

# World Journal of *Hepatology*

*World J Hepatol* 2016 January 8; 8(1): 1-82

## Editorial Board

2014-2017

The *World Journal of Hepatology* Editorial Board consists of 469 members, representing a team of worldwide experts in hepatology. They are from 53 countries, including Algeria (1), Argentina (6), Armenia (1), Australia (1), Austria (4), Bangladesh (2), Belgium (3), Botswana (2), Brazil (13), Bulgaria (2), Canada (3), Chile (1), China (98), Czech Republic (1), Denmark (2), Egypt (12), France (6), Germany (19), Greece (11), Hungary (5), India (15), Indonesia (2), Iran (4), Israel (1), Italy (52), Japan (35), Jordan (1), Malaysia (2), Mexico (3), Moldova (1), Netherlands (3), Nigeria (1), Pakistan (1), Philippines (2), Poland (1), Portugal (2), Qatar (1), Romania (6), Russia (2), Saudi Arabia (4), Singapore (1), South Korea (11), Spain (20), Sri Lanka (1), Sudan (1), Sweden (1), Switzerland (1), Thailand (4), Turkey (21), Ukraine (3), United Kingdom (17), and United States (56).

### EDITORS-IN-CHIEF

## Contents

*World Journal of Hepatology*  
Volume 8 Number 1 January 8, 2016

### ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Henning Gronbaek, MD, PhD, Professor, Department of Hepatology and Gastroenterology, Aarhus University Hospital, 8000 Aarhus, Denmark

### AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### INDEXING/ ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed Central, PubMed, Digital Object Identifier, Directory of Open Access Journals, and Scopus.

### Abstract

Metabonomics has recently been widely used to

discover the pathogenesis and find potential metabolic markers with high sensitivity and specificity. Furthermore, it develops new diagnosis and treatment methods, increases early phase diagnosis rates of certain diseases and provides a new basis for targeted therapy. This review mainly analyzes the research progress of the metabonomics of hepatitis B virus (HBV)-related hepatic diseases, hoping to discover some potential metabolic markers for identification of HBV-related hepatic diseases from other etiologies and for HBV-related hepatitis, liver cirrhosis and hepatocellular carcinoma. This can contribute to early discovery, diagnosis and treatment, eventually increasing the survival rate of HBV-related hepatic diseases.

**Key words:** Metabonomics; Hepatitis B virus-related hepatic diseases; Hepatitis B; Hepatitis B virus-related liver cirrhosis; Hepatitis B virus-related hepatocellular carcinoma

## METABONOMICS AND THE LIVER IN BRIEF

The main function of the liver is the synthesis and metabolism of various proteins, polysaccharides and fats and the detoxification of the body's normal metabolic wastes, such as uric acid, drugs and chemical products<sup>[1,2]</sup>. There are many hepatic diseases that threaten health. However, because of a lack of effective early diagnosis methods, a large number of the diseases are in the middle to late stages when detected, which seriously affects the prognosis. Therefore, it is important to find tumor markers with high sensitivity and specificity as well as to elucidate the pathogenesis.

Metabonomics, a branch of systematic biology, is a recent newly developing subject. It aims to explore biological systems, like the changes in metabolites of the cells, tissues and certain organisms in the environment of exogenous stimulations, especially studying metabolites weighing less than 1000. Metabonomics integrates gene regulation, post-transcriptional regulation and the interaction of the pathways together, which makes different metabolites manifest significant biological phenotypes through the stages of the cell directly. Compared to the vast information in genomics, transcriptomics and proteomics, there is more information about apparent learning<sup>[3]</sup>. Thus, metabonomics has recently been widely used to discover the pathogenesis, finding potential metabolic markers with high sensitivity and specificity and exploring new diagnosis and treatment methods in order to increase early phase diagnosis rates of certain diseases and provide a new basis for targeted therapy<sup>[4]</sup>.

The morbidity of hepatocellular carcinoma (HCC) ranks 5<sup>th</sup> and its mortality ranks 3<sup>rd</sup> as a malignancy worldwide<sup>[5]</sup>. The incidence in southeast Asia and Africa is especially high, about 20 per 100000 population<sup>[6]</sup>. HCC has many risks with HBC as the primary one, causing 780000 death yearly<sup>[7]</sup>. The evolutionary progress of chronic hepatic disease is from chronic hepatitis B (CHB), hepatitis B virus (HBV)-related cirrhosis to HBV-related HCC. Nowadays, liver biopsy is the golden criteria in differentiating hepatic fibrosis, liver cirrhosis (LC) and HCC but cannot be used universally because of the invasiveness. Abdominal ultrasound is still the first screening method for hepatic diseases. It is widely used clinically because it is noninvasive and cheap. However, its sensitivity is affected by the machine, operators and different states of the disease. The sensitivity of diagnosing early cirrhosis is especially low, only 32% to 65% in HCC<sup>[8,9]</sup>. However, as a widely used clinical serum biomarker for HCC, alpha fetoprotein shows no increase in 80% of small HCC and its overall sensitivity is just 70%<sup>[8-11]</sup>. Some liver fibrosis indexes, such as hyaluronic acid, procollagen type III, procollagen type IV and laminin, can indicate early hepatic cirrhosis by analyzing the proliferation and degeneration of hepatic fibrosis. However, its sensitivity and specificity remain

unknown<sup>[12]</sup>. As an essential metabolic organ, any organic disease of the liver will lead to changes in the whole body's metabolism, causing widespread concern for medical staff. Research on the relationship between hepatic diseases and metabonomics has been increasing yearly. This review mainly analyzes the research progress of the metabonomics of HBV-related hepatic diseases, hoping to discover some potential metabolic markers for identification of HBV-related hepatic diseases from other etiologies and for HBV-related hepatitis, LC and HCC. It can contribute to early discovery, diagnosis and treatment, eventually increasing the survival rate of HBV-related hepatic diseases.

## THE METABONOMIC WINDOW INTO HBV-RELATED HEPATIC DISEASES

### CHB

Chronic HBV infection is a global problem, mainly in developing countries and especially in southeast Asia and Africa. About 600000 people die of acute or chronic HBV infection each year<sup>[13]</sup>. Chronic HBV infection can result in hepatitis, hepatic fibrosis and even LC and HCC. Presently, the main treatment methods for chronic HBV infection are interferon treatment<sup>[14-16]</sup>, nucleotide analogue treatment<sup>[17-19]</sup>, immune treatment<sup>[20-22]</sup>, *etc.* Although they can reduce the transformation from CHB to LC and HCC, their cure rates still need to improve. In the meantime, the pathogenic pathway of chronic HBV infection is still unclear. In the metabonomic study of patients with chronic HBV infection, some metabolites with a significant difference were found, which may provide some basis for discovering a pathogenic pathway and ideas for new targeted therapy.

As shown in Table 1, there are 2 studies concerning CHB. Zhou *et al.*<sup>[23]</sup> analyzed the metabolites in serum from CHB patients and a control group by liquid chromatography-mass spectrometry (LC-MS) and discovered 12 metabolites with a difference that were involved in fatty acids, amino acids, bile acids and energy metabolism and other pathways<sup>[24]</sup>. To date, there are still few metabonomic studies about CHB so it is a research domain that needs to be expanded. Autoimmune hepatitis (AIH) is an inflammatory reaction of the liver caused by autoantibodies. Early diagnosis can result in successful treatment. However, due to the unknown pathogenesis, the diagnostic rate is low and the prognosis cannot be estimated. Wang *et al.*<sup>[25]</sup> studied metabonomic characteristics of AIH by nuclear magnetic resonance (NMR) for the first time, providing a basis for researching the pathogenesis of AIH and discovering potential metabolic markers further. About 11% of patients with nonalcoholic steatohepatitis (NASH) will develop LC after 15 years and 7% will develop HCC through LC or directly after 6.5 years<sup>[26]</sup>. The metabolic changes of NASH refer to the metabolism of fatty acids, carbohydrates and bile acids<sup>[27-29]</sup>. The metabonomic research for chronic hepatitis C has discovered that the

up-regulation of AKR1B10 expression in urine leads to abnormal glucose metabolism<sup>[30]</sup>. In studies about acute alcoholic hepatitis, Rachakonda *et al*<sup>[31]</sup> detected metabolites that were distinctly different from those in alcoholic LC that were involved in the metabolic process of fatty acids, bile acids, proteins and carbohydrates.

## LC

LC is the terminal stage of chronic liver diseases (CLD), with a high morbidity worldwide. Chronic HBV infection is an important pathogenic factor of LC<sup>[32]</sup> and the evolution of HBV-related LC is a gradual progress<sup>[33]</sup>. Due to a lack of specific diagnostic methods, the incidence rate of LC is 3.7 per 100 person-years in HBV carriers<sup>[34]</sup> and the 5 years survival rate of decompensated LC patients is only 14% to 35%<sup>[35,36]</sup>, while 70% to 90% of HBV-related HCC developed from decompensated LC<sup>[37,38]</sup>. To date, there are still few valuable markers for early diagnosis of HBV-related LC and it is especially important to detect potential biomarkers with a higher

sensitivity and specificity.

Table 2 shows 5 studies regarding the metabonomics of HBV-related LC, 4 of them based on serum and 1 based on urine. According to the Child-Pugh scores, all the LC patients were classified into three groups, A, B and C. Wang *et al*<sup>[39]</sup> carried out a urinary metabonomic study on the different stages of HBV-related LC and healthy controls using a gas chromatography-mass spectrometer (GC-MS) and ultra performance liquid chromatography time-of-flight mass spectrometry. They found metabolites with a significant difference in the three groups of LC, which may be potential metabolic markers in different stages of LC, providing a basis for the estimate of progress. Differently from the other three studies, Xue *et al*<sup>[40]</sup> chose patients with CHB as a control group and found nine metabolites with an obvious difference in total. The study also further verified the distinguishing ability by SAS software, showing that five out of twenty LC patients in Child-Pugh A were misdiagnosed as patients with CHB due to the small

sample size. Zhou *et al.*<sup>[23]</sup> and Yin *et al.*<sup>[41]</sup> analyzed the metabolites in the serum of a HBV-related LC group and healthy control group by LC-MS and NMR, with both methods discovering metabolites with differences<sup>[42]</sup>. Among these five articles, only one used hepatitis B patients as a control group and the others chose healthy volunteers. In these present studies, we still lack research that uses CHB patients as a control group. The identification sensitivity of potential metabolic markers in patients with early HBV-related LC and patients with CHB found in present studies should be further discussed.

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are two diseases relevant to metabolic disorders of bile acid. Due to the insidious onset and lack of effective diagnostic methods with high specificity, patients are usually in an advanced stage when diagnosed<sup>[43]</sup>. Trottier *et al.*<sup>[44]</sup> analyzed the metabolic changes of 17 bile acids in patients with these two diseases by LC-MS. Compared to healthy volunteers, the primary bile acid in serum in the two diseases increased significantly, which may be associated with impairment of the enterohepatic circulation. Compared with PBC, the levels of secondary bile acid in the PSC group decreased obviously. It suggests that PBC is only relevant to the impairment of the extrahepatic bile duct, while PSC involves both the intrahepatic and extrahepatic bile duct. Furthermore, Bell *et al.*<sup>[45]</sup> also drew similar conclusions by LC-MS. Acute-on-chronic liver failure (ACLF) is acute liver failure resulting from the acute deterioration of liver function on the basis of CLD, which can be accompanied by multiple organ failure at the same time. Due to its yearly increasing incidence and high mortality rate, ACLF is receiving more and more attention from the medical profession<sup>[46]</sup>. Amathieu *et al.*<sup>[47,48]</sup> studied the metabonomic characteristics of LC patients with and without ACLF and detected obvious differences in the metabolic features of the two groups. Nie *et al.*<sup>[49]</sup> discovered 17 potential markers by comparing HBV-related ACLF with HBV-related LC in Child-Pugh A and 11 of them had improved survival after treatment, which has implications for the early diagnosis and prognosis assessment of ACLF. Lian *et al.*<sup>[50]</sup> researched metabolic differences in alcoholic LC and HBV-related LC by LC-MS and found that oleamide and myristamide increased significantly in patients with alcoholic LC but decreased distinctly in patients with HBV-related LC, which indicated that they both could be used as specific metabolic markers to distinguish alcoholic LC from HBV-related LC. By GC-MS and LC-MS, Fitian AI, Soga *et al.*<sup>[24]</sup> and Fitian *et al.*<sup>[51]</sup> found that some bile acids and dicarboxylic acids increased in hepatitis C virus (HCV)-related LC. Also,  $\gamma$ -glutamyl dipeptides were mentioned in both studies and there was thought to be some expressed differences in different types of hepatic diseases. Therefore, it can be used as a potential metabolic marker to differentiate various hepatic diseases. So far, metabonomics of various hepatic diseases is still in the primary stages,

lacking the metabolomic difference analysis comparing the diverse types of hepatic diseases. Therefore, the field of metabonomics of hepatic diseases needs further research.

## HCC

In China, over 80% of HCC cases resulted from chronic HBV infection, an evolutionary progress from CHB to LC and eventually to HCC<sup>[32,33]</sup>. To improve the diagnostic rate for early HCC, potential biomarkers with high specificity which can be adopted to screen the HBV-related LC need to be explored. Some metabolites which are specifically expressed in HBV-related HCC may provide a new horizon for the targeted treatment of HCC in the future.

In Table 3, 4 studies from China exploring metabonomics of HBV-related HCC are shown, complying with the regional differences of HCC. The potential metabolic markers found in these studies involve the metabolism pathways of fatty, amino and bile acids, energy and so on. Liu *et al.*<sup>[52]</sup> researched the metabolomic characteristics of liver tissue in 10 patients with liver carcinoma by LC-MS. Based on the comparison of the central area of the tumor and distant tissue, 14 metabolites were found with obvious differences and 9 of them<sup>[53-55]</sup> have also been mentioned in other studies. However, betasitosterol, quinaldic acid, arachidyl carnitine, tetradecanal and oleamide have rarely been mentioned, possibly because the levels of these 5 metabolites are too low in serum to be detected. It indicates that although metabolic profiling of tissue cannot reflect the changes of systemic metabolism in the human body, it could actually reflect the changes of metabolic characteristics of certain tissues or organs. Li *et al.*<sup>[56]</sup> compared the metabolomic characteristics of HBV infected HCC host cells HepG2.2.15 with HCC host cell HepG2 by NMR and found that 11 metabolites were obviously different. N-acetyl glucosamine kinase had a significantly increased expression in HepG2.2.15 and was involved in the hexosamine biosynthesis pathway, which demonstrated that the hexosamine biosynthesis pathway was activated in HBV infected cells, providing a new thought for studying targeted therapy for HBV infection in the future. Zhou *et al.*<sup>[23]</sup> and Yin *et al.*<sup>[41]</sup> analyzed the metabolites of HBV-related HCC and normal bodies by LC-MS and found some potential biomarkers of metabolism involved in the metabolism of fatty acid, phosphoric acid, amino acid and glucose. Both studies found that the expression of glycochenodeoxycholic acid, lysophosphatidylcholine and glycocholic acid were significantly different in patients with HCC.

