to find such an obstruction without elevation of these enzymes<sup>[10]</sup>. In this type of obstruction, the hepatocellular enzymes, AST and ALT, will be only mildly elevated. Conversely, a patient with RUQ fullness, malaise, and AST and ALT in the hundreds and even thousands of international units per liter (IU/L), with or

without jaundice, and with only mildly elevated ALKP and GGT is considered a “medical” patient, who is suffering from viral, autoimmune or drug-induced hepatitis. These patterns that have served so well for so many years represent entrenched dogma.

We and others<sup>[11-13]</sup> have also observed another distinct pattern of a sharp (up to 100-fold above the upper limit of the normal reference range), short-lived (usually less than a week) rise in AST and ALT, and only a mild rise in ALKP, bilirubin and GGT, which we think is characteristic of acute “biliary colic”. Our clinical impression is that this pattern has high specificity for the diagnosis of “biliary colic” especially in the first hours of the patient’s admission, which is paradoxically counterintuitive in a patient, who has “surgical” pain with a “medical” enzyme pattern.

Our observations are mentioned (unreferenced) in the two latest editions of the leading textbooks in internal medicine, the leading textbook in gastroenterology as well as in a respected textbook on laboratory tests<sup>[2,8,14,15]</sup>. It is noteworthy that this pattern is not mentioned in the latest versions of two leading textbooks in general surgery<sup>[4,6]</sup>.

Our current study will examine the existence and the utility of this paradoxical “biliary colic” enzyme pattern in our own patient population.

## MATERIALS AND METHODS

### Study design and patients

This was an observational retrospective chart review, which was approved by the Medical Center’s Helsinki committee (number: p 92/13). We reviewed the medical records of 1039 patients, who were admitted to the Share’e Zedek Medical Center ED between December 1<sup>st</sup> 2013 and January 1<sup>st</sup> 2012, and who were assigned the coded diagnosis of “acute biliary disease”. Inclusion criteria were: (1) 18 years of age and older; (2) two or more blood tests including a liver profile; and (3) a diagnosis of biliary colic or symptomatic cholelithiasis. Symptomatic cholelithiasis was also included as it was clear that this term was used interchangeably with biliary colic. It was used to differentiate this entity from acute cholecystitis. Exclusion criteria were: (1) acute cholecystitis; (2) ascending cholangitis; (3) ultrasound-confirmed choledocholithiasis; and (4) sepsis. The search for cases meeting the inclusion and exclusion criteria was closed once the first sequential 100 suitable patients (out of 1039 during 23 mo) were identified. The case acquisition flow chart is shown in Figure 1.

Data were collected from the Medical Center computerized database. Clinical data were derived from the either the ED file (if the patient was not hospitalized) or the hospital chart. Laboratory data were collected from the computerized laboratory records. Laboratory tests were performed using the standard techniques used for all biochemical tests at the hospital. Ultrasound interpretations were retrieved from the diagnostic imaging computerized database in written or dictated format.

### Primary and secondary end points

The primary variables we examined were the serum biochemical laboratory results, including: Bilirubin, ALKP, AST, ALT and GGT, throughout the patient’s stay in the ED or hospital, relating to the particular ED visit with biliary colic.

The secondary variables examined were the location of the patient’s pain, radiation of the pain, whether it was post-prandial, and associated symptoms such as anorexia, nausea, vomiting, fever and chills, and physical examination findings. The interpretation of the radiologic tests performed was also evaluated.

### Statistical analysis

Statistical analysis was performed by Tali Bdolah-Abram from The Hebrew University, Jerusalem, Israel. Paired *t*-tests as well as non-parametric Wilcoxon signed-rank tests were used to assess the differences between pairs of quantitative variables. The one-sample *t*-test was used to test the significance of percent changes between two measurements. Repeated measures ANOVA models were applied to quantitative variables in order to simultaneously test trends over time, the difference between subgroups of patients and the interaction between time and group. The significance of the trends and the interactions were tested using the Greenhouse-Geisser test. The Friedman non-parametric test was used for testing a trend over time for quantitative variables when the data was not normally distributed.

All tests applied were two-tailed, and a *P*-value of 5% or less was considered statistically significant.

## RESULTS

### Demographic characteristics

The basic demographic characteristics of the 100 cases studied are presented in Table 1. The mean age of the patients in our study was 40 years, 76% of cases were women. On average, the women were younger than the men with mean ages of 37.4 years and 50.0 years respectively. In 47% of cases, cholelithiasis was already known from the patient’s history.

### Clinical characteristics

Clinical presentations were extracted from the patients’ files and are reported in Table 2. The clinical variables analyzed were: Location of pain and tenderness, presence of peritoneal irritation, Murphy sign, fever, chills, nausea or vomiting and whether the pain was post-prandial. The location of the pain was noted to be in the RUQ or epigastrium in the large majority of cases (92.8%).