Besides the infection with HBV, infection with HCV, the addition of alcohol and steatohepatitis are also important pathogenic factors in HCC. We found 3 studies regarding HCV-related HCC<sup>[51,57,58]</sup> from the United States. Compared to the research of HBV-related HCC, other body fluid samples were added, as well as serum, containing metabolomic characteristics of HCV-related HCC and LC. Bowers *et al.*<sup>[57]</sup> analyzed the metabolomic

LC-MS: Liquid chromatography-mass spectrometry; LysoPC: Lysophosphatidylcholine; LysoPE: Lysophosphatidylethanolamine; LPC: Lysophosphatidylcholine; GCA: Glycocholic acid; TCDCA: Taurochenodeoxycholic acid; GCDCA: Glycochenodeoxycholic acid; UPLC-TOFMS: Ultra-high performance liquid chromatography-time of flight-mass spectrometer; CN: C16:1-acylcarnitine; HCC: Hepatocellular carcinoma.

characteristics in serum and urine from HCV-related HCC and chronic hepatitis C patients by LC-MS. Fitian *et al.*<sup>[51]</sup> and Baniasadi *et al.*<sup>[58]</sup> also studied the diversity of serum metabolomics in patients with HCV-related HCC and LC, resulting in some potential metabolic markers with significant differences being detected. There are increasing numbers of people addicted to alcohol with the speeding pace of modern society and about 1/3 of HCC cases result from alcohol worldwide<sup>[59]</sup>. Nahon *et al.*<sup>[60]</sup> analyzed the metabolic changes of alcoholic LC and HCC by NMR and discovered that the metabolites in a group of alcoholic LC without HCC were apparently different from that of alcoholic LC with large HCC. Glutamine decreased greatly, while metabolites such as glutamate and glycoprotein increased sharply. It indicated that glutamine degradation and glycolysis might be the main metabolic pathway of energy in hepatoma cells. With the improvement of living standards and the changes in lifestyle, the incidence of non-alcoholic fatty liver disease is increasing yearly and is currently up to 30% in developed countries<sup>[61,62]</sup>. Excessive deposition of fat in the liver can cause NASH, liver fibrosis, LC and even HCC<sup>[63]</sup>. Beyoğlu *et al.*<sup>[64]</sup> specifically analyzed the research about non-alcoholic HCC in their review. Most of the research used healthy people as the control group, while a small part used patients with LC. The potential metabolic markers detected were involved in the metabolic processes of fatty acids, bile acids and so on. There are some differences between the metabolic markers found in this research and in the research on HBV-related HCC. More research is needed to find the

pathogenesis in order to provide the basis for targeted treatment of HCC of different etiologies in the future.

## PROSPECTS

Metabonomics is still in the beginning and developing stage but it has drawn wide attention from the medical community. There are some short comings in its analysis technology and data analysis methods which require further completion and improvement. At present, metabonomics is just applied to common diseases. In our review, there are some obvious metabonomic differences between HBV-related hepatic diseases and other liver diseases, which have some research value and may provide evidence for detecting specific markers and elucidating the pathogenesis of HBV-related hepatic diseases. With the continuous development of medical technology, the prospect of metabonomics is immeasurable. It is expected to develop and enhance clinical diagnosis and treatment in the future, with genomics, transcriptomics and proteomics.

## Abstract

The hepatitis C virus (HCV) infects approximately 3% of the world population or more than 185 million people worldwide. Each year, an estimated 350000-500000 deaths occur worldwide due to HCV-associated diseases including cirrhosis and hepatocellular carcinoma. HCV is the most common indication for liver transplantation in patients with cirrhosis worldwide. HCV is an enveloped RNA virus classified in the genus *Hepacivirus* in the *Flaviviridae* family. The HCV viral life cycle in a cell can be divided into six phases: (1) binding and internalization; (2) cytoplasmic release and uncoating; (3) viral polyprotein translation and processing; (4) RNA genome replication; (5) encapsidation (packaging) and assembly; and (6) virus morphogenesis (maturation) and secretion. Many host factors are involved in the HCV life cycle. Chaperones are an important group of host cytoprotective molecules that coordinate numerous cellular processes including protein folding, multimeric protein assembly, protein trafficking, and protein degradation. All phases of the viral life cycle require chaperone activity and the interaction of viral proteins with chaperones. This review will present our current knowledge and understanding of the role of chaperones in the HCV life cycle. Analysis of chaperones in HCV infection will provide further insights into viral/host interactions and potential therapeutic targets for both HCV and other viruses.

**Key words:** Hepatitis C; Hepatitis C virus; Chaperones; Heat shock proteins; Viral life cycle

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Interaction of viral proteins with host chaperones is critical for the hepatitis C viral (HCV) life cycle. Some of these chaperones, such as cyclophilins have been studied in detail recently and have led to the advent of new therapies for HCV infection with high success rates. Further investigation of the role of chaperones in the viral life cycle may allow for development of novel therapies both for HCV and related viruses.

## INTRODUCTION

The hepatitis C virus (HCV) infects approximately 3% of the world population or more than 185 million people worldwide<sup>[1,2]</sup>. While infection is less prevalent in developed countries including North America, other areas face prevalence rates as high as 3.5% or more<sup>[1]</sup>. Each year, an estimated 350000-500000 deaths occur worldwide due to HCV-associated diseases<sup>[1-3]</sup>. HCV is mainly responsible for liver transplantation in patients with cirrhosis worldwide<sup>[4-6]</sup>. Furthermore, HCV is the most common chronic bloodborne pathogen in the United States affecting 1.5% of the population and is the major etiologic factor responsible for the recent doubling of hepatocellular carcinoma<sup>[5,7-9]</sup>.

HCV is an enveloped RNA virus classified in the genus *Hepacivirus* in the *Flaviviridae* family. It possesses an approximately 9.6 kb positive-sense RNA genome that is translated as a single polypeptide approximately 3000 amino acids in length<sup>[10,11]</sup>. It is subsequently proteolytically cleaved into 10 viral proteins including the structural proteins core, E1, and E2 as well as the non-structural (NS) proteins p7, NS2, NS3, NS4A, NS4B, NS5A and NS5B<sup>[12]</sup>. Core is the viral nucleocapsid protein that encapsidates the viral genome in the virion. E1 and E2 are glycoproteins on the viral envelope that are involved in receptor-mediated viral entry. p7 is an integral membrane ion channel also called viroporin that functions to protect virions from acidification during maturation by allowing protons to flow<sup>[13]</sup>. NS2, NS3, and NS4A are the viral proteases, while NS4B is a helicase. NS5A, a 56-59 kDa multifunctional phosphoprotein, lacks any known enzymatic activity, is a component of the viral replicase complex, and has been implicated in regulation of HCV genome replication, internal ribosomal entry site (IRES)-mediated viral protein translation, and infectious virion assembly<sup>[14-18]</sup>. NS5B is the viral RNA-dependent RNA polymerase. In addition to these originally identified 10 proteins, another viral protein called the HCV F protein was observed<sup>[19,20]</sup> and later identified<sup>[21-23]</sup> to be expressed as a result of a ribosomal

frameshift near the beginning of the core protein coding sequence. The F protein has been implicated in the regulation of protein degradation, inhibition of apoptosis, and immunoregulation<sup>[24-31]</sup>.

The 5' non-coding region (NCR) of the viral genome possesses an IRES, a cis-acting element found in some host RNA transcripts as well as in viruses that allows ribosomal translation initiation to occur internally within a transcript in lieu of 5' 7-methylguanylate cap-dependent translation<sup>[12,32]</sup>. The HCV viral life cycle in a cell can be divided into six phases: (1) binding and internalization; (2) cytoplasmic release and uncoating; (3) viral polyprotein translation and processing; (4) RNA genome replication; (5) encapsidation (packaging) and assembly; and (6) virus morphogenesis (maturation) and secretion<sup>[33]</sup> (Figure 1).

The viral life cycle begins with the attachment of the enveloped virion to the cell followed by entry, which is mediated by interaction of the E1 and E2 glycoproteins in the viral membrane with a number of hepatocyte cell surface receptors and proteins which include the low-density lipoprotein receptor (LDLR), glycosaminoglycans (GAGs), CD81, scavenger receptor B1 (SR-B1), claudin 1, occludin, and the cholesterol absorption receptor Niemann-Pick C1-like 1<sup>[34]</sup>. Subsequently, the viral particle is internalized through clathrin-mediated endocytosis or an alternative clathrin-independent pathway after which, the viral and cellular membranes fuse through acidification of the endosomal compartment, and the core-encapsidated viral genome is released into the cytosol, uncoated, and subsequently translated<sup>[35,36]</sup>. The resulting polyprotein is cleaved with the help of the cellular proteases signalase and signal peptide peptidase and the viral proteases NS2-NS3 and NS3-NS4A<sup>[37]</sup>. Viral genome replication is carried out by NS5B utilizing a negative-sense viral genome intermediate<sup>[38]</sup>. New virions are assembled at the sites of cytosolic lipid droplets in the vicinity of endoplasmic reticulum (ER) membrane where core protein encapsidates the viral genome followed by budding of the nascent virion into the lumen of ER<sup>[39]</sup>. The virions follow the Golgi-dependent secretory pathway during which they undergo maturation by addition of lipid components significantly decreasing their buoyant density<sup>[40,41]</sup>. Finally the mature virions are secreted through exocytosis<sup>[42]</sup>.

In order to establish successful infection, HCV depends on numerous host factors during its entire life cycle. In addition to performing virus-specific functions such as viral genome replication and virion assembly, HCV proteins alter cellular metabolism, critical signaling pathways, and organellar morphology and function to establish persistent infection and to escape the immune responses. Accumulation of misfolded viral proteins in the ER leads to ER stress and the unfolded protein response (UPR) which is a cellular program to help restore ER protein homeostasis by shutting down cellular protein synthesis, properly folding the misfolded proteins, targeting them to ER-associated degradation (ERAD) if folding is unsuccessful, and inducing apoptosis if the

**Figure 1 A schematic of the hepatitis C virus life cycle.** The six steps of the viral life cycle are indicated in colored boxes with numbers. (1) Binding and internalization. HSC70 is part of the viral particle and may play a role in viral entry. Also HCV internalization occurs at least in part through clathrin-mediated endocytosis which involves HSC70; (2) Cytoplasmic release and uncoating. The chaperone activity of E1 and E2 may be involved in membrane fusion that releases the core-encapsulated viral genome into the cytosol; (3) Protein translation and processing. HSP70, together with the DNAJA2 member of HSP40 co-chaperones, is the main chaperone involved in IRES-mediated translation of the viral genome, while HSP90 may play some role as well. Calnexin, calreticulin, and CypA are also involved; (4) Genome replication. HSP90, some members of HSP40 co-chaperones, TRiC/CCT, FKBP38, SigR1, and some Cyps are involved in viral genome replication. Core and NS3 may play some roles in genome replication as well; (5) Packaging and assembly. HSC70, PDI, and MTTP are the principal chaperones involved in infectious virion assembly, and Cyps also play important roles; and (6) Morphogenesis and secretion. MTTP which is involved in the VLDL pathway also plays important roles in viral particle maturation and secretion. Cyps are also involved. Cyp: Cyclophilin; ER: Endoplasmic reticulum; FKBP: FK506-binding protein; HCV: Hepatitis C virus; HSC70: Heat shock cognate protein 70; HSP: Heat shock protein; MTTP: Microsomal triglyceride transfer protein; NS: Non-structural; PDI: Protein disulfide isomerase; SigR1: Sigma non-opioid intracellular receptor 1; TRiC/CCT: TCP-1 ring complex/chaperonin-containing TCP-1; VLDL: Very low-density lipoprotein.

cell cannot cope with the ER stress<sup>[43]</sup>. HCV suppresses ERAD and apoptosis thereby maintaining cells under ER stress in order to persistently produce its own proteins. However, HCV maintains a balance between ER stress and the UPR and virus production through

different mechanisms some of which are presented in this review<sup>[44-46]</sup>. Additionally, HCV replication in cells disrupts mitochondrial homeostasis leading to formation of irregular mitochondrial morphology, overproduction of reactive oxygen species (ROS), and oxidative stress<sup>[47]</sup>. Oxidative stress leads to activation of antioxidant programs to cope with the stress, and if unsuccessful, apoptosis is triggered. As is the case with ER stress, HCV not only induces oxidative stress, but also activates antioxidant programs and suppresses mitochondria-induced apoptosis<sup>[44,47,48]</sup>. Again, this leads to persistent infection and benefits virus production<sup>[44]</sup>. Thus, while HCV infection and some viral proteins may be capable of inducing apoptosis<sup>[49-51]</sup>, it is generally agreed that apoptosis is effectively suppressed during infection. A few mechanisms that HCV utilizes to suppress apoptosis are also discussed in this review.

Virus infection of hepatocytes leads to rearrangements of ER membranes to generate double-membrane vesicles (DMVs) and to a lesser extent multi-membrane vesicles that are collectively referred to as the membranous web<sup>[52]</sup>. Viral genome replication occurs within the membranous web in replication complexes (RCs). Infection by all positive-strand RNA viruses results in the formation of membranous web. It is thought that the membranous web benefits viral replication by: (1) protecting viral RNA and proteins from degradation and intracellular antiviral defense; (2) increasing the local concentration of the factors involved in RNA replication; and (3) ensuring spatial proximity of viral RNA translation, viral genome replication, and virion assembly for efficient progression through the viral life cycle<sup>[39]</sup>.

HCV also hijacks the hepatocyte very low-density lipoprotein (VLDL) pathway for the maturation and secretion of infectious viral particles<sup>[53]</sup>. Lipid secretion is reduced during infection, and maturing viral particles acquire VLDL characteristics, while secreted viral particles are bound to VLDL particles<sup>[40,54]</sup>.

An important group of host factors intimately involved in essentially all steps of the HCV life cycle are molecular chaperones. The term chaperone reflects the significant role of these cytoprotective proteins in: (1) assisting client proteins to achieve native/functional conformation that is required for their function; (2) assembling/disassembling protein subunits; (3) preventing newly synthesized proteins or assembled protein subunits from forming nonfunctional aggregates and molecular crowding; (4) transporting proteins to particular subcellular compartments which is referred to as intracellular protein trafficking; and (5) targeting proteins to degradation if attempts to (re)fold or (re)assemble are not successful<sup>[55-57]</sup>. Newly synthesized proteins are assisted to fold properly by chaperones. Under stress conditions such as heat shock or viral infection, proteins can become misfolded, and chaperones attempt to refold such proteins. If folding is not successful, the protein gets targeted for proteasome-mediated degradation.

A large number of molecular chaperones belong

to the family of heat shock proteins (HSPs) originally identified as proteins that helped refolding proteins that were denatured as a result of heat stress<sup>[58]</sup>. HSPs are a highly evolutionarily conserved family of proteins that are typically classified into four different systems based on their molecular weight: HSP70, HSP90, HSP60, and small HSPs<sup>[57]</sup>. The HSP70, HSP90, and HSP60 systems consist of the adenosine triphosphate (ATP)-dependent main chaperones that utilize their enzymatic activity to induce conformational changes in the client polypeptide by hydrolyzing ATP to adenosine diphosphate (ADP). In addition, a number of co-chaperones may assist and regulate the activity of the main chaperones. Small HSPs, on the other hand, do not possess enzymatic activity, and instead, perform their chaperone function by functioning as holdases, *i.e.*, binding to client polypeptides, preventing their aggregation, and directing them to one of the ATP-dependent HSPs.

HCV has evolved a remarkable ability to interact with numerous chaperones to coordinate the diverse molecular systems and pathways that it requires for its propagation in hepatocytes (Table 1). This review presents our current knowledge and understanding of the chaperones that are involved in the HCV life cycle. First, HSPs are presented covering all four HSP systems HSP70, HSP90, HSP60, and small HSPs. Next, a diverse group of other molecular chaperones are discussed including BAG3, FK506-binding proteins (FKBPs), p23, prefoldin, apolipoprotein J [apoJ or clusterin (CLU)], protein disulfide isomerases (PDIs), microsomal triglyceride transfer protein (MTTP), calnexin (CANX), calreticulin (CALR), "endoplasmic reticulum degradation enhancer, mannosidase alpha-like 1" (EDEM1), EDEM3, sigma non-opioid intracellular receptor 1 (SigR1), prohibitin (PHB), and cyclophilins (CyPs). Finally the chaperone activity of the HCV proteins core, E1, E2, NS3, and NS4A are described. The gene names for the chaperones are also included in parentheses.

## HSP70/HSP40 SYSTEM

The HSP70 family of chaperones consists of a large number of proteins that are ubiquitously expressed throughout the cell. They play important roles in proper protein folding, protection of proteins from stress-induced damage, recovery/renaturing of damaged/aggregated proteins, protein degradation, protein translocation, and disassembly of protein complexes such as the DNA replication machinery<sup>[59,60]</sup>. This family of HSPs typically functions as a group of three proteins where the main HSP70 chaperone interacts with the client polypeptide through its substrate-binding domain (SBD), while the nucleotide-binding domain (NBD) binds to an ATP hydrolyzing it to ADP to induce conformational changes in SBD for its chaperone function. The hydrolysis is stimulated by substrate binding the chaperone resulting in a closed state where it tightly binds the substrate and helps with (re)folding it. Cofactor HSPs also known as co-chaperones, such as HSP40, typically interact with the

NBD to modulate chaperone activity and to determine the clients of HSP70s *via* their specificity in binding particular target proteins. A nucleotide exchange factor (NEF) assists with the removal of hydrolyzed ADP which causes the chaperone to revert to its open conformation releasing the substrate.

### HSP70 (HSPA1A)

HSP70 is an inducible chaperone that is expressed in conditions of stress such as heat shock and viral infection. HSP70 has been identified as one of the numerous host factors important for HCV production<sup>[61-64]</sup>. Knockdown of HSP70 led to decreased virus production<sup>[61,63]</sup> or replication in subgenomic replicon (SGR) systems<sup>[62,63]</sup>. Both HSP70 overexpression and autoantibodies against HSP70 in the sera of HCV-infected patients have also been reported<sup>[65]</sup>. Huh7 cells harboring an HCV SGR demonstrated upregulation of HSP70<sup>[66]</sup>. It was also found that expression of NS5A alone in huh7 cells was sufficient for upregulation of HSP70<sup>[67]</sup>. This upregulation was the result of NS5A-induced increased levels of nuclear factor of activated T cells 5 (NFAT5), one of the transcription factors responsible for HSP70 expression. The increased NFAT5 levels itself is mediated by NS5A-driven ROS production.

Our laboratory has shown NS5A to colocalize with HSP70 and HSP40 as well<sup>[63]</sup>. We further showed that knockdown of HSP70 inhibited NS5A-augmented IRES-mediated translation. The HSP synthesis inhibitor quercetin, a bioflavonoid, also suppressed the NS5A-augmented IRES-mediated translation<sup>[63,68]</sup>. In addition, we demonstrated that the NS5A/HSP70 interaction is direct and identified the site of NS5A/HSP70 interaction on NS5A to be a hairpin moiety at the C terminus of NS5A domain I<sup>[17]</sup>. Treatment of cells with a synthetic peptide corresponding to this hairpin moiety, which we termed the HSP-binding domain<sup>[69]</sup>, disrupted the NS5A/HSP70 interaction and suppressed NS5A-augmented IRES-mediated translation and virus production<sup>[17]</sup>. Others have shown that overexpression of HSP70 leads to increased viral RNA and protein levels, while knockdown of HSP70 has the opposite effect<sup>[64]</sup>. HSP70 was found to interact with NS3-NS4A protein and NS5B as well. HSP70 increases RC formation by interacting with viral proteins in RCs, increasing the stability of viral proteins, and enhancing NS5A-driven viral IRES-mediated translation. Further, HSP70 was found to interact with the 3' NCR of the viral genome<sup>[70]</sup>.

### Heat shock cognate protein 70 (HSPA8)

Heat shock cognate protein 70 (HSC70) is a constitutively-expressed housekeeping gene with diverse cellular functions including protein folding, signal transduction, apoptosis, autophagy, and many others<sup>[71]</sup>. Viral entry occurs at least in part through the HSC70-dependent clathrin-mediated endocytosis<sup>[35]</sup>. HSC70 activity was found to be significantly increased in an HCV SGR system<sup>[72]</sup>, and HSC70 levels were increased in a proteomic analysis of RCs<sup>[73]</sup>. HSC70 was also identified

**Table 1** Chaperones and their roles in the hepatitis C virus viral life cycle

Chaperone	Subcellular localization	Function in HCV infection/stage of viral life cycle
HSP70 family		
GRP75 (HSPA9)	Mitochondrial	Varied expression/activity <sup>[66,72]</sup> Interacts with NS5A <sup>[105]</sup>
GRP78 (HSPA5)	ER	Regulation of viral protein homeostasis and maintaining a balance between viral and cellular translation to prevent viral protein overload (involves induction of ER stress and the UPR) <sup>[43,85-96]</sup> Increased expression and activity <sup>[72,85,88,93,95]</sup>

Apo: Apolipoprotein; BAG: BCL2-associated athanogene; Cyp: Cyclophilin; EDEM: Endoplasmic reticulum degradation enhancer, mannosidase alpha-like; ER: Endoplasmic reticulum; ERAD: ER-associated degradation; FKBP: FK506-binding protein; GRP: Glucose-regulated protein; GW: Glycine-tryptophan; HCV: Hepatitis C virus; Hip: HSP70-interacting protein; HSC70: Heat shock cognate protein 70; HSP: Heat shock protein; IFN $\beta$ : Interferon beta; IRES: Internal ribosomal entry site; LDLR: Low-density lipoprotein receptor; MTTP: Microsomal triglyceride transfer protein; NCR: Non-coding region; NS: Non-structural; ROS: Reactive oxygen species; PDI: Protein disulfide isomerase; RC: Replication complex; SigR1: Sigma non-opioid intracellular receptor 1; TRiC/CCT: TCP-1 ring complex/chaperonin-containing TCP-1; UPR: Unfolded protein response; VLDL: Very low-density lipoprotein.

to be part of the HCV viral particles, and the viral E2 protein was found to contain the HSC70-interacting histidine-proline-aspartic acid (HPD) motif<sup>[74]</sup> which is required for the interaction of the HSP40 co-chaperones with HSP70 family of chaperones<sup>[75]</sup>. Pretreatment of the virus with HSC70 antibody significantly diminished infectivity suggesting that HSC70 is a part of the viral particle<sup>[74]</sup>. In addition, HSC70, core, and E2 were found to colocalize around lipid droplets, the site of virion assembly. RNAi-mediated knockdown of HSC70 significantly decreased the volume of lipid droplets and viral secretion, but not viral RNA replication levels. These results suggest that HSC70 plays an important role during virion assembly and may play a structural role for the virion as well. It has been observed that HSC70 associates with positive-strand subgenomic viral RNA (corresponding to domains III and IV of the 5' NCR and 36 nucleotides of core) and the 3' NCR of the viral genome as well<sup>[70,76]</sup>.

A number of compounds including IMB-DM122, N-substituted benzyl matrinic acid derivatives, and (+)-lycoridine were shown to downregulate HSC70 mRNA expression leading to decreased virus production<sup>[77-79]</sup>. Our lab demonstrated that HSC70 directly binds to NS5A *in vitro* and colocalizes with NS5A in infected cells<sup>[18]</sup>. We further showed that knockdown of HSC70 significantly impacted intracellular infectious virion assembly thereby establishing distinct functions of HSC70 and HSP70 in the HCV life cycle. This is further supported by the fact that HSC70 and HSP70 do not interact with each other. Based on the available evidence, therefore, it seems that HSC70 is important for virion assembly.

### HSP70B' (HSPA6)

HSP70B' is another member of the HSP70 family which is highly similar to HSPA1A in terms of sequence homology (82%) and function<sup>[80]</sup>. Both chaperones are stress inducible and work in conjunction to protect cells from stress. However, HSP70B' is the secondary responder to stress after HSPA1A, and proteasome inhibition is a potent inducer of HSP70B' expression<sup>[81]</sup>. HSP70B' was found to be associated with the 3' NCR of the HCV genome<sup>[70]</sup>.

### Glucose-regulated protein 78 (HSPA5)

Glucose-regulated protein 78 (GRP78), also known as

the binding immunoglobulin protein (BiP), is another member of the HSP70 family and is the major molecular chaperone in the ER<sup>[82]</sup>. The ER is involved in vital cellular processes including protein folding, protein transport, the UPR, and calcium homeostasis. The UPR is an adaptive signaling program that is activated in response to accumulation of unfolded or misfolded proteins in the ER, referred to as ER stress. Proteins that are not successfully folded are either sent for refolding or tagged for degradation through the ERAD pathway<sup>[83]</sup>. If the UPR program is unable to successfully relieve cells from ER stress, it initiates mitochondria-mediated apoptosis<sup>[84]</sup>. Under certain conditions such as heat stress and pathogen infection, unfolded or misfolded proteins can accumulate in the ER leading to ER stress and activation of UPR. Stimulation of GRP78 transcription is an indication of ER stress and induction of UPR, which occurs in HCV infection likely to repress cellular protein translation in order to utilize cellular resources for the IRES-mediated translation of viral proteins and to suppress innate immunity in order to establish persistent infection<sup>[43,85-96]</sup>. GRP78 activity was also found to be significantly increased in an HCV SGR system<sup>[72]</sup>.

UPR signaling can be initiated by three factors: Activating transcription factor 6 (ATF6), inositol-requiring enzyme 1 (IRE1), and double-stranded RNA-activated protein kinase R-like ER kinase (PERK)<sup>[43,92]</sup>. These three factors act as ER stress sensors and lead to induction of expression of GRP78, which is itself a negative regulator of the three ER stress sensors. ER stress may lead to the proteolytic cleavage of ATF6, an ER membrane-associated transmembrane protein. The 90 kDa ATF6 precursor, also known as pATF6 $\alpha$ (P), is cleaved to form an approximately 50 kDa N-terminal fragment pATF6 $\alpha$ (N) which translocates to the nucleus and activates transcription of ER chaperone genes such as GRP78 involved in the UPR. ER stress also leads to phosphorylation of IRE1 which results in the splicing of unspliced X-box-binding protein 1 to spliced XPB1 (sXBP1), a transcription factor that can induce expression of GRP78 and other genes involved in the UPR. Upon initiation of ER stress, PERK can also get activated and phosphorylate the eukaryotic initiation factor 2 alpha (eIF2 $\alpha$ ). Phosphorylated eIF2 $\alpha$  (peIF2 $\alpha$ ) results in global inhibition of cellular protein synthesis and enhanced ATF4 expression which leads to induction of UPR genes. HCV can activate all three ER stress

sensors.

It was found that the viral glycoprotein E2, and not E1, can induce transcription of GRP78 and that only E2 bound to GRP78<sup>[97]</sup>. Another group reported that both E1 and E2 bind GRP78<sup>[98]</sup>. However, it seems that GRP78 tends to bind to E1/E2 aggregates rather than monomeric glycoproteins. Expression of both E1 and E2 was also shown to lead to the UPR<sup>[99,100]</sup>. The HCV core protein has also been reported to induce expression of GRP78<sup>[101]</sup>. Induction of core, E1, E2, and p7 in mice liver led to ER stress and overexpression of GRP78<sup>[95]</sup>. Expression of HCV NS genes led to upregulation of GRP78<sup>[102]</sup>. The NS2 alone also induces ER stress and leads to upregulation of GRP78 protein levels<sup>[46]</sup>. NS4B alone can also induce ER stress and the UPR and upregulate GRP78 expression<sup>[87,103]</sup>. NS5A weakly binds GRP78, enhances GRP78 expression, and protects hepatocytes from ER stress-induced apoptosis leading to persistent infection<sup>[104,105]</sup>. It was also shown that HCV bearing certain mutations in NS5A and NS5B proteins (C2441S, P2938S or R2985P) displayed higher levels of GRP78 expression<sup>[94]</sup>. However, it was not clear whether NS5A alone can induce ER stress in these studies. Another group reported that NS5A does not lead to ER stress and the UPR<sup>[89,106]</sup>. An SGR system expressing all the NS proteins led to the UPR as well<sup>[106]</sup>. Thus, it is not clear whether the NS5 proteins alone can cause ER stress and the UPR. GRP78 was also shown to benefit virus production in a genome-wide expression analysis of multiple huh7-derived cell lines where interactions with core, E1, E2, p7, NS3, NS4B and NS5A were implicated<sup>[107]</sup>. Furthermore, GRP78 is a target of miR-30a, miR-30c, and miR-30e that were found to be downregulated in acute HCV infection potentially leading to GRP78 overexpression<sup>[108]</sup>.

In addition to the ER-targeted E1 and E2 proteins, cytosol-targeted E1 and E2 proteins have also been described with opposing functions in the context of ER stress<sup>[109-112]</sup>. In the cytosol, E1 binds to the cytoplasmic domain of PERK. Furthermore, cytosolic E1 leads to downregulation of GRP78. Similarly, E2 binds to PERK as well, inhibits its kinase activity, reverses PERK-mediated global translation repression, and confers resistance to ER stress. In addition, NS2 leads to phosphorylation of eIF2 $\alpha$  and decreased protein synthesis as well as reduction of IRES-mediated translation suggesting that NS2 can also provide a negative feedback regulation of ER stress by decreasing viral protein translation that is responsible for inducing ER stress<sup>[46]</sup>.

Thus, it seems that GRP78, as well as other ER-resident chaperones, play an important role in regulating and maintaining viral protein homeostasis to ensure the availability of sufficient viral proteins to establish a persistent infection while minimizing cellular protein expression and preventing viral protein overload. GRP78 was also found to be associated with positive-strand subgenomic viral RNA (corresponding to domains III and IV of the 5' NCR and 36 nucleotides of core) and the 3' NCR of the viral genome<sup>[70,76]</sup>.

A recent study reported that there was no significant difference in the mRNA levels of GRP74 and a number of other genes involved in ER stress and UPR between infected patients and healthy controls<sup>[113]</sup>. No difference in GRP78 protein levels were observed either. This may be attributed to the fact that typically HCV infects a small percentage of hepatocytes, and therefore, changes may not be detected.

### GRP75 (HSPA9)

GRP75 also known as mtHSP70 or mortalin is the mitochondria-resident HSP70 family member. It plays a number of critical roles in the cells including anti-apoptosis, protein transport into mitochondria which may involve HSP60 as well, protection of cells from ROS, and mitochondrial biogenesis<sup>[114]</sup>. It has also been implicated in membrane trafficking and human immunodeficiency virus (HIV) virion release<sup>[115]</sup>. In the context of HCV, it has been reported that GRP75 activity was significantly increased in one HCV SGR system<sup>[72]</sup>, while GRP75 protein was significantly downregulated in another SGR system<sup>[66]</sup>. These different results may reflect the HCV-mediated modulation of GRP75 activity/expression to accommodate its needs during the viral life cycle. Furthermore, NS5A was shown to co-immunoprecipitate with GRP75<sup>[105]</sup>.