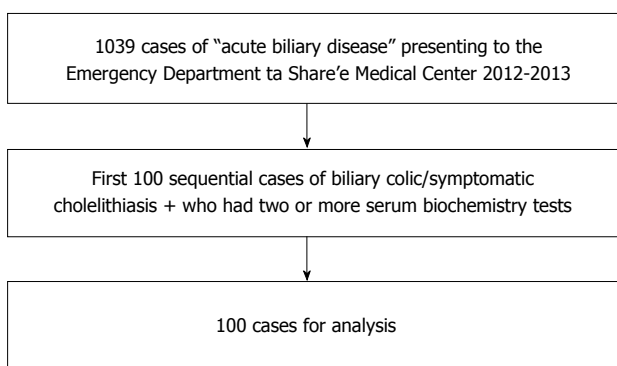

### Analysis of blood biochemistry tests

The primary endpoint of our study was the result of the analysis of the serial blood biochemistry laboratory tests, notably: Bilirubin, AST, ALT, ALKP and GGT. All tests were done according to the standard routine of the hospital laboratory. We retrieved the sequential laboratory results

**Figure 1** Flow chart illustrating case selection process. Of 1039 patients who presented to the emergency department (ED) of Share'e Zedek Medical Center during 23 mo (2012-2013) with various forms of acute biliary disease, 100 who were designated in the ED as having Biliary Colic and who fulfilled study criteria, were selected sequentially for analysis of concomitant serum bilirubin and enzyme temporal patterns.

for the 100 cases of interest, and analyzed the results from up to four sequential tests in each patient. Some patients had more than four tests done, but as this subset was small, we limited our analysis to four tests. The goal of the study was to differentiate which enzyme variable was most significantly indicative of the clinical event, namely biliary colic. To facilitate comparison between the four enzyme patterns, we normalized the data as percent changes per hour. For example, a change in AST from 50 to 150 units over a 10 h interval, would calculate to a change of 10 units per hour, representing a 20% per hour increase from 50 units. Figure 2 shows the time intervals between the sequential measurements tests, which allows a visual appreciation of the time course of the changes in enzyme levels. The average time between tests grew longer from the first to the last test, at 15.8, 25.3 and 29.8 h, respectively.

We compared changes in all five primary variables to one another at three different points, *i.e.*, percent changes per hour between tests 1 and 2, 2 and 3, and 3 and 4, as is shown in Figure 3.

It can be readily seen that the largest percent changes in enzyme levels, which were also statistically significant,

were seen between the first and second tests, and that ALT changed the most followed by AST, GGT, bilirubin and ALKP. Between tests two and three, the effects were far smaller with AST being the only variable with greater than one percent change. Between tests three and four effect percent changes were of similar magnitude to the changes between test two and three. AST still showed the largest absolute change, but this was smaller than between the previous tests, at 1.2%.

### The enzyme pattern

In order to demonstrate the enzyme pattern we plotted the percent change over time as seen in Figure 4. As this is a retrospective study and not protocol-driven, blood was drawn for testing at different intervals in each case. Therefore, the time between tests is represented as the average time interval between tests. To permit a graphic presentation of the different enzyme patterns, the hourly percent changes are multiplied by the corresponding

**Figure 3 Comparison of relative percent changes (per hour) in bilirubin and liver enzymes, between serial tests.** Percent change per hour is shown for these five variables. <sup>a,c</sup>Denote significant statistical difference from ALT and AST respectively in the same time frame (i.e., ALT between test one and two compared with AST between test one and two). The number of cases in the analysis in the different time frames is shown on the top right. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT: Gamma-glutamyl transferase; ALKP: Alkaline phosphatase.

average time intervals.

As shown above, the largest initial change was in ALT, at 140% between the first and second tests. AST rose less dramatically (86%) but showed the most dramatic average fall (50%). GGT rose initially by 53% but then hardly changed at all, while bilirubin and ALKP showed only minor fluctuations.

To determine how many of the 100 patients studied presented with the aforementioned enzyme pattern that is characteristic for biliary colic, we devised two criteria to separate patients into those either positive or negative for the pattern; positivity for either criterion was considered a characteristic pattern.

The first criterion was that a patient had at least doubled the levels of AST or ALT between the first two tests, compared to any subsequent test. The second criterion was that a patient had at least halved the first test results for AST or ALT in any one of the following three tests. Additionally, to be counted positive for the second criterion, only patients who had a first test result of more than double the upper limit of normal (ULN) for AST or ALT were counted. We used more than twice the ULN of normal as a cut-off as this has been used for many years in the field of chronic hepatitis B surveillance and in treatment algorithms (between 1-2 times the ULN is considered minimally raised)<sup>[16,17]</sup>. ULN for AST and ALT in our medical center are 36 and 52 units, respectively.