### HSP40 family

The HSP40 family are co-chaperones of HSP70 proteins that regulate the activity of HSP70s and determine their client range by binding specific target proteins<sup>[60,116]</sup>. This large family of proteins are homologous with the bacterial DnaJ chaperone, and the term DNAJ is utilized in the gene nomenclature of the isoforms of this family. DNAJA1 and DNAJA2 are the most abundant cytosolic HSP40 co-chaperones<sup>[116]</sup>. DNAJA1 was reported to co-immunoprecipitate with the NS3-NS4A protein<sup>[105]</sup>. We have shown that DNAJA2 participates together with HSP70 in regulating the NS5A-augmented IRES-mediated translation of the viral genome<sup>[63]</sup>. The interaction of viral proteins with these co-chaperones may, therefore, modulate chaperone activity to benefit the viral life cycle. A genome-wide siRNA screening identified DNAJB1 to be important for HCV production<sup>[61]</sup>. DNAJB1 plays important roles in regulating apoptosis and cell proliferation<sup>[117]</sup>. DNAJC7 co-immunoprecipitates with NS3-NS4A protein<sup>[105]</sup>. DNAJC7 also regulates apoptosis by binding to the pro-apoptotic p53 protein and increasing its activity and stability<sup>[118]</sup>. Thus, it can be speculated that binding of NS3-NS4A may prevent the pro-apoptotic function of DNAJC7/p53 thereby suppressing apoptosis and contributing to persistent HCV infection. DNAJC8 was reported to be upregulated in quantitative reverse transcriptase polymerase chain reaction (qRT-PCR) as well as microarray analyses of host gene expression in infected huh7 cells<sup>[119]</sup>. DNAJC8 has been shown to play an important role in regulating pre-mRNA splicing by the spliceosome<sup>[120]</sup>. This is achieved by the binding of DNAJC8 with "serine/arginine-rich splicing

factor protein kinase 1". DNAJB6 interacts with NS5B, and shRNA-mediated knockdown of DNAJB6 led to a significant decrease in viral RNA replication<sup>[105]</sup>. DNAJB6 may, therefore, be required for the stability or activity of NS5B for viral RNA replication. In addition, miR-17, miR-106a, and miR-106b with DNAJB6 as their target were found to be downregulated in acute HCV infection<sup>[108]</sup>.

There are seven ER-resident HSP40 co-chaperones: DNAJB9, DNAJB11, DNAJC1, DNAJC3, DNAJC10, DNAJC23 and DNAJC25. DNAJC14 was found as a host factor involved in HCV replication in an siRNA screen where knockdown of DNAJC14 led to increased viral replication<sup>[62]</sup>. Further, DNAJC14 has been reported to be involved in RNA replication of yellow fever virus (YFV) and other flaviviruses including HCV<sup>[121]</sup> and has been shown to be important for RC assembly in YFV<sup>[122]</sup>. Overexpression of DNAJC14 blocked viral RNA replication in all flaviviruses tested including HCV, while NS2/3 cleavage was not inhibited. siRNA-mediated knockdown of DNAJC14 also demonstrated similar results indicating that both elevated and reduced levels of DNAJC14 interferes with viral RNA replication. Also DNAJC14 is recruited to YFV RCs consistent with the normal cellular function of DNAJC14 as an ER-localized co-chaperone involved in protein transport<sup>[121,123]</sup>. DNAJB9 was identified in a microarray analysis as one of the host genes with most consistently modified expression as a result of acute HCV infection<sup>[108]</sup>. Further, miR-17, miR-106a, and miR-106b that target DNAJB9 were found to be downregulated. DNAJB9 has been shown to be involved in regulation of apoptosis<sup>[124]</sup>. DNAJC10 expression was found to be increased in HeLa cells expressing HCV polyprotein<sup>[125]</sup>. DNAJC10 is also a member of the PDI family of chaperones (discussed below) which is responsible for removing non-native disulfide bonds in conjunction with BiP and targeting misfolded proteins for degradation<sup>[126]</sup>. Interaction of DNAJC10 with EDEM1, an ER chaperone (discussed below), is required for disulfide bond reduction. Interestingly, DNAJC10 is also required for the correct folding of LDLR, one of the cell surface receptors utilized by HCV for entry. DNAJC1 was identified as an antiviral protein in a genome-wide expression analysis of multiple huh7-derived cell lines where interactions with E1 and E2 were implicated<sup>[107]</sup>.

Five members of the HSP40 family have been identified in mitochondria: DNAJA3, DNAJC11, DNAJC15, DNAJC19, and DNAJC20. DNAJA3 was identified as an HCV-interacting protein<sup>[61]</sup>. DNAJA3 is normally involved in maintaining mitochondrial morphology, and altering DNAJA3 levels leads to mitochondrial fragmentation and reduced cell viability<sup>[127]</sup>. HCV infection leads to mitochondrial dysfunction, and DNAJA3 may play a role in this process.

### NEFs

NEFs play an important role in normal chaperone functioning by facilitating replacement of the hydrolyzed ADP with an ATP<sup>[128]</sup>. Three families of NEFs have been identified for the HSP70 chaperones: (1) HSP110/

GRP170; (2) HSP70-interacting protein (Hip) (HSPBP1)/BiP-associated protein (SIL1); and (3) the BCL2-associated athanogene (BAG) family of proteins. The HSP110/GRP170 family consists of three cytosolic members HSP105 (HSPH1), HSP70RY (Apg-2) (HSPA4), and OSP94 (Apg-1) (HSPA4L), and one mitochondrial member GRP170 (HYOU1).

It was found that HSP105 and HSP70RY expression levels increase in HCV SGR systems<sup>[66,129,130]</sup>. Also knockdown of HSP70RY in an SGR system decreased viral RNA replication levels<sup>[130]</sup>. This is expected as the levels and activity of HSP70 family members increase during HCV infection which may require more NEFs for their function. Furthermore, HSP110 levels increase in stressed cells likely to assist in coping with stress, and in the context of HCV infection, increased HSP110 levels may help cells with HCV-induced ER stress. Similar effects of overexpression of HSP110 has been reported in cancer and gastric ulcer where targeting HSP110 had beneficial effects<sup>[131-133]</sup>. In siRNA screens, it was found that knockdown of Hip led to a significant decrease in virus production levels<sup>[62,134]</sup>. The role of BAG3 in HCV infection is discussed below.

## HSP90 SYSTEM

The HSP90 proteins are highly conserved evolutionarily and are involved in the folding of proteins especially those involved in signal transduction<sup>[135]</sup>. Thus, HSP90 possesses a more discrete range of clients compared with the HSP70 system. Like HSP70, HSP90 also undergoes conformational changes to assist with the folding of client proteins, a process which is driven by ATP hydrolysis, and co-chaperones also assist in regulating HSP90 function. HSP90 has been shown to be important for a large group of viruses including HCV<sup>[136]</sup>. The HSP90 family consists of the inducible cytosolic isoform HSP90 $\alpha$  (HSP90AA1), the constitutively expressed cytosolic isoform HSP90 $\beta$  (HSP90AB1), the inducible ER isoform GRP94 (HSP90B1), and the mitochondrial isoform "tumor necrosis factor (TNF) receptor-associated protein 1" (TRAP1) (HSP90L).

### HSP90 (HSP90AA1 and/or HSP90AB1)

HSP90 has been shown to be important for virus production<sup>[137]</sup>. siRNA-mediated knockdown of HSP90 as well as HSP90 inhibitors geldanamycin, "17-dimethylaminoethylamino-17-demethoxygeldanamycin" (17-DMAG), herbimycin A, and radicicol resulted in dose-dependent suppression of HCV in a replicon system<sup>[138]</sup>. Further, viral levels in chimeric mice with a humanized liver treated with 17-DMAG were significantly reduced. Other derivatives of geldanamycin as HSP90 inhibitors have also been reported to block HCV RNA replication<sup>[139]</sup>.

HSP90 is required for the maturation of the viral polyprotein complex specially to generate functional NS2/3 protease<sup>[140]</sup>. HSP90 inhibitors were shown to block NS2/3 cleavage. Expression of HCV core in *Saccharomyces cerevisiae* impaired the growth of yeast cells, and it was found that HSC82, the yeast homolog

of HSP90, is required for the stability of core protein<sup>[141]</sup>. Treatment of yeast cells with the HSP90 inhibitors geldanamycin, radicicol, herbimycin A, and herbimycin C suppressed core-induced growth impairment. HSP90 directly binds to NS3 through the NS3 helicase region and is required for NS3 stabilization<sup>[142,143]</sup>. In an SGR system, the HSP90 inhibitor “17-N-allylamino-17-demethoxygeldanamycin” (17-AAG) resulted in NS3 degradation specifically<sup>[142]</sup>. In the same SGR system, 17-AAG also suppressed HCV RNA replication in a dose-dependent manner. However, it was not clear if replication was affected directly or through decreased IRES translation. A subsequent study demonstrated the indirect interaction of HSP90 with the subunit C of eIF3c which involves and is dependent on the viral IRES RNA<sup>[144]</sup>. This interaction prevents the ubiquitination and the subsequent proteasome-dependent degradation of eIF3c which is required for IRES-mediated translation of the viral genome. Therefore, treatment with HSP90 inhibitors may prevent the chaperoning of eIF3c by HSP90 which leads to its degradation. Knockdown of eIF3c inhibited IRES-mediated translation, but not cellular 5' 7-methylguanylate cap-dependent translation.

HSP90 was found to colocalize and co-immunoprecipitate with glycine-tryptophan (GW) 182, an important component of GW bodies which are involved in mRNA degradation and translational repression *via* miRNAs<sup>[145]</sup>. Both HSP90 and GW182 also colocalized with NS3, core, and NS5A. Knockdown of GW182 significantly decreased HCV RNA levels in infected cells, while overexpression of GW182 resulted in a significant increase in viral RNA levels. The HSP90 inhibitor 17-DMAG and knockdown of HSP90 significantly decreased GW182 and miR-122 levels leading to decreased HCV RNA levels. Ethanol was shown to upregulate both GW182 and HSP90 thereby facilitating HCV RNA replication. Interestingly, the same group discovered infectious exosomes from sera of HCV-infected patients or supernatants of infected huh7.5 cells that contained negative-strand viral RNA in association with Argonaute 2 [a component of the RNA-induced silencing complex (RISC)], HSP90, and miR-122<sup>[146]</sup>. These exosomes are capable of transmitting HCV infection in a CD81, SR-B1, and apolipoprotein E (apoE) receptor-independent manner, which was blocked by miR-122 and HSP90 inhibitors. An interaction between NS5A and HSP90 was also implicated in a genome-wide expression analysis of multiple huh7-derived cell lines<sup>[107]</sup>. Thus, viral proteins may modulate GW182 activity in an HSP90-dependent manner in order to regulate viral RNA replication and miRNA levels. A number of miRNAs have been shown to be modulated by HCV infection<sup>[108]</sup>.

Treatment with the HSP90 inhibitor 17-DMAG was shown to destabilize phosphoinositide-dependent kinase 1 (PDK1), an upstream kinase of protein kinase C-related kinase 2 (PRK2)<sup>[147]</sup>. The PDK1-PRK2 signaling pathway leads to phosphorylation of NS5B, which is required for HCV RNA replication<sup>[148,149]</sup>. 17-DMAG-driven destabilization and degradation of PDK1 diminished NS5B

phosphorylation levels leading to suppression of viral RNA replication<sup>[147]</sup>. An interaction between NS5B and HSP90 has also been reported in a yeast two-hybrid system<sup>[143]</sup>. NS5B co-immunoprecipitates with both isoforms of HSP90 as well<sup>[105]</sup>.

Peripheral B cells have been proposed to serve as reservoirs for persistent HCV infection<sup>[150,151]</sup>. It was found that peripheral B cells in patients with chronic HCV infection circumvent the interferon beta (IFN $\beta$ )-mediated antiviral response in part by downregulating HSP90 which acts as a stabilizer of TANK-binding kinase 1 involved in phosphorylation of the interferon-regulatory factor 3 (IRF3) transcription factor that induces IFN expression<sup>[151]</sup>. Thus, by using this HSP90-mediated strategy, HCV in B cells evades detection by the immune system contributing to recurring infection even after liver transplant.

The constitutively expressed isoform of HSP90, HSP90AB1, was found to be significantly overexpressed in the mononuclear cells of HCV-infected patients<sup>[152]</sup>. Co-infection with HIV decreased the overexpression of HSP90AB1 in the same study. HSP90AB1 was also reproducibly enriched in the detergent-resistant membrane fraction of an SGR system<sup>[130]</sup>.

HSP90 also plays an important role in HCV RNA replication in conjunction with FKBP38, a co-chaperone of HSP90 family, which is a member of the immunophilin family of proteins. The role of FKBP38 and its interaction with HSP90 is discussed in detail in the FKBP38 section below. Another HSP90 co-chaperone p23 is also involved in the HCV life cycle and is discussed below as well.

### GRP94 (HSP90B1)

GRP94 is the ER-resident HSP90 isoform which is involved in folding of secreted proteins, ER stress, and the UPR<sup>[153]</sup>. It was found that the viral glycoprotein E2, and not E1, can lead to the ER stress response and induce transcription of GRP94<sup>[97]</sup>. This leads to activation of nuclear factor kappa B and induction of anti-apoptotic proteins<sup>[50]</sup>. In addition, knockdown of GRP94 abolished the anti-apoptotic activity of E2 suggesting that E2 inhibits apoptosis induced by HCV infection and leads to persistent viral infection in hepatocytes. The HCV core protein also contributes to ER stress by inducing the expression of GRP94<sup>[101]</sup>. Increased expression of GRP94 was also observed in the liver of mice conditionally expressing HCV structural proteins core, E1, E2 and p7<sup>[95]</sup>. No binding of GRP94 to either E1 or E2 glycoproteins was observed<sup>[98]</sup>. GRP94 was reproducibly enriched in the detergent-resistant membrane fraction of SGR cells<sup>[130]</sup>. HCV utilizes GRP94 as well as other ER-resident chaperones especially GRP78 to maintain viral protein homeostasis in the ER in order to establish persistent infection and suppress cellular protein translation. GRP94 was also shown to be beneficial for virus production in a genome-wide expression analysis of multiple huh7-derived cell lines where interactions with core, E2, NS3, and NS4B were implicated<sup>[107]</sup>. Knockdown of GRP94 in an SGR system led to a significant decrease

in viral RNA replication levels as well<sup>[130]</sup>.

GRP94 is prevented from translocating to the cell surface by "aminoacyl tRNA synthetase complex-interacting multifunctional protein 1" (AIMp1)/p43<sup>[154]</sup>, which is a cofactor of aminoacyl tRNA synthetase complex and is involved in regulating transforming growth factor beta (TGF- $\beta$ ) signaling. Translocation of GRP94 to the cell surface leads to activation of dendritic cells and leads to autoimmune diseases. The HCV E2 protein has been reported to directly bind AIMp1/p43 and lead to its degradation through ubiquitination and the proteasome pathway<sup>[155]</sup>. In addition, E2 interferes with the AIMp1/p43-GRP78 interaction leading to lower cellular AIMp1/p43 levels. Decreased AIMp1/p43 levels in cells leads to elevated TGF- $\beta$  signaling and cell surface expression of GRP94. Therefore, these mechanisms may be responsible for HCV-induced liver fibrosis and autoimmune diseases.

## HSP60 SYSTEM

HSP60 chaperones also known as chaperonins are an important family of HSPs involved in protein folding and macromolecular assembly<sup>[156]</sup>. The HSP60 family consists of mitochondrial and cytosolic proteins. The mitochondrial HSP60 (encoded by *HSPD1* and *HSPE1* genes), also known as mtHSP60, is thought to have originated in the bacterial ancestors that were engulfed by early eukaryotic cells giving rise to the mitochondrial organelle. HSPD1 (the homolog of bacterial GroEL) forms tetradecamers, composed of two stacked heptameric rings with a central cavity that accommodates the target protein. HSPE1 (the homolog of bacterial GroES) forms one heptameric ring that serves as a cap for the HSPD1 structure. The HSPD1/HSPE1 complex functions in protein folding in an ATP-dependent manner. The eukaryotic/cytosolic chaperonin, also known as "TCP-1 ring complex/chaperonin-containing TCP-1" (TRiC/CCT), is homologous to the Archean thermosome complexes forming hexadecamers consisting of two octameric rings to assist in oligomeric protein assembly<sup>[157]</sup> and folding of approximately 10% of the proteome<sup>[158]</sup>. TRiC/CCT is composed of eight paralogous subunits encoded by *TCP1* and *CCT2-8* genes. The TRiC/CCT complex lacks a GroES-like homolog and instead uses a built-in cap system. Typically, the term HSP60 is used to refer to the mitochondrial chaperonin, whereas the eukaryotic cytosolic homolog is referred to as TRiC/CCT.

### HSP60 (HSPD1/HSPE1)

Proteomic analyses of huh7 cells harboring an HCV SGR demonstrated downregulation of HSP60<sup>[66]</sup>, while it was shown to be reproducibly enriched in the detergent-resistant membrane fraction of another SGR system<sup>[130]</sup>. However, these studies did not validate HSP60 levels by Western analysis or in the context of viral infection. HSP60 has been shown to interact with core<sup>[107,159]</sup>. This interaction led to production of ROS and sensitization of cells to TNF $\alpha$ -induced apoptosis<sup>[159]</sup>.

Further, overexpression of HSP60 decreased ROS production and prevented apoptosis in core-expressing cells. Thus, binding of core to HSP60 seems to impair the function of HSP60 in regulating ROS production and apoptosis as a possible pro-oncogenic process. However, significant research is still required to elucidate the function of the HSP60 system in the context of HCV infection. Nevertheless, HSP60 has been shown to be important for Dengue virus production (also a positive-stranded RNA virus) although the exact function has not been elucidated<sup>[160]</sup>. Further, HSP60 is overexpressed in HBV and HIV infection<sup>[156,161]</sup>. Autoantibodies against HSP60 have been detected in sera of chronic HCV infected patients<sup>[162]</sup>. HSP60 has also been shown to co-immunoprecipitate with the NS3-NS4A protein<sup>[105]</sup> and associate with positive-strand subgenomic viral RNA (corresponding to domains III and IV of the 5' NCR and 36 nucleotides of core)<sup>[76]</sup>.

### TRiC/CCT (TCP1/CCT2-8)

The activity of TRiC/CCT, the cytosolic chaperonin, was reported to be increased in an SGR system<sup>[129]</sup>. Also TCP1, CCT2, and CCT5 were reproducibly enriched in the detergent-resistant membrane fraction of an SGR system<sup>[130]</sup>. TRiC/CCT also plays an important role in the assembly of RCs which mediate HCV RNA replication<sup>[73]</sup>. This may be facilitated by an interaction between the subunit CCT5 of TRiC/CCT and NS5B. siRNA-mediated knockdown of CCT5 suppressed viral RNA replication. Treatment with an antibody against CCT5 also suppressed HCV RNA synthesis in an *in vitro* cell-free assay. These observations suggest that NS5B may recruit TRiC/CCT to the RCs to assemble components of RCs in order to facilitate HCV RNA replication. It was also reported that that CCT4 can co-immunoprecipitate with the NS3-NS4A protein<sup>[105]</sup>. CCT4 activity was decreased in an SGR system<sup>[129]</sup>.

TRiC/CCT is regulated by a number of co-chaperones including prefoldin. The role of prefoldin in the HCV life cycle is discussed below.

## SMALL HSPS

Small HSPs constitute a family of ten proteins with molecular mass in the range of 12-43 kDa with diverse functions including protein folding, development, and eye lens tissue formation to name a few<sup>[163]</sup>. They lack enzymatic activity and work as holdases in conjunction with the ATP-dependent chaperones to carry out their functions<sup>[57]</sup>.

### HSP27 (HSPB1)

Proteomic analyses of huh7 cells harboring an HCV SGR have demonstrated upregulation of HSP27<sup>[66]</sup>. HSP27 was found to bind NS5A (and not NS5B) in co-immunoprecipitation studies and colocalize by immunofluorescence under heat shock conditions<sup>[164]</sup>. The N-terminal regions of both proteins were found to be involved in the interaction (amino acids 1-122 of

HSP27 and 1-181 of NS5A). While the function of this interaction is not known, it has been speculated that it may decrease infection-induced apoptosis. This is likely as HCV is known to modulate apoptosis in order to establish persistent infection. In fact, HSP27 is overexpressed and has anti-apoptotic roles in several cancers as well<sup>[165]</sup>.

### **HSP22 (HSPB8)**

HSP22 is a multifunctional chaperone involved in regulation of protein folding, macroautophagy, carcinogenesis, and apoptosis<sup>[166]</sup>. HSP22 was reported to be significantly overexpressed in infected huh7 cells as determined by qRT-PCR as well as microarray analyses of host gene expression<sup>[119]</sup>. HSP22 is an anti-apoptotic protein, and its upregulation by HCV may be one of the mechanisms that HCV utilizes to block apoptosis in hepatocytes.

## **OTHER CHAPERONES**

In addition to HSPs, cells possess a number of other molecular chaperones and co-chaperones that play critical roles in numerous cellular functions by assisting with protein folding and stability in their respective pathways.

### **BAG3 (BAG3)**

BAG3 is one of the BAG family of proteins and serves as a NEF for the HSP70 family of chaperones. BAG3 is the only heat stress-inducible BAG isoform and plays important roles in cell proliferation, apoptosis, adhesion, and migration<sup>[167]</sup>. It acts as an anti-apoptotic protein in different cancers. In the context of HCV infection, it was found that overexpression of NS5A in HepG2 cells upregulated a number of anti-apoptotic genes including BAG3 when the cells were treated with thapsigargin, an inducer of ER stress<sup>[104]</sup>. GRP78 was also overexpressed.

### **FKBP38 (FKBP8) and FKBP54 (FKBP5)**

FKBP38 is a co-chaperone of the HSP90 family and a member of the immunophilin family of chaperone proteins which possess peptidylprolyl isomerase (PPIase) activity and also serve as receptors for the immunosuppressive drug FK506<sup>[168]</sup>. FKBP38 was identified as an NS5A interacting protein in a fetal liver cDNA library screen, and both NS5A and FKBP38 colocalize to mitochondria and the ER<sup>[169]</sup>. NS5A and FKBP38 were also shown to co-immunoprecipitate<sup>[105]</sup>. FKBP38 interacts with HSP90 and plays an important role in HCV RNA replication. FKBP38 forms a complex with HSP90 and NS5A where FKBP38 binds to both HSP90 and NS5A through different sites in its tetratricopeptide repeat domain<sup>[137]</sup>. Both knockdown of FKBP38 and treatment with geldanamycin suppresses HCV RNA replication in a replicon system indicating that the HSP90/NS5A/FKBP38 complex is important for the regulation of HCV RNA replication. In fact, the FKBP38/NS5A interaction is so critical for the virus that a single amino acid mutation in NS5A that disrupts its binding with FKBP38 impairs virus

production<sup>[170]</sup>. The same group found that HSP90 binds to human butyrate-induced transcript 1 (hB-ind1)<sup>[171]</sup>, which is a member of the Rho family of GTPases and a component of the Ras-related C3 botulinum toxin substrate 1 (Rac1) signaling pathway<sup>[172,173]</sup>. hB-ind1 was found to bind to NS5A and is involved in viral RNA replication through its interaction with HSP90. Thus, by interacting with NS5A, hB-ind1 recruits HSP90 and FKBP38 to the RCs. In addition, through immunofluorescence analyses, it was found that hB-ind1 colocalizes with NS5A, FKBP38, and double-stranded viral RNA at the site of the membranous web<sup>[174]</sup>. These results further support the role of HSP90 in viral RNA replication. Moreover, treatment with an HSP90 inhibitor decreased the HCV-induced UPR which points to a potential involvement of HSP90 in an hB-ind1-mediated protein folding mechanism in the membranous web in order to circumvent the virus-induced UPR.

It was also found that a few members of the S100 family of proteins, S100A1, S100A2, S100A6, S100B and S100P directly bind FKBP38 in cell-free *in vitro* assays in a Ca<sup>2+</sup>-dependent manner<sup>[175]</sup>. The S100 proteins are a family of 24 Ca<sup>2+</sup> binding proteins which are involved in regulating inflammation, cell proliferation and differentiation, apoptosis, cell migration and invasion, and Ca<sup>2+</sup> homeostasis<sup>[176]</sup>. The S100/FKBP38 interactions blocked both NS5A/FKBP38 and HSP90/FKBP38 interactions<sup>[175]</sup>. Furthermore, overexpression of S100A1, S100A2 and S100A6 suppressed HCV RNA replication. S100P was identified as one of the proteins with most consistently modified expression in acute HCV infection<sup>[108]</sup>.

FKBP38 has also been reported to be involved in HCV suppression of apoptosis<sup>[177]</sup>. NS5A plays an important role in HCV pathogenesis by activating the mammalian target of rapamycin (mTOR) pathway. This leads to suppression of apoptosis and hepatocyte cell survival which is required for persistent infection. NS5A exerts its anti-apoptotic activity by blocking the interaction between FKBP38 and mTOR.

FKBP54 (p54), another FKBP family member, was reported to co-immunoprecipitate with NS5B<sup>[105]</sup>. FKBP54 is an important co-chaperone involved in regulating a number of signaling pathways, steroid hormone receptors, and autophagy<sup>[178]</sup>.

### **p23 (PTGES3)**

p23 (prostaglandin E synthase 3) is another HSP90 co-chaperone and an inhibitor of HSP90 ATP turnover<sup>[179]</sup>. In addition, p23 together with HSP90 are essential telomerase components, and telomerase activity as well as expression of multiple telomerase components were reported to be significantly induced in HCV infection of huh7.5 cell<sup>[180]</sup>. The same group also showed that expression of the La protein (Sjogren syndrome antigen B), a regulator of HCV IRES-mediated translation<sup>[181]</sup>, significantly correlated with the expression of telomerase components including telomerase RNA, p23 and HSP90 in HCV-infected patient tissues. Thus, HCV may regulate

telomerase activity in an HSP90-dependent manner which may potentially be linked to HCV-induced hepatocarcinogenesis.

### **Prefoldin (PFDN1-2/VBP1/PFDN4-6)**

Prefoldin is the co-chaperone of the cytosolic chaperonin TRiC/CCT. It is a hexameric protein complex consisting of the six subunits encoded by the PFDN1-2, VBP1 (PFDN3), and PFDN4-6 genes<sup>[182]</sup>. Newly synthesized proteins at ribosomes bind to prefoldin which in cooperation with HSP70/HSP40 transports them to TRiC/CCT for proper folding and preventing protein aggregation. Prefoldin also plays an important role in clearing aggregated proteins as a result of ER stress or proteasome inhibitor treatment.

The HCV F protein, a 17 kDa product of ribosomal frameshift at the beginning of the core protein coding sequence, was found to bind prefoldin 2<sup>[183]</sup>. Prefoldin is involved in the proper folding of actin and tubulin subunits and plays an important role in the formation of the cytoskeleton. It was found that overexpression of the HCV F protein interfered with the prefoldin 1 and 2 interaction and resulted in an aberrant tubulin cytoskeleton. It was speculated that since an intact cytoskeleton is needed for HCV production in infected cells<sup>[184-187]</sup>, the HCV F protein may modulate and decrease virus production in order to establish a persistent chronic infection<sup>[183]</sup>.

### **ApoJ/clusterin (CLU)**

ApoJ, also known as clusterin, is another chaperone with both intracellular and extracellular functions including protein folding and extracellular protein degradation and is involved in a number of age-related diseases including cardiovascular and neurodegenerative diseases and cancer likely by interacting with HSP60<sup>[188,189]</sup>. HCV infection led to increased clusterin expression both in cell culture and serum of infected patients<sup>[190]</sup>. siRNA-mediated silencing of clusterin led to decreased virus production without affecting viral RNA replication levels suggesting a subsequent step such as translation, assembly, or secretion is affected. It was found that clusterin binds to and stabilizes core and NS5A.

### **PDI (PDI family) and MTTP (MTTP)**

The PDI family of proteins are ER chaperones that are responsible for disulfide bond formation<sup>[191]</sup>. The term PDI typically refers to the beta subunit of the prolyl 4-hydroxylase (P4H) enzyme, PDIA1 (P4HB), which is the first characterized member of the PDI family<sup>[192]</sup>. P4HB is involved in the folding and transfer of MTTP, a chaperone itself, from the cytosol into the lumen of ER<sup>[193,194]</sup>. P4HB and MTTP subsequently form a heterodimer, and MTTP then lipidates and stabilizes apolipoprotein B (apoB), a component of the VLDL produced by hepatocytes. ApoB associates with triglyceride containing particles generating VLDLs, and MTTP is involved in VLDL secretion as well<sup>[194,195]</sup>.

It has been shown that core expression leads to

decreased MTTP activity, in an HCV genotype 3-dependent manner<sup>[196]</sup> thereby reducing VLDL formation and secretion, which leads to accumulation of lipids in HCV-infected hepatocytes and subsequently liver steatosis<sup>[193,197,198]</sup>. Viral NS proteins have also been shown to decrease MTTP expression and activity and implicated in inhibition of VLDL secretion likely due to interaction of NS5A and apoB<sup>[199]</sup>. NS5A overexpression was also shown to decrease the expression of MTTP and increase lipid droplet size<sup>[200]</sup>. Furthermore, MTTP gene polymorphisms contribute to the accumulation of lipids in hepatocytes and may predict sustained virological response (SVR) to antiviral therapy in patients infected with genotype 4<sup>[201-204]</sup>. Thus, HCV infection is highly dependent on modulation of lipid metabolism, possibly in a genotype-specific manner<sup>[205-207]</sup>, through interactions with MTTP<sup>[208]</sup>. During maturation, the newly assembled virions acquire low-density configuration prior to being secreted, a process that requires MTTP, and the secreted viral particles are bound to VLDL<sup>[54,209,210]</sup>. Secretion of viral particles depends on the apoB-positive lipoprotein particles in an MTTP-dependent manner, while virion assembly (and infectivity through LDLR and GAGs) requires apoE and is not MTTP and VLDL dependent<sup>[34,211-216]</sup>.