We found 33 (33%) patients positive for the first criterion (of a doubling in aminotransferases) all of whom showed a rise in ALT and 18 (54.5%) of whom had a rise in AST. Fifty-two (52%) patients were positive for the second criterion (of a significant subsequent fall in enzymes) - all had a fall in AST and 14 (26.9%) of whom also showed a fall in ALT. All told, 71 (71%) patients were positive for either one or the other of the criteria and 14 (57.6%) out of the 71 were positive for both criteria.

**Figure 4 Time trends in percent changes of bilirubin and liver enzymes with serial testing.** Time between tests is represented using the average time interval between tests (as seen in Figure 2). The hourly percent change between each test was multiplied by this interval, to provide a graphic presentation of the enzyme patterns. The intersection of the axes represents the first test and the following points represent each change from the previous result. For example, bilirubin increased by 20% between tests one and two and decreased by 15% between tests two and three; therefore, the next point is 5%. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT: Gamma-glutamyl transferase; ALKP: Alkaline phosphatase.

### Ultrasonography findings

Trans-abdominal ultrasonography was performed in all but one case, a woman who had had sonography performed the previous day, when she was found to have gallbladder stones. The sonography reports given by the hospital radiologists, in either written or dictated form, were reviewed. We divided the findings into two categories, namely (1) highly suggestive or compatible with a cause for biliary colic; and (2) questionable or possibly non-contributory to the diagnosis of biliary colic. The results and the categorization of the different findings are displayed in Table 3. As can be seen, in only a third of the cases were the sonographic findings highly suggestive or compatible with a cause for biliary colic. In other words there was definite, albeit somewhat indirect, evidence of CBD disease. In the remaining 64 cases, whereas there was no evidence of CBD disease, it is conceivable, nonetheless, that gallstones could have migrated from the gallbladder in 62 cases without causing visible CBD injury.

### DISCUSSION

Biliary colic is a common symptom that is defined as

**Table 3** Ultrasound findings

	Frequency
Non contributory	64
Contracted gallbladder	2
Cholelithiasis	58
Contracted gallbladder + cholelithiasis	4
Compatible or highly suggestive	35
Dilated CBD	5
Dilated CBD + filling defect	1
Thickened gallbladder wall	6
Distended gallbladder + cholelithiasis	13
Distended gallbladder	2
Stone in cystic duct	4
Distended gallbladder + pericystic fluid	2
Thickened gallbladder wall + cholelithiasis	2
Total valid	99
Missing	1
Total	100

CBD: Common bile duct.

pain caused by spasm of the cystic duct or CBD, usually caused by intraluminal calculi that have migrated from the gallbladder, or occasionally that form *in situ*<sup>[1]</sup>. Patients diagnosed with biliary colic present with symptoms of RUQ and/or epigastric pain. In some cases, diagnosis is straightforward but in some the differential diagnosis is wide and the evaluation is time and resource-consuming and occasionally potentially harmful.

Trans-abdominal sonography is readily available, but has low sensitivity and a low negative predictive value for choledocholithiasis. Indeed, in our study all but one of the patients were finally diagnosed as having biliary colic due to the passage of a stone through the CBD despite, the fact that choledocholithiasis was not proven directly in 99% of them. Ultrasonic findings, *i.e.*, CBD abnormalities, were compatible or highly suggestive of biliary colic, in only 35% of the patients. But even in this minority, sonography did not clinch the diagnosis, since there seemingly was enough uncertainty to prevent the clinician from discharging the patient or referring him/her for laparoscopic cholecystectomy without additional tests. The same is truer for those 62 patients with typical biliary colic in whom cholelithiasis was present, but there was no visible CBD abnormality. The ED staff in Galveston, Texas, made similar observations on the utility of ultrasound scans, and this led to overuse of computed tomography scanning, especially at night<sup>[18]</sup>.

Jafari *et al.*<sup>[7]</sup> also point out that passage of stones through the CBD can be fast, so that by the time the patient is transported to the radiology department the diagnostic picture - a dilated CBD containing a stone, can be missed. They advocate that ultrasound scans should be performed in the ED, and for CBD diameter to be measured routinely. It is in this situation that the characteristic enzyme elevation and fall pattern comes into its own.

As opposed to these limitations of ultrasound scanning, we found that serial liver and biliary enzyme tests (2-4 tests performed during the first 80 h from admission)

increase and decrease with statistical significance, and reveal a characteristic liver enzyme pattern that helps the ED clinician determine quickly, cheaply and safely, in concert with simultaneous other diagnostic maneuvers, that the cause of RUQ/epigastric pain is biliary colic. Thus, our findings confirm and extend what is already known. We assume that in most of the 29% of patients in whom the characteristic temporal pattern was not seen, the first blood sample was taken too late for the sharp rise and fall to be fully appreciated.