P4HB activity was found to be increased in an HCV SGR system<sup>[129]</sup>. GRP58 (PDIA3), an important ER chaperone<sup>[191,217]</sup>, was found to be overexpressed in HeLa cells expressing HCV polyprotein<sup>[125]</sup>. Further, GRP58 was reproducibly enriched in the detergent-resistant membrane fraction of an SGR system, and knockdown of GRP58 led to a significant decrease in viral RNA replication<sup>[130]</sup>. The activity of two other PDI family members ERp72 (PDIA4) and PDIR (PDIA5) were also significantly increased in an HCV SGR system<sup>[72,191]</sup>. ERp5 (PDIA6) activity was reduced in an SGR system. It should be noted that SGR systems do not produce infectious virus, and the activity/expression of PDIs may, therefore, not correspond with the context of viral infection.

The PDI family also includes DNAJC10, an HSP40 family member, which is discussed in the HSP40 section above.

### **Calnexin (CANX) and calreticulin (CALR)**

Protein glycosylation among other post-translational modifications is carried out in the ER/Golgi apparatus. Calnexin and calreticulin are ER-resident chaperones that play a crucial role in the proper folding and glycosylation of glycoproteins. Both chaperones are part of a quality control mechanism in the ER that occurs in a cyclical manner<sup>[218]</sup>. Both HCV E1 and E2 being glycoproteins undergo the same cycles of quality control until they achieve the proper folding conformations required for the assembly of virions<sup>[98]</sup>. siRNA-mediated knockdown of calnexin and calreticulin decreased virus production<sup>[62]</sup>.

Both E1 and E2 rapidly associate with calnexin immediately after synthesis in the ER, but dissociate slowly<sup>[61,98,107,219]</sup>. While E2 folding occurs rapidly and is complete upon cleavage of the E2-NS2 precursor

polyprotein, folding of E1 is slow. Their association with calnexin parallels this timing suggesting that calnexin plays a role in proper folding of the E1/E2 glycoprotein complexes<sup>[220]</sup>. Calreticulin binds to E1 and E2 glycoproteins as well<sup>[98,107]</sup>. Whereas calnexin preferentially binds to monomeric glycoproteins, calreticulin seems to bind to E1/E2 aggregates. The N-linked oligosaccharides on these glycoproteins are important for the formation of E1/E2 complexes and for their interactions with some chaperones as treatment with tunicamycin, a glycosylation inhibitor, blocked the interaction of E1/E2 complexes with calnexin and calreticulin preventing their maturation and suppressing virus production<sup>[98,221,222]</sup>. Virus infectivity may also be impaired due to incorporation of immature glycoproteins in some virions<sup>[222]</sup>. Rather than being secreted, the E1/E2 complexes seem to remain in the ER and do not migrate past the cis-Golgi apparatus and are subsequently utilized in assembly of virions after undergoing proper folding and complex formation. Properly folded E1/E2 heterodimers no longer interact with calnexin<sup>[223-225]</sup>.

NS2 was reported to co-immunoprecipitate with CANX in infected cells<sup>[105]</sup>. All viral NS proteins were found to colocalize with the newly synthesized HCV RNA and calnexin at RCs which are ER-derived perinuclear structures<sup>[52]</sup>. In agreement with this observation, calnexin was reported to be associated with positive-strand subgenomic viral RNA (corresponding to domains III and IV of the 5' NCR and 36 nucleotides of core)<sup>[76]</sup>. Calnexin is also a target of miR-130a, miR-130b and miR-310 that were shown to be downregulated in acute HCV infection<sup>[108]</sup>. HCV core protein causes ER stress thereby inducing the expression of calreticulin<sup>[101]</sup>. Calreticulin was reproducibly enriched in the detergent-resistant membrane fraction of an SGR system<sup>[130]</sup>. HCV infection was also found to increase calreticulin expression<sup>[226]</sup>.

### **EDEM1 (EDEM1) and EDEM3 (EDEM3)**

EDEMs that consist of three proteins EDEM1, EDEM2, and EDEM3 are lectin chaperones and regulators of ERAD that are involved in targeting misfolded glycoproteins to the ERAD pathway<sup>[227,228]</sup>. EDEMs binds to the target glycoproteins that are destined for degradation<sup>[229]</sup>. EDEMs also bind GRP78 and appear to provide the signal for degradation of the target glycoprotein<sup>[227]</sup>. EDEM1 and EDEM3, but not EDEM2, directly bind HCV glycoproteins and increase their ubiquitination<sup>[230]</sup>. Knockdown of EDEM1 and EDEM3 as well as treatment with kifunensine, an ERAD inhibitor, increased the half-life of E1 and E2 and virus production, and overexpression of the two EDEMs decreased virus production.

As mentioned above, misfolded proteins in the ER are targeted to the ERAD pathway if attempts to properly fold these proteins are unsuccessful<sup>[83]</sup>. While HCV production in cells leads to ER stress and the UPR, the virus has evolved strategies to prevent its proteins from being degraded through the ERAD pathway<sup>[44]</sup>. The ERAD pathway is activated downstream of the

IRE1 pathway, and the IRE1 pathway is activated in response to HCV-induced ER stress and activation of the UPR<sup>[92]</sup>. However, despite activation of the IRE1 pathway, activation of the ERAD pathway is inhibited in HCV infection<sup>[231]</sup>. Thus, although sXBP1 is produced indicating activation of the IRE1 pathway, expression of EDEM1 is suppressed. This seems to be unique for HCV as other flaviviruses do not suppress EDEM expression in presence of sXBP1 production<sup>[83,231]</sup>. HCV NS4B similarly leads to production of sXBP1, but suppresses EDEM expression<sup>[103]</sup>. The lack of EDEM induction may also lead to increased IRES-mediated translation of viral proteins<sup>[231]</sup>. These results suggest that EDEMs may play a crucial role in regulating viral protein homeostasis and maintaining a balance in viral protein production to establish persistent infection.

### **SigR1 (SIGMAR1)**

SigR1 is a cholesterol-binding chaperone in lipid-rich areas of ER and mitochondrion-associated ER membranes (MAMs)<sup>[232]</sup>. MAMs play an important role in pathogenesis of HCV by serving as interorganellar communication sites between ER and mitochondria both of which are crucial for HCV production<sup>[44]</sup>. SigR1 is normally involved in crucial processes including cellular response to stress, lipid and protein trafficking, cell survival, and neuroprotection<sup>[232,233]</sup>. SigR1 has been reported to play an important role for viral RNA replication immediately after virion entry, but not afterwards during persistent infection<sup>[44,234]</sup>. siRNA-mediated knockdown of SigR1 reduced viral RNA replication only in early stages of infection.

### **Prohibitin (PHB) and prohibitin 2 (PHB2)**

The mitochondrial chaperone prohibitin is involved in a variety of processes including mitochondrial protein folding and membrane potential, cell cycle, and apoptosis<sup>[235]</sup>. It forms a ring structure composed of two subunits encoded by the *PHB* and *PHB2* genes. The HCV core protein as well as viral infection lead to overexpression of prohibitin<sup>[236,237]</sup>, which is a target of the HCV core protein<sup>[238]</sup>. Core binds to prohibitin and impairs its chaperone function thereby preventing the proper function of mitochondrial respiratory chain leading to overproduction of ROS which may result in hepatocarcinogenesis<sup>[237,238]</sup>. This is likely caused by the core-mediated suppression of the interaction between prohibitin and subunit I and IV of cytochrome C oxidase<sup>[239,240]</sup>.

### **Cyps (PPI family)**

Cyps are an important family of molecular chaperones most of which possess PPIase activity and are involved in diverse cellular processes including protein folding, scaffolding, protein trafficking, and apoptosis<sup>[241]</sup>. The genes that encode Cyps are referred to as PPIs. Cyps have been reported to be important for replication of HCV as well as other flaviviruses<sup>[242]</sup>, and Cyp inhibitors such as cyclosporine A (CsA) have been shown to effectively block virus production when used alone

or in combination with other antiviral agents such as IFN<sup>[243-262]</sup>. CyPs have been suggested to play important roles in the HCV life cycle including viral RNA replication, membranous web formation, viral polyprotein cleavage, lipid trafficking, virion assembly, suppression of IFN-based antiviral response, and induction of mitochondrial dysfunction.

It has been suggested that NS5B is recruited to the RCs in the membranous web by cyclophilin A (CypA) (PPIA) likely to ensure NS5B retains its proper conformation for viral RNA replication<sup>[263]</sup>. In fact, both NS5B and CypA share a common binding site on NS5A<sup>[264]</sup> suggesting that CypA delivers NS5B to the RCs at which point NS5B binds NS5A. This function of CypA is supported by the finding that treatment of cells with CsA reduces the levels of NS5B in RCs, but not NS5A or NS3<sup>[263]</sup>. In addition, mutant NS5B from CsA-resistant replicons retained their RC incorporation in presence of CsA. Other published Cyp inhibitor-selected mutations in NS5B have been reported to increase its RNA binding capacity<sup>[265-267]</sup>. Also the observed CsA resistance of the JFH1 strain (genotype 2a) is NS5B dependent<sup>[268]</sup>. PPIase mutant CypA maintained its NS5B binding<sup>[263]</sup>. However, the mutant CypA was unable to rescue HCV replication in CypA knockdown cells implicating its PPIase activity is important for HCV replication. Another study reported that CypA does not recruit NS5B or NS5A to RCs as CsA treatment did not affect the RC association of NS5B and NS5A, concluding the possibility of a CypA-independent recruitment of NS5B and NS5A to RCs<sup>[269]</sup>. A recent report seems to resolve this discrepancy<sup>[270]</sup>. It was found that Cyp inhibitor treatment did not affect the replicase activity of RCs after active RCs are established. This suggests that Cyp inhibitors exert their antiviral activity prior to formation of active RCs supporting the originally proposed CypA-mediated NS5B recruitment model.

In addition, NS5B binds to CypB (PPIB) which is required to stimulate the RNA-binding activity of NS5B and RNA synthesis<sup>[271-273]</sup>. Both CypA and CypB activate NS5B replicase function, particularly RNA binding, *in vitro* where CypB demonstrates viral genotype 1b specificity<sup>[274]</sup>. It was shown that the lack of PPIase activity in mutant CypA and CypB had some effect on NS5B activation, but the PPIase mutant CypA and CypB were still capable of activating NS5B to a significant extent suggesting that the PPIase activity is dispensable for NS5B activation. However, these experiments were performed in a cell free system, whereas the previous experiments showing the importance of PPIase activity in HCV replication were performed in a replicon system. Others have shown NS5B/CypB interaction to be mediated by CsA-associated helicase-like protein in GST pulldown assays<sup>[275]</sup>.

Significant evidence also points to a role of CyPs in viral RNA replication through their PPIase activity likely inducing conformational changes in viral and/or host proteins for optimal functioning. NS5A is a substrate for the PPIase activity of CypA and CypB through many

proline residues in NS5A domain II and the linker region between NS5A domains II and III (known as the low-complexity sequence II or LCS-II)<sup>[276-278]</sup>. A three amino acid structural motif, a proline-tryptophan turn, is essential for HCV RNA replication and proper interaction with CypA and influences the PPIase activity of CypA on NS5A domain II<sup>[279]</sup>. CypA also binds NS5A domain III and has PPIase activity towards some peptidylprolyl bonds in NS5A domain III<sup>[280]</sup>. The NS5A/CypA interaction and the PPIase activity of CypA, which are both disrupted by Cyp inhibitors, have been shown to be critical for HCV production<sup>[280-289]</sup>, and the PPIase activity of CypA is required for the NS5A/CypA interaction<sup>[281]</sup>. Further, wild-type CypA rescued viral RNA replication under CypA knockdown, but a PPIase mutant did not<sup>[284]</sup>. Indeed, it was found that CypA interacts with NS5A and stimulates RNA binding of NS5A domain II in a PPIase-dependent manner<sup>[290,291]</sup>. Furthermore, some SNP mutations in the PPIase domain of CypA render hepatocytes resistant to HCV replication likely by decreasing the intracellular stability of CypA<sup>[292]</sup>. Mutant NS5A from Cyp inhibitor resistant virus still binds to CypA as wild-type NS5A *in vitro*<sup>[281,282,286]</sup>, whereas in cell culture the interaction appears much stronger than with wild-type NS5A implying other cellular proteins are important for this interaction<sup>[170]</sup>. NS5B was found to further strengthen this interaction as well. Others have provided an alternative mechanism for resistance through NMR analyses showing that the resistant NS5A exhibited a trans to cis conformational shift possibly rendering NS5A less dependent on the PPIase activity of CypA for isomerization<sup>[285]</sup>. Importantly, the Cyp inhibitor-induced NS5A mutation can rescue viral replication under CypA knockdown conditions<sup>[282]</sup> although it still requires CypA at lower levels<sup>[293]</sup>. Thus, most of the evidence to date suggests that CypA is the most important Cyp in the context of HCV replication and that CypA and NS5A are the main targets of Cyp inhibitor-mediated antiviral activity as knockdown of CypB, CypC (PPIC), and CypD (PPIF) failed to suppress viral replication, and NS5A mutations have the major role in Cyp inhibitor resistance compared with NS5B and other viral proteins<sup>[263,265,283,284,293-298]</sup>.

Cyp inhibitor treatment also prevents formation of DMVs that are required for RNA replication at RCs suggesting that CyPs are involved in formation of RCs as well<sup>[270]</sup>. While the NS3-NS5B polyprotein and even NS5A alone suffices for formation of DMVs, knockdown of CypA prevents DMV formation suggesting that CyPs and, in particular, CypA is required for DMV formation. In addition, the PPIase activity of CypA was found to be required for DMV formation indicating that both NS5A and CypA are crucial for formation of DMVs.

The JFH1 SGR (lacking NS2) is not very sensitive to CsA or NIM811 (another Cyp inhibitor)<sup>[299]</sup>, and it was shown that full-length JFH1 was inhibited much more efficiently by CsA implicating NS2 to be important for CsA-mediated viral inhibition in a CypA-dependent manner<sup>[283,300,301]</sup>. Subsequently, it was found that NS2

itself is not a target of CsA, but that the rate-limiting NS2-NS3 cleavage determines sensitivity to CsA<sup>[301]</sup>. It has been suggested that NS3 also binds Cyps and that mutations in NS3 may also lead to CsA resistance<sup>[297,302]</sup>. Also it was found that the CypA dependence of HCV replication correlates with the NS5A-NS5B cleavage kinetics as demonstrated by substitution mutants at this cleavage site<sup>[283]</sup>. These findings indicate that viral polyprotein cleavage may at least in part be dependent on Cyps especially CypA.

CsA has also been shown to affect hepatocyte lipids pointing to an additional role of Cyps in lipid trafficking and in HCV pathogenesis<sup>[303]</sup>. Cyp inhibitor treatment disrupts the VLDL pathway of virus maturation described above resulting in increased lipid droplet size, accumulation of apoB on lipid droplets, removal of NS5A from lipid droplets, and inhibition of infectious virion assembly<sup>[291,303]</sup>. The Cyps involved were found to be CypA and Cyp40 (PPID).