The most statistically significant changes in the variables we examined were seen between the 1<sup>st</sup> and the 2<sup>nd</sup> test. The most prominent effect is seen with ALT followed by AST. However, GGT and ALKP, the classic "obstructive" biliary enzymes, and bilirubin, contribute little, if at all, to the diagnosis. This finding is compatible with our assumption that ALT and AST, the "medical" hepatocellular enzymes, are deranged early in biliary colic, for which the most plausible hypothesis is that high biliary pressures lead to impairment of bile secretion and retention of bile acids with accompanying hepatocyte apoptosis, necrosis or leakage of enzymes<sup>[19]</sup>. The classic rise in the "biliary" enzymes, alkaline phosphatase and GGT, in prolonged obstruction is thought to reflect increased enzyme synthesis rather than cholangiocyte damage and leakage<sup>[20]</sup>. Moreover, the greatest changes in enzyme levels occur early and up to the first 24 hours of the patient's admission, which makes this a diagnostic tool particularly useful in the ED setting.

In our study many patients were seen to have both the rise and the fall of hepatocellular enzymes, unlike the findings in two earlier studies that showed mainly the down-sloping phase of the temporal enzyme pattern<sup>[12,21]</sup>. This can be explained by lesser availability of liver enzyme testing in the late 1980s, when these studies were published. And indeed, in a later study, published in 2010, an enzyme pattern almost identical to ours was found, in which both the ascending and descending phases were detected. This latter study was performed on subjects in whom choledocholithiasis was proven invasively, which, admittedly, is a different and far less common situation<sup>[22]</sup>.

The pattern of a short term (less than a week), sharp rise and sharp (but to a lesser degree) fall in ALT and AST is classically recognized in two clinical scenarios, namely ischemic liver injury - so-called Hypoxic Hepatitis - and acetaminophen intoxication<sup>[23-25]</sup>. It is our opinion that this pattern is also typical of a third clinical scenario - biliary colic due to passage of a biliary stone that causes transient biliary obstruction.

Our impression is that this pattern is not widely appreciated by general clinicians although it is mentioned in several articles and in some leading textbooks<sup>[2,8,12-15,21-22,26]</sup>. One explanation for this pattern's relative anonymity is the dogma that elevated cholestatic enzymes mean biliary obstruction has served so well for prolonged biliary obstruction. The corollary has been assumed, that all biliary obstruction is accompanied by a cholestatic enzyme pattern. This is clearly not the case, as transient

biliary obstruction due to passage of a stone through the CBD causes elevation of ALT and AST - the medical or hepatocellular enzymes.

Limitations of this enzyme temporal analysis include the fact that this is a retrospective study, with its unavoidable selection bias, and that the exact timing of the clinical event, *i.e.*, the passage of the CBD stone, is unknown. Hence, the appropriateness of the time of first blood drawing is also uncertain. A third limitation of this study is that we only included patients who had two or more blood tests performed, which introduces further selection bias of patients who had initial enzyme elevations. Irrespective, the more prominent abnormal enzymes were the hepatocellular. Another bias is that our subjects were already diagnosed as suffering from biliary colic. It remains to be tested, therefore, whether the characteristic "biliary colic" pattern will be useful in the more real life scenario of a patient presenting to the ED with abdominal pains. We hope to be able to resolve this question in a prospective study, in which all patients presenting with abdominal pain will undergo serial liver enzyme measurement at protocol-defined intervals, along with a precise history of the time of onset of the abdominal pain. Finally, although we were careful to exclude cases of cholecystitis, it must still be acknowledged that aminotransferase elevation occurs in active gallbladder inflammation, usually associated with fever and leukocytosis (both absent in our 100 cases) and of slower resolution than seen in our cases. In gallbladder inflammation, the mechanism of aminotransferase rise is usually attributed to cytokine release and other mediators of the Systemic Inflammatory Response Syndrome<sup>[27]</sup>.

### Conclusions and practical implications

Based on a retrospective statistical analysis of 100 patients who were diagnosed as having biliary colic - which is defined as upper abdominal pain due to passage of a gallstone through the cystic duct or CBD, we found that a sharp, short term rise and fall of ALT and AST, typically thought to be indicative of ischemic hepatic injury and acetaminophen intoxication, is also typical of biliary colic. Whereas the current observations are not entirely novel, they are worth emphasizing and bringing to general attention as they do not appear to be widely appreciated. Thus, in the ED, when a patient presents with an appropriate history and physical exam, we recommend adding liver enzymes to the list of blood tests already ordered. If liver enzymes are found to be elevated, we recommend repeating these tests twice or thrice at intervals over the next 24 h. If the pattern that is characteristic of biliary colic is seen, concomitant with the resolution or even only marked improvement of the pain, and no other diagnosis is suspected (*e.g.*, an acute coronary event, pancreatitis, cholecystitis, *etc.*), then the patient can be discharged home or admitted for laparoscopic cholecystectomy according to local practice<sup>[28]</sup>.

## ACKNOWLEDGMENTS

We would like to thank Tzina Lindenberg, director of Share'e Zedek Medical Center's archive, for her support of this project.

## COMMENTS

### Background

Patients complaining of abdominal pain are frequently seen in the emergency department. The differential diagnosis is vast and therefore the clinical workup is resource and time consuming. However, some clinical observations led us to the thought that a few cheap and routine blood tests could greatly aid the clinician in this diagnostic challenge.

### Research frontiers

A few studies, mainly from the 1980's and 1990's described the enzymatic profile of biliary colic and reached. However this very useful profile did not become common knowledge.

### Innovations and breakthroughs

In recent years more patients were tested for liver enzymes as part of the routine workup of acute abdominal pain. Additionally many patients had more than one blood sample taken. This has allowed us to follow the level of liver enzymes and observe a unique pattern.

### Applications

This pattern helps clinicians in the clinical scenario of acute abdominal pain diagnosis. It is cheap, rapid, readily available, accurate and non-invasive.

### Terminology

Biliary colic is a term used to describe pain arising from stones obstructing the cystic duct or the passage of a stone through the common bile duct.

### Peer-review

This manuscript provides the updated evidence to the readers. The topic is an important one and deserves a practical value.

### Abstract

#### AIM

To describe one case of bilateral Tapia's syndrome in a liver transplanted patient and to review the literature.

#### METHODS

We report a case of bilateral Tapia's syndrome in a 50-year-old man with a history of human immunodeficiency virus and hepatitis C virus child. A liver cirrhosis and a bi-nodular hepatocellular carcinoma, who underwent liver transplantation after general anesthesia under orotracheal intubation. Uneventful extubation was performed in the intensive care unit during the following hours. On postoperative day (POD) 3, he required urgent re-laparotomy due to perihepatic hematoma complicated with respiratory gram negative bacilli infection. On POD 13, patient was extubated, but required immediate re-intubation due to severe respiratory failure. At the following day a third weaning failure occurred, requiring the performance of a percutaneous tracheostomy. Five days later, the patient was taken off mechanical ventilation and severe dysphagia, sialorrhea and aphonia revealed. A computerized tomography and a magnetic resonance imaging of the head and neck excluded central nervous injury. A stroboscopy showed bilateral paralysis of vocal cords and tongue and a diagnosis of bilateral Tapia's syndrome was performed. With conservative management, including a prompt establishment of a speech and swallowing rehabilitation program, the patient achieved full recovery within four months after liver transplantation. We carried out MEDLINE search for the term Tapia's syndrome. The inclusion criteria had no restriction by language or year but must provide sufficient

available data to exclude duplicity. We described the clinical evolution of the patients, focusing on author, year of publication, age, sex, preceding problem, history of endotracheal intubation, unilateral or bilateral presentation, diagnostic procedures, type of treatment, follow-up, and outcome.

## RESULTS

Several authors mentioned the existence of around 70 cases, however only 54 fulfilled our inclusion criteria. We found only five published studies of bilateral Tapia's syndrome. However this is the first case reported in the literature in a liver transplanted patient. Most patients were male and young and the majority of cases appeared as a complication of airway manipulation after any type of surgery, closely related to the positioning of the head during the procedure. The diagnosis was founded on a rapid suspicion, a complete head and neck neurological examination and a computed tomography and or a magnetic resonance imaging of the brain and neck to establish the origin of central or peripheral type of Tapia's syndrome and also the nature of the lesion, ischemia, abscess formation, tumor or hemorrhage. Apart from corticosteroids and anti-inflammatory therapy, the key of the treatment was an intensive and multi-disciplinary speech and swallowing rehabilitation. Most studies have emphasized that the recovery is usually completed within four to six months.

## CONCLUSION

Tapia's syndrome is almost always a transient complication after airway manipulation. Although bilateral Tapia's syndrome after general anesthesia is exceptionally rare, this complication should be recognized in patients reporting respiratory obstruction with complete dysphagia and dysarthria after prolonged intubation. Both anesthesiologists and surgeons should be aware of the importance of its preventing measurements, prompt diagnosis and intensive speech and swallowing rehabilitation program.

**Key words:** Liver transplantation; Follow-up; Outcome; Postoperative complications; Bilateral Tapia's syndrome

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Tapia's syndrome is a rare entity characterized by the concomitant extracranial injury of the hypoglossal nerve (XII) and the recurrent laryngeal branch of the vagus nerve (X) at the base of the tongue and the pyriform fossa. Anesthesiologists, surgeons and otorhinolaryngologist should be aware of its presentation at any type of surgery as in the present case, after liver transplantation. The purpose of this study is to present our even rarer presentation of bilateral Tapia's syndrome to the liver transplant community and to review the literature to update the current management and treatment. The most relevant common feature in most cases of bilateral syndrome was orotracheal intubation prolonged for more than 14 d.