Yet another role of CypA in viral infection has been suggested in the context of the IFN pathway<sup>[304]</sup>. It was found that CypA and IRF9, a component of the JAK/STAT pathway, directly bind each other *via* the PPIase domain of CypA and the newly-identified CypA binding site in the IRF-association domain of IRF9. Cyp inhibitors prevent this complex formation. Interestingly, NS5A and IRF9 compete for binding to CypA, and CypA inhibition led to increased IFN-induced transcriptional activity through interferon-sensitive response elements (ISREs). Thus, it seems that HCV utilizes NS5A to dampen the IFN response by replacing IRF9 in the CypA/IRF9 complex, in order to establish persistent infection in hepatocytes. Furthermore, it was observed that Cyp inhibitor treatment blocks phosphorylation of protein kinase R (PKR) and its target eIF2 $\alpha$  which inhibits translation of interferon-stimulated genes<sup>[305,306]</sup>. Cyp inhibitors also blocked stress granule formation. CypA binds PKR, and this interaction was disrupted by Cyp inhibitor treatment as well<sup>[305]</sup>. However, it was reported that Cyp inhibitor-mediated inhibition of PKR phosphorylation is due to suppression/clearing of viral infection rather than being a direct effect<sup>[306]</sup>. Thus, the significance of the CypA/PKR interaction and its disruption by Cyp inhibitors is not clear.

It is also reported that CsA treatment of uninfected huh7 cells induces the UPR and upregulation of GRP78<sup>[307]</sup>. Further, treatment of cells with UPR-inducing agents suppressed HCV replication. This may suggest that CsA may also exert its antiviral activity by inducing UPR which likely leads to improper viral glycoprotein/protein folding, their aggregation, and subsequent degradation.

The Cyp inhibitor alisporivir has also been found to prevent and to some extent reverse the negative impacts of HCV infection on mitochondrial function revealing another potential role for Cyps in the context of viral infection<sup>[308]</sup>. In particular, alisporivir prevents HCV-mediated collapse of the mitochondrial membrane potential, overproduction of ROS, and mitochondrial

calcium overload through inhibition of CypD-mediated opening of the mitochondrial permeability transition pore<sup>[308-310]</sup>.

## HCV PROTEINS AS CHAPERONES

Remarkably, some HCV proteins possess chaperone functions that are critical for virus production. For example, core, in particular the N-terminal domain I, has been shown to play important chaperone roles for viral RNA stabilization, dimerization, and structural rearrangements<sup>[311-315]</sup>. Also core appears to be involved in folding of the E1 glycoprotein<sup>[316]</sup>. Both viral glycoproteins E1 and E2 have been reported to possess chaperone functions. E2 has been reported to be required for proper E1 folding<sup>[317]</sup>. The disulfide bonds in E1 have been shown to be required for the proper function of E2 during viral assembly and entry<sup>[318]</sup>, and E2 does not seem to be able to reach a native structure in the absence of E1<sup>[319]</sup>. Further, a monoclonal antibody was reported to recognize properly folded E2 only when complexed with E1<sup>[224]</sup>. Also the ectodomain of E2 was shown to fold only in presence of E1<sup>[320]</sup>. CANX may be important for the chaperone activities of HCV glycoproteins<sup>[220]</sup>. This is in agreement with the observation that E2, unlike E1, did not associate with cellular chaperones such as CANX in an infection-free system<sup>[319]</sup>. In many class II enveloped viruses, of which HCV is a member, one viral glycoprotein acts as a chaperone for the folding of the other one which carries out the membrane fusion after viral entry in order to release viral genome in the cytosol<sup>[321]</sup>. However, for HCV, the mechanism of membrane fusion and the role of glycoproteins is not fully understood. The NS3 protein which possesses a helicase domain has been reported to mediate functions beyond the known helicase activity as it is involved in "intermolecular annealing, resolves three-stranded RNA duplexes, and assists dsRNA and ssRNA inter-conversions to establish a steady state among RNA structures"<sup>[322]</sup>. NS4A directs NS3 to ER and increases the intracellular stability of NS3<sup>[323]</sup>.

## CONCLUSION

Chaperones play crucial roles in HCV infection, and essentially all phases of the viral life cycle depend on chaperone functions and the interaction of viral proteins with chaperones (Table 1). The critical roles of Cyps and HSP90 in HCV RNA replication among others, HSP70 in viral protein translation, HSC70 in virion assembly, and the ER chaperones GRP78 and GRP94 in viral protein stability and persistent infection are important examples. Better understanding of the role of chaperones in the viral life cycle will provide further insights into the mechanism of virus production and suppression of immune response. Recently, significant advancements have been achieved in HCV therapy, and IFN-free therapies utilizing combinations of direct-acting antivirals (DAAs) with or without ribavirin (RBV) are being used successfully to achieve SVR in the majority of cases.

Besides very high costs associated with some therapies, other issues include variability in activity across different genotypes, such as genotype 3 that can result in failure to achieve SVR<sup>[324]</sup>. If RBV is required, significant side effects can occur such as hemolytic anemia<sup>[325]</sup>. Treatment with DAAs can also result in resistant virus as targeting viral proteins puts direct selective pressure for resistant mutants. Furthermore, a small percentage of patients are infected with intergenotypic recombinant strains of HCV which may not respond optimally to the current standard treatments<sup>[326,327]</sup>. Analysis of the role of chaperones in the viral life cycle may allow for development of novel strategies to target HCV infection. Targeting host factors may reduce selective pressure on the virus to generate resistant mutants. Furthermore, insights obtained by studying chaperones in HCV infection may allow for development of therapies for other viruses especially flaviviruses.

### Abstract

Although vascular complications (VCs) following orthotopic liver transplantation (OLT) seldom occur, they are the most feared complications with a high incidence of both graft loss and mortality, as they compromise the blood flow of the transplant (either inflow or out-flow). Diagnosis and therapeutic management of VCs constitute a major challenge in terms of increasing the success rate of liver transplantation. While surgical treatment used to be considered the first choice for management, advances in endovascular intervention have increased to make this a viable therapeutic option. Considering VC as a rare but a major and dreadful issue in OLT history, and in view of the continuing and rapid progress in recent years, an update on these uncommon conditions seemed necessary. In this sense, this review comprehensively discusses the important features (epidemiological, clinical, paraclinical, prognostic and therapeutic) of VCs following OLT.

## INTRODUCTION

Although vascular complications (VCs) following orthotopic liver transplantation (OLT) are seldom, they are one of the most dreaded complications with a high incidence of both graft loss and mortality, as they compromise the blood flow of the transplant (either inflow or outflow). Khalaf<sup>[1]</sup>, in 2010, reported that patient who presented VCs had significantly inferior graft and patient survival rates. The overall incidence of VCs in adults varies widely among transplant centers worldwide, but remains around 7% in various series of deceased donor liver transplantation (DDLT), and around 13% involving living donor liver transplantation (LDLT)<sup>[1-5]</sup>. Bleeding, stenosis and thrombosis can arise at any of the vascular anastomoses, as well as aneurysms at the arterial anastomosis and exceptionally on the portal vein<sup>[6,7]</sup>, with an overall reported incidence of 7.2%-15% in adults (mainly arterial 5%-10%, following by portal 1%-3% and caval < 2%) (Table 1)<sup>[5,8-10]</sup>. In this sense, diagnosis and therapeutic management of VCs constitute a major challenge in terms of increasing the success rate of liver transplantation. This explains why, currently, many transplant teams perform close surveillance of all vascular anastomoses using Doppler ultrasonography, which allows prompt detection and treatment before ineluctable graft failure. All vascular problems must be treated aggressively, particularly in- or out-flows and sudden vascular occlusions (*i.e.*, thrombosis or kinking), such as hepatic artery thrombosis (HAT) and portal vein thrombosis (PVT), which are the most common, and more rarely hepatic veins or cavo-caval thrombosis. Indeed, they can suddenly interrupt hepatic blood supply with both high graft loss and retransplantation rates<sup>[1,5,10]</sup>. Usually, therapeutic options include surgical revascularization, percutaneous thrombolysis, percutaneous angioplasty, retransplantation and a conservative approach. Although surgical treatment used to be considered the first choice for management, advances in endovascular intervention have increased to make this a viable therapeutic option following OLT. In recent decades, huge advances in

the field of interventional radiology have radically changed the diagnostic and therapeutic approaches to VCs in liver transplant patients. For example, technical improvements made in the catheterization of hepatic vessels and computed imaging allow a specific and localized intervention on these pathological vessels, in a less invasive way<sup>[1,5,11-18]</sup>. As a matter of fact, percutaneous endovascular therapies (*i.e.*, catheter-based thrombolytic intervention, balloon angioplasty and stenting) provided by an experienced interventional radiologist are commonly employed and have supplanted surgery as the therapy of choice in almost all cases<sup>[18-20]</sup>.

Considering VCs as rare but as major and dreadful issues of OLT history, and in view of the continuing and rapid progresses in recent years, an update on these uncommon conditions seems necessary. In this sense, this review comprehensively presents the important features (either epidemiological, clinical, paraclinical, prognostic and therapeutic) of VCs following OLT. In this review, only VCs following adult OLT (DDLT or LDLT) are presented, excluding pediatric liver transplantation. Taking into account that biliary complications following OLT also constitute a major therapeutic challenge, and that they are intrinsically linked with hepatic arterial pathology, they are beyond the subject of this article and therefore will not be discussed herein.

## ARTERIAL COMPLICATIONS

Arterial complications are still a major source of morbidity and mortality after OLT. Normally, the liver allograft maintains a dual inflow blood supply: Portal and arterial. Hepatic artery (HA) plays a major physiological role, because it provides the blood supply for both the liver parenchyma and the biliary tree. Arterial reconstruction is a frequent therapeutic option after the ligation of different collaterals until, finally, the celiac trunk remains the only arterial vascular supply to the transplanted liver<sup>[21]</sup>. In patients with traumatic liver rupture with curative ligation of the hepatic artery, it has been reported that bile duct necrosis is not always associated<sup>[22]</sup>. On the contrary, the interruption or the reduction of arterial flow during liver transplant is frequently associated with biliary tree complications due to ischemic processes (*i.e.*, bile duct necrosis, liver abscesses and graft dysfunction)<sup>[23]</sup>. This discrepancy can be explained by the absence of collaterals in an OLT recipient<sup>[2,24]</sup>. In the native liver, HAT or even acute ligation, is usually well-tolerated due to the abundant arterial collateral sources which avoid ischemia of the liver parenchyma. In contrast, disruption of these collaterals inevitably occurs when performing total hepatectomy for OLT. Thus, the allograft may survive by portal and arterial inflows *via* portal and hepatic artery anastomoses. In cases of HA complications (HAC) perturbing the arterial inflow, the allograft may survive by portal inflow, but only if arterial collaterals exist<sup>[2,24,25]</sup>. These facts explain why recognition and prompt management of HAC is of great importance

**Table 1 Vascular complications following orthotopic liver transplantation**

Type	Delay (incidence)	Clinical presentation	Diagnosis	Treatment
Arterial complications HAT incidence: 3.5%	Early HAT (2.9%)	Abnormal transaminase	DUS	Emergent revascularization by endovascular intervention or surgical revascularization or rLT
		Fever	ce-MDCT	
		Biliary complications	Angiography	
		Graft failure		
		Coagulopathy		
	Late HAT (2.2%)	Asymptomatic		
		Fever		
		Abnormal transaminase		
		Bile leak		
		Hepatic abscess		
HAS incidence: 2%-13%	Early HAS	Cholangitis		Endovascular intervention or surgical revascularization
		Graft failure	DUS	
		Biliary complications	ce-MDCT	
	Late HAS	Asymptomatic	Angiography	Endovascular intervention or surgical revascularization
		Fever	DUS	
		Abnormal liver function	ce-MDCT	
HAP incidence: 2.5%		Asymptomatic	Angiography	Endovascular intervention or surgical resection and revascularization
		Abdominal pain	DUS	
HAR incidence: 0.64%		Fever	ce-MDCT	
		Gastrointestinal bleeding	Angiography	
		Massive bleeding through abdominal drains	None in emergency	
		Hemorrhagic shock		
Portal vein complications PVT incidence: < 3%	Early	Abnormal transaminase		rLT or surgical repair or endovascular interventions
		Graf dysfunction	DUS	
		Multi-organe failure	ce-MDCT	
		Variceal bleeding	(portal phase)	
			Portography	
	Late	Ascite	DUS	Curative anticoagulant therapy
		Portal vein hypertension	ce-MDCT	
		Splenomegaly	(portal phase)	
		Variceal bleeding	Portography	
			DUS	
	Early	Asymptomatic		Endovascular interventions
		Portal vein hypertension	ce-MDCT	
		Abnormal transaminase	(portal phase)	
			Portography	
			DUS	
	Late	Asymptomatic		Anticoagulant therapy and/or Endovascular interventions
		Ascite	ce-MDCT	
		Abnormal liver test function	(portal phase)	
			Portography	
Caval anastomosis complications Caval resection and end-to-end cavo-caval anastomosis	Early	Acute Budd-Chiari syndrome		Endovascular intervention or surgical repair or rLT
		Graf failure	DUS	
		Intestinal congestion	ce-MDCT	
		Renal dysfunction	Cavography	
		Lower limb edema		
	Late	Moderate Budd-Chiari syndrome		Endovascular intervention
		Ascite	DUS	
			ce-MDCT	
Piggy-back	Early	Acute Budd Chiari		Surgical repair or rLT
		Graf failure	DUS	
		Intestinal congestion	ce-MDCT	
		Renal dysfunction	Cavography	
		Lower extremity edema		
	Late	Moderate Budd-Chiari		Endovascular intervention
		Ascite	DUS	
		Lower extremity edema	ce-MDCT	
		Renal dysfunction	Cavography	
		Abdormal liver test function		

Clinical characteristics of arterial and caval complications. rLT: Re-liver transplantation; DUS: Doppler ultrasound; HAT: Hepatic artery thrombosis; HAS: Hepatic artery stenosis; HAP: Hepatic artery pseudoaneurysm; HAR: Hepatic artery rupture; PVT: Portal vein thrombosis; PVS: Portal vein stenosis; MDCT: Multi-detector computed tomography.