Bilbao I, Dopazo C, Caralt M, Castells L, Pando E, Gantxegi A, Charco R. Isolated bilateral Tapia's syndrome after liver transplantation: A case report and review of the literature. *World J Hepatol* 2016; 8(36): 1637-1644 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i36/1637.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i36.1637>

## INTRODUCTION

Tapia's syndrome was described for the first time by the Spanish otorhinolaryngologist Antonio García Tapia in 1904<sup>[1]</sup>. It is characterized by the unilateral paralysis of the tongue and the vocal cord caused by extracranial injury to the hypoglossal nerve (XII) and the recurrent laryngeal branch of the vagal nerve (X) at the base of the tongue and the pyriform fossa<sup>[1-6]</sup>. Although the Tapia's syndrome refers to the extracranial lesion of the hypoglossal and recurrent laryngeal nerves, some authors also describe a central type of Tapia's syndrome, referring to those patients with the same symptoms, but whose damage has occurred in the nucleus ambiguus, the nucleus of the hypoglossal nerve, and the pyramidal tract in the central nervous system. We describe one case of bilateral Tapia's syndrome in a liver transplant patient, which is not previously reported in the literature.

## MATERIALS AND METHODS

We report herein a case of bilateral Tapia's syndrome together with a review of the literature. We carried a literature research in the MEDLINE database through the PubMed search service for the term Tapia's syndrome. The inclusion criteria had no restriction by language or year but must provide sufficient available data to exclude duplicity. We described the clinical evolution of the patients, focusing on author, year of publication, age, sex, preceding problem, history of endotracheal intubation, unilateral or bilateral presentation, diagnostic procedures, type of treatment, follow-up, and outcome.

### Case report

A 50-year-old man with a history of human immunodeficiency virus (HIV) and hepatitis C virus positive serology, with class A of Child-Pugh classification liver cirrhosis and a bi-nodular hepatocellular carcinoma underwent liver transplantation after general anesthesia under orotracheal intubation. Body mass index at time of transplantation was 21 kg/m<sup>2</sup>. An 8.0 endotracheal tube was placed. The cuff was inflated with 3 mL of air and verified with a manual manometry to reach a filling pneumotamponade of 20 cm water. Surgery lasted 375 min. The procedure was well tolerated and required a low dose of inotrops (noradrenalin 0.5 mL/h) during surgery. Immunosuppression therapy during induction was based on mycophenolate mophetil and tacrolimus. Patient was transferred to the intensive care unit (ICU) under mechanical ventilation, sedated with remifentanyl. Uneventful weaning was performed during the following

hours. On postoperative day (POD) 3, he required urgent re-laparotomy due to a perihepatic hematoma and was transferred to the ICU under mechanical ventilation, sedated with propofol and remifentanyl. Extubation was postponed due to a respiratory gram negative bacilli infection and agitation after several attempts of decreasing sedation. On POD 13, patient was extubated and required immediate re-intubation after severe respiratory failure. A third weaning failure occurred the following day requiring re-intubation for the third time. Then percutaneous tracheostomy was performed with no events. Five days later, patient was taken off mechanical ventilation progressively and oral diet was started the day after, appearing severe dysphagia and important sialorrhea, being hardly able to swallow a pureed diet. Aphonia was another significant symptom presented at that time. At POD 28 patient was decanulated and persisted with swallowing difficulty, requiring parenteral nutrition. A computerized tomography (CT) of the head and neck and a magnetic resonance imaging (MRI) of the brain and neck were then performed to exclude central nervous injury. Both explorations did not show pathological findings.

At POD 34, patient was transferred to the ward and enteral nutrition was initiated *via* nasogastric tube. He was evaluated by speech and swallow therapists and diagnosis of a bilateral tongue paralysis and aphonia was made. Evaluation by otorhinolaryngologist excluded a recurrent laryngeal nerve injury. Detailed neurological examination revealed bilateral tongue paralysis, severe dysarthria and dysphagia for liquids and solids. A stroboscopy was performed showing bilateral paralysis of vocal cords in addition to the bilateral tongue paralysis. Cervical electromyography was also performed. Bilateral Tapia's syndrome was then diagnosed; a bilateral hypoglossal and laryngeal recurrent nerve neuroapraxia. At three months post-transplant, subjective improvement in aphonia and dysphagia were observed and the patient was discharged with enteral nutrition.

Outpatient neurological follow-up regarding speech and swallow training was performed twice weekly. Satisfactory recovery of his aphonia and dysphagia were observed. At four months post-transplant, videofluoroscopy was performed with no significant findings; however, laryngeal stroboscopy showed severe hypomotility of cricoarthenoideal articulations, cordal atrophy and minimal adduction movements with severe longitudinal hiatus. Despite that, the patient presented no problems during intake, being able to take out the nasogastric feeding tube. At that time, the nasogastric tube was preferred to the percutaneous gastrostomy to avoid invasive procedures in a patient with a complex postoperative.

## RESULTS

In total around 70 cases were initially described in the literature, but only 53 fulfilled the inclusion criteria: To have patients with sufficient available data in the description of cases in order to rule out duplicity. Table

1<sup>[1-2,7-51]</sup> summarizes the 54 cases (including ours) of Tapia's syndrome, focusing on author, year of publication, age, sex, preceding problem, history of endotracheal intubation, unilateral or bilateral presentation, diagnostic procedures, type of treatment, follow-up and outcome.

The majority were young. Only 13 cases were older than 50 years (range 16-95). All cases except 10 were males. Two cases were attributed to a central cause (metastatic hemangiosarcoma in the medulla oblongata<sup>[2]</sup> and infiltration of a large B-cell lymphoma<sup>[14]</sup>), but the remaining 53 patients were peripheral type. Six patients<sup>[8,22,24,36,42,43]</sup>, apart from ours, had a bilateral presentation of the syndrome; four with complete deficit of hypoglossal and recurrent laryngeal nerves and three<sup>[22,24,43]</sup> incomplete with bilateral paralysis of the hypoglossus nerves and unilateral recurrent laryngeal nerve palsy. All the cases, except one<sup>[36]</sup>, followed to a prolonged oro-tracheal intubation for more than 14 d. In the systematic review, we have found two other cases of isolated bilateral hypoglossal paralysis without other nerve involvement after oro-tracheal intubation<sup>[52,53]</sup>.

All, except seven of peripheral cases<sup>[9,15,29,39,40,47,51]</sup>, have been attributed to orotracheal intubation for surgery or respiratory failure. The most frequently involved operations were: Osteoarticular surgery of the shoulder, mandible and cervical spine in 14 cases, otorhinolaryngology surgical procedures in 11 cases, cardiac surgery in 4 cases, thoracic surgery in 2 cases, abdominal surgery in 2 cases, and direct traumatic nerve injury in 2 cases. However, several causes have been described in the literature such as: Vascular (vertebral artery dissection, carotid artery aneurism); metastatic or primary neoplasia (lymphoma, hemangiosarcoma, prostate, pseudotumor of the neck, nasopharyngeal carcinoma, neurilemoma, neurofibroma, etc.); infectious of the neck (bacterial, viral, fungal), etc.

The diagnosis and management of Tapia's syndrome in the majority of cases was based on a complete neurological examination, including laryngeal endoscopy and a head and neck CT or MRI. Some authors have advocated for the use of video-fluoroscopic swallowing and electromyography to confirm the diagnosis and to predict prognosis.

The treatment was supportive in all cases with a prompt establishment of a swallowing rehabilitation program. The administration of intravenous or oral steroids in combinations with B1, B6, B12 vitamins or hyaluronic acid injection has been proposed by many authors in the acute setting. At least 4 patients<sup>[8,17,23]</sup> required percutaneous endoscopic gastrostomy and 2 a naso-gastric tube insertion<sup>[20,42]</sup> to ensure nutritional requirements while the oro-esophageal route was unable to be used. In two cases (Takimoto<sup>[43]</sup> and ours), where bilateral paralyses were discovered, reintubation with subsequent tracheotomy was necessary to prevent respiratory failure.

Recovery was excellent for the majority of non-tumour peripheral cases after a duration of 3 to 6 mo, ranging from 15 d to 3 years. In 9 cases the patients reported only

partial recovery.

## DISCUSSION

The case described above, is the first reported case of complete bilateral Tapia's syndrome (paralysis of the tongue muscles and vocal cords because of an extracranial injury of the X and XII cranial nerves) occurring after liver transplantation and oro-tracheal general anaesthesia requiring re-intubation for three times. There are many causes of Tapia's syndrome, including general anaesthesia, fungal infections<sup>[44]</sup>, neoplasms<sup>[2,9,14,15,24,43,45,47]</sup>, vascular<sup>[29,40]</sup> and traumatic problems<sup>[1,33,50]</sup>, being general anaesthesia the main cause. Intubation tube or its cuff and motion of the head during surgery can lead to injury to the pharyngeal wall and its underlying neurovascular structures (X and XII cranial nerves)<sup>[32]</sup>. Excessive dorsiflexion of the head during laryngoscopy, excessive cuff pressure, malposition of the cuff in the larynx rather than the trachea, or extubation while the cuff is still inflated is the most likely cause<sup>[18]</sup>. The tracheal tube and its cuff may press on a localized area just at the crossing of the vagal and hypoglossal nerves, compressing the anterior branch of the inferior laryngeal nerve against the postero-medial part of the thyroid cartilage and this can lead to a recurrent laryngeal paralysis<sup>[6]</sup>. Hypoglossal nerve damage can be caused by a stretching of the nerve against the greater horn of the hyoid bone by an oro-tracheal tube or compression of the posterior part of the laryngoscope or oro-tracheal tube<sup>[35]</sup>. There was no clear mechanism for injury to the hypoglossal and recurrent laryngeal nerves in our patient. Intracranial pathology was unlikely because of negative CT scan and MRI. We postulate that low blood pressure during surgery and post-operatively due to intrabdominal hemorrhage requiring reintervention and the need of several oro-tracheal reintubations (3 times), 2 of them in emergency conditions, in addition to prolonged intubation with probable unnoticed overinflation and malposition of the endotracheal cuff, might have been the source of the bilateral nerve compression. A change in the position of the neck at some point, compression by the endotracheal tube and pressure to the lateral roots of the tongue with the McIntosh blade during intubation could be additional mechanisms. The caquexia of the patient and some degree of lypodistrophy due the HIV coinfection at time of transplant could also play a role. Liver transplantation is usually a long lasting surgical procedure, which could contribute, along with other factors to the development of Tapia's syndrome. This fact should be taken into account by all clinicians involved in the liver transplantation care:

Liver surgeons, anesthetists, intensivists, hepatologists, gastroenterologists, *etc.*

Although most patients were male and young, there is no an explanation to relate the syndrome to sex or age. We believe that this syndrome is more related to anatomical, positional and lasting-time issues than to other characteristics.

The diagnosis is founded on a rapid suspicion, a complete history around the paralysis and a complete head and neck neurological examination. A computed tomography and or a magnetic resonance imaging of the brain and neck is essential to establish the diagnosis of central or peripheral type of Tapia's syndrome and also the nature of the lesion, ischemia, abscess formation, tumor or haemorrhage.

Tapia's syndrome classification and a treatment protocol have been proposed by Aktas and Boğa<sup>[32]</sup>: Grade I /mild type, unilateral cord and tongue paralysis, no uvula distortion, minimal slowdown in speaking, no swelling in tongue and no trouble in swallowing, Corticosteroid treatment is not recommended; Grade II/moderate type, unilateral cord and tongue paralysis, no uvula distortion, mild slowdown in speaking, swelling in tongue, dryness in pharynx, trouble in swallowing, cracked speech and normal feeding and drinking, 15 d of corticosteroid treatment is recommended; Grade III/severe type, unilateral cord and tongue paralysis, significant uvula distortion, significant difficulty in speaking, swelling in tongue, dryness in pharynx, trouble in swallowing and difficulties in feeding and drinking, endovenous corticosteroid is recommended for 1 wk.

To our knowledge, only six cases<sup>[8,22,24,36,42,43]</sup> of isolated bilateral Tapia's syndrome have been reported in the literature and all of them were related to transoral intubation during general anaesthesia. The most relevant common feature was the prolonged oro-tracheal intubation for more than 14 d in all the cases except one<sup>[36]</sup>. Our patient was reintubated three times, two of them as an urgent procedure, and remained ventilated for more than 18 d.

The majority of all reported cases, even unilateral or bilateral, recovered in 4-6 mo and this progressive recovery of function suggests nerve damage of a neuropraxic type, which is typical of compression injury. But there are some reports in the literature regarding its irreversible form<sup>[43,44,46,47]</sup> or partially reversible form<sup>[16,19,22,24,29,30,39,42,48,51]</sup>.

Apart from corticosteroids and anti-inflammatory therapy described above as key of the therapy, other support treatments recommended are speech and swallow therapy and warm air inhalation. Most studies

have emphasized that the recovery is usually completed within 6 mo, but with an intensive and multidisciplinary approach the patients' recovery time could be reduced. In our case, despite no corticosteroids were administered, the recovery was complete four months post-transplant after intensive speech and swallow training.

In conclusion, Tapia's syndrome is mainly a rare complication of airway manipulation. It can occur after any type of surgery under endotracheal general anesthesia. Clinicians should be aware of its preventive strategies, diagnosis, treatment and almost always transient outcomes. Although bilateral Tapia's syndrome after general anaesthesia is exceptionally rare, this complication should be recognized in patients reporting respiratory obstruction with complete dysphagia and dysarthria after extubation. Special attention should be paid to correct positioning of the head during surgery to avoid such problems.

## COMMENTS

### Background

Tapia's syndrome is an extracranial ipsilateral palsy of the recurrent laryngeal and the hypoglossal nerves. It is a very rare complication with few cases reported in the literature. The predisposing factors are most commonly orotracheal intubation for general anesthesia but also other etiologies.

### Research frontiers

This study tries to collect all articles published to date, emphasizing the common aspects of all reported cases.

### Innovations and breakthroughs

The rarity in the presentation of Tapia's syndrome makes its incidence probably underestimated if clinicians are not aware of its symptoms. The publication of this review will help the scientific community to keep in mind Tapia's syndrome and to establish common guidelines for diagnosis, management and treatment.

### Peer-review

This is a very interesting case report and a good literature review about the topic.