**Table 2** Hepatic artery thrombosis highlights**Summary of the clinical characteristics about HAT**

HA supplies exclusively the bile duct, so HAT is associated with a high frequency of biliary complications  
 HAT represents more than 50% of all arterial complications following OLT  
 The incidence of HAT following OLT is 3.5% with early and late HAT incidences of 2.9% and 2.2%, respectively  
 HAT carries an incidence of graft failure and mortality of more than 50% without prompt treatment  
 The median time to detection of early and late HAT was 6.9 d (range: 1-17.5 POD) and 6 mo (range: 1.8-79 mo), respectively  
 No differences in HAT incidences were observed between DDLT and LDLT  
 Clinical presentation spectrum: Mild elevation of serum transaminase and bilirubin levels (75%), biliary complications (15%), fever and sepsis (6%), graft dysfunction or failure (4%)  
 Risk factors of early HAT are mainly represented by technical problems, LDLT, cigarette smoking and hypercoagulability state, while late HAT is usually related to ischemic or immunologic injury: CMV positive donor, female donor and male recipient and hepatitis C seropositive recipient  
 Early diagnosis is achieved by assessing the serum transaminase level and performing Doppler ultrasound monitoring in the postoperative period and confirmed by contrast-enhanced abdominal CT scan and/or visceral angiography  
 Currently, the literature on the curative management of early HAT suggests the following procedures: First endovascular radiological intervention (IAT, PTA and stent placement), secondly open surgical revascularization, and finally retransplantation, which is associated with the best survival rate compared with revision or thrombolysis, but is a limited therapeutic option due to organ shortage

HA: Hepatic artery; HAT: Hepatic artery thrombosis; OLT: Orthotopic liver transplantation; DDLT: Deceased donor liver transplantation; LDLT: Living donor liver transplantation; CMV: Cytomegalovirus; IAT: Intra-arterial thrombolysis; PTA: Percutaneous transluminal angioplasty; CT: Computed tomography.

for graft and patient survival. The etiology underlying most HAC involves the anastomosis, including: (1) HAT: 1.9%-16.6% (the most frequent and pejorative); (2) anastomotic stricture [*i.e.*, hepatic artery stenosis (HAS)]: 0.8%-9.3%; (3) pseudoaneurysm formation [*i.e.*, hepatic artery pseudoaneurysm (HAP)]: 0%-3%; and (4) hepatic artery rupture (HAR): 0.64%<sup>[8,9,18,26]</sup>. These complications can be classified into two categories (Table 1): Early (< 1 mo) or late (delayed, *i.e.*, > 1 mo). Very particular attention should be focused on early complications, because they are associated with graft loss and a high mortality rate. In different studies, the definition of early and late complications continues to be discussed. Most of the authors have defined late complications as those occurring after 4 wk, and others after 6 mo<sup>[13,25,27,28]</sup>. In this review, we consider the recent consensus which defines early complication when it appears within the first month<sup>[10,13,18,27,28]</sup>.

**HAT**

HAT represent more than 50% of all arterial complications. It is the most frequent and severe vascular complication following OLT. Table 2 usually more frequent after pediatric liver transplantation<sup>[5,10,16,17,28-31]</sup>. It is the first cause of primary non-function of the liver transplant, which can lead to allotransplant loss and patient death in the early postoperative period. HAT is associated with a high incidence of liver transplant failure (more than 50%) and carries a mortality of more than 50% in the absence of revascularization or retransplantation. In recent years, early revascularization by means of endovascular catheter-based intervention has been a viable option for graft salvage before considering retransplantation. Indeed, the retransplantation rate is very high in untreated HAT (25%-83%) compared to graft revascularization treated patients (28%-35%)<sup>[3,10,13,16,17,30,32-40]</sup>.

**Definition:** HAT is defined as a thrombotic occlusion of the hepatic artery. It has been classified, as described above, into two types depending on the time of presentation following OLT: Early HAT [within the first 30 d of liver transplantation (LT)] and late HAT (after 30 d of LT)<sup>[13,17,28]</sup>. The hepatic artery supplies the biliary tree of the transplant, explaining the high frequency of biliary complications in HAT (*i.e.*, biliary ischemia, necrosis, stricture, sepsis) and eventually hepatic insufficiency and graft loss<sup>[31]</sup>.

**Incidence:** The true incidence of early HAT following OLT is unknown, but it varies widely from 0% to 12% in adults<sup>[5,9,24,25,27,30,38,41]</sup>. Bekker *et al*<sup>[28]</sup> (2009) reported in a systematic review comprising 21822 OLT cases an incidence of 843 cases (adults and children) of early HAT with an overall incidence of 4.4%. In adults, the incidence of HAT was 2.9%. They also showed that the incidence of early HAT had decreased over time since the first report in 1982 by Starzl (6.9% in 1996 vs 3.2% in 2006) with improvements in perioperative care. They reported that there were no differences in incidence among transplantation centers worldwide<sup>[2,28]</sup>. Median times to the occurrence detection of early and late HAT were respectively 6.9 postoperative days (range: 1-17.5) and 6 mo (range: 1.8-79 mo)<sup>[17]</sup>.

In literature, it does not confirm that HAT incidence in LDLT is significantly lower or higher compared to HAT incidence in DDLT. Many studies show contradictory results<sup>[1,9,17,28,41]</sup> but, a meta-analysis on HAT found no significant difference with an incidence of 3.1% and 4.6% in LDLT and DDLT, respectively<sup>[28]</sup>. Furthermore, it was reported that arterial anastomosis with operation microscope or loupe magnification did not show any difference in incidence HAT<sup>[9,17,28,41]</sup>.

Late HAT shows a lower incidence, ranging from 1% to 25%<sup>[38,42]</sup>. Torras *et al*<sup>[34]</sup> (1999) reported an

incidence of 7.5% (35/413) following OLT. Sixteen cases occurred during the first month (early HAT): Diagnosis made from 1 to 13 d after OLT (median: 2.5). Nineteen cases were late HAT (> 30 d, from 2 to 79 mo after OLT (median: 5 mo)<sup>[34]</sup>.

**Clinical presentation:** The clinical presentation of HAT range from a mild elevation in serum amino transferase (most frequently in patients with HAT) and bilirubin levels to fulminant hepatic necrosis. HAT is associated with elevated transaminases in 75%, biliary complications in 15%, fever and sepsis in 6% and graft dysfunction or failure in 4% of cases<sup>[5]</sup>. The clinical expression depends on the timing of the onset of HAT as well as on the existence of collaterals<sup>[5,25,27]</sup>. Usually, initial non-function or severe allograft dysfunction predominately occurs in patients with early HAT. This explains the importance of symptomatic expression, whereas biliary tract complications (*i.e.*, bile duct strictures or bile leaks sometimes leading to biliary hepatic abscesses) are more frequently, but not exclusively, associated with late HAT. Indeed, clinical expression depends on the existence of collaterals, which can develop as early as within two weeks<sup>[17,24,27]</sup>. Therefore, two main forms of HAT are recognized: (1) acute presentation (early HAT) characterized by a severe clinical course; and (2) delayed presentation (late HAT) generally associated with a milder clinical course<sup>[25]</sup>.

In every cases, early HAT clinically manifests with fever, increase leukocytosis and a important elevation in liver enzyme levels. The natural history of early HAT could be summarized as biliary tract necrosis followed by uncontrolled septic shock in the immunosuppressed population, and even by the patient's death<sup>[17,27,28,31,38]</sup>. The pathophysiological process of early HAT results in injury to the bile duct epithelium and to hepatocytes. This leads to massive necrosis in the allograft, partly due to the disruption of arterial inflows (*i.e.*, main flow by HA and accessory physiological collaterals), explaining the high incidence of biliary sepsis in early HAT<sup>[25,27,28]</sup>.

It is usually assumed that late HAT is due to ischemic or immunological damages with a more insidious onset. Up to 50% of patients with late HAT can be asymptomatic with elevated liver function tests only<sup>[10,19,27,36]</sup>. Symptomatic patients often present with biliary complications including recurrent cholangitis, bile duct stricture/stenosis, biliary leakage, biliary tract necrosis and abscess formation revealed by relapsing fever and bacteremia. The presentation may be insidious. Liver graft ischemia and liver failure are other classical insidious clinical outcomes revealing late HAT<sup>[17,27,28,36,38,42,43]</sup>.

**Risk factors:** Several reports studied the risk factors associated with HAT<sup>[5,10,17,19,25,27,28,34,44,45]</sup>. They can be divided into several categories. It is usually considered that technical problems are mainly associated with early HAT. Conversely, risk factors for late HAT are less well-defined. However, a donor positive CMV status and a

recipient negative cytomegalovirus (CMV) status have repeatedly been shown to be a possible risk factor for late HAT<sup>[27,45]</sup>. Moreover, specific factors of late HAT reported include the association of female donor and male recipient, hepatitis C virus positive recipients, episodes of rejection, tobacco consumption and retransplantation<sup>[10,17,27,45,46]</sup>. Besides, while some authors believe that HAS and hepatic artery kinking are the initiating factors, others suggest a perioperative hypercoagulable state as a possible underlying cause<sup>[5,10,17,28,29]</sup>.

Truly, the cause of early HAT is still under debate and remains unknown in most cases. Up to 20% of HAT cases are probably due to surgical causes (technical problems) in the arterial anastomosis, such as difficult anastomosis, technical imperfections with the anastomosis, kinking, stenotic anastomosis, small vessel size, reduction in a disparate diameters of the arteries, dissection of the hepatic arterial wall, celiac stenosis or compression by the median arcuate ligament, the presence of multiple arteries, aberrant or complex donor/recipient arterial anatomy or arterial abnormalities requiring complex arterial reconstructions, complex backtable arterial reconstruction of the allograft, poor quality donor and recipient vessels and high-resistance microvascular arterial outflow caused by rejection or severe ischemia-reperfusion injury. Those problems are more common among centers performing fewer than 30 OLT a year; the incidence of HAT diminishes with the surgical team's experience. Therefore, surgical causes probably do not represent the main risk factor for HAT<sup>[17,28,29,31,38]</sup>.

It has been reported that HAT can occurs within a few hours after LDLT, which indicates a population at higher risk of HAT. Indeed it has been shown that these patients displayed a higher rate of VCs explained by the complexity vascular reconstructions linked to smaller and shorter caliber of donor and recipient vessels<sup>[1,10,47]</sup>.

Regarding the non-surgical risk factors involved in the occurrence of HAT, donor age > 60 years, extended cold ischemia time, lack of ABO compatibility, cigarette smoking, hypercoagulability state, donor positive for CMV in a CMV-negative recipient, rejection, regrafts and transplant for primary sclerosing cholangitis have been shown to be statistically linked with the occurrence of HAT<sup>[17,28,38,46]</sup>. However, the literature review dealing with this issue displayed conflicting results. Indeed, some authors reported that some parameters like cold ischemic time, donor age and the presence of rejection were not found to be factors related to the development of HAT<sup>[34]</sup>. This emphasizes the difficulty in accurately determining the risk factors associated with early HAT. In a recent study, Panaro *et al.*<sup>[48]</sup> (2014) have shown a statistical association between TACE and the radiological and histological arterial wall injury, as in the past 25 years TACE has been widely used in the treatment of HCC. This procedure may potentially cause vascular lesions in the arterial wall (catheterization and drug infusion), suggesting that previous transarterial chemoembolization (TACE) could constitute a risk factor

**Figure 1** Contrast-enhanced-multidetector-row computed tomography-scan showing hepatic artery thrombosis after an endovascular intervention with stent placement. Thrombus (arrow).

of HAT when future OLT is performed<sup>[5,48]</sup>.

Some practices could prevent the occurrence of HAT, and the data reported by Duffy *et al.*<sup>[5]</sup> (2009) demonstrates that arterial reconstructions which restore the normal anatomy and gentle handling of vessels are of great importance in the accomplishment of hepatic arterial anastomosis. Some studies reported that recipients with multiple anastomoses for arterial reconstruction should receive aspirin and Doppler ultrasound (DUS) assessment to screen the patency of the reconstructed hepatic artery. Moreover, the use of aortic conduits for arterial reconstruction is a risk factor that warrants the initiation of prophylaxis in the post-transplant period<sup>[5,10,17,19,25,31,44]</sup>. For patients with inheritable thrombophilic diseases; given the devastating effects of HAT on graft outcomes, it should be necessary to identify these to prevent thrombotic complications. It is likely that patients who present both hematological and operative factors are most at risk, and routine anticoagulation in the post-OLT setting should be instituted. In sum, many studies recommend peritransplantation anticoagulation with heparin or an antiplatelet agent in patients with extraanatomic conduits, complex backtable reconstruction, or pre-OLT TACE. However, the best prophylactic approach is controversial, and this should be clarified by randomized, controlled trials<sup>[5,10,17,19,31,44,25]</sup>. An interesting report by Marín-Gómez *et al.*<sup>[40]</sup> (2012) demonstrates that intraoperative blood flow allows for a prediction of the occurrence of HAT when it is less than 100 mL/min with 84.5% sensitivity and a predictive positive value of 97.8%.

**Diagnosis:** Early diagnosis is mandatory to allow immediate treatment and to prevent graft loss. The detection of these patients includes biological (serum transaminase levels) and morphological (DUS) exams, while visceral angiography allows to confirm the diagnosis. DUS is a proven non-invasive technique and the gold standard investigation to assess hepatic artery patency. It detects the absence of hepatic artery flow, even in its intrahepatic branches. The DUS diagnosis comprises the lack of HA signal (Se = 92%) or an increased resistive index (RI)<sup>[25,17,38]</sup>. Even though the

screening protocol varies between liver transplant centers, a DUS surveillance protocol of the hepatic artery can detect reduced hepatic arterial flow and to allow for prompt revascularization management, which may result in transplant salvage<sup>[17]</sup>. In sum, in case of an abnormal elevation in liver enzymes and suggestive findings on DUS, abdominal computed tomography (CT) angiogram or angiography confirmed diagnosis and it can precisely shows an underlying anatomical defects (stenosis or kinking) with a high sensitivity and specificity specificity (Figure 1)<sup>[17]</sup>. Pareja *et al.*<sup>[38]</sup> (2010) established a screening protocol for early HAT, consisting of a first Doppler ultrasound within 48 h of OLT and in another Doppler ultrasound 7 d later. If the first examination is conclusive, they perform contrast ultrasound (microbubbles) or computed tomography. When HAT is confirmed, arteriography should be performed<sup>[38]</sup>. Intimal hyperplasia causing progressive HAS may precede late HAT and may be screen by regular (yearly) post-OLT DUS assessment. In some cases, HAS is likely to stimulate the development of arterial collaterals that protect the liver from ischemia at the time of HAT<sup>[25,48]</sup>.

**Therapeutic management:** Classically, we consider several treatment modalities for HAT: (1) revascularization (surgical or endovascular); (2) retransplantation; and (3) observation. Currently, the most effective treatment approach remains controversial and the choice of any of these treatments depends on the time of diagnosis. Early diagnosis, prompt revascularization and retransplantation have been considered the only solution to rescue patients with HAT. Historically, retransplantation is the treatment of choice for most groups, offering the best survival results<sup>[5,16]</sup>. However, this possibility is strongly conditioned by the shortage of donors and by the patient's condition<sup>[16,17,27,38,39]</sup>. Percutaneous endovascular treatments including intra-arterial thrombolysis (IAT), percutaneous transluminal angioplasty (PTA) and stent placement have shown hopeful outcomes in the literature. Finally, some patients survive without revascularization or retransplantation by developing collateral circulation distal to the thrombosis, but this occurs in rare cases<sup>[17,20,24,38,39]</sup>. Despite these encouraging results of endovascular interventions, the efficacy and risk of complications (mainly represented by hemorrhage risk) make this therapeutic option still controversial. Moreover, in some cases these are ineffective and surgical intervention (including anastomotic revision and retransplantation) must be applied. The complications of PTA include thrombosis, vascular dissection and rupture. Thus, urgent revascularization by means of endovascular interventions as a primary option offers could give a chance to avoid rLT, but only in asymptomatic patients<sup>[8,10,17,20]</sup>. Despite the proof of efficacy and safety of thrombolytic treatment with different products and regimens (urokinase, streptokinase, alteplase), the best protocol is not still known and there are currently no specific guidelines for

thrombolytic therapy application. Furthermore, several studies recommend low dose of heparin in association with thrombolytic despite increasing the risk of adverse bleeding. Indeed, hemorrhage is the most frequent adverse effect and concern about 20% of patients: Ranging from blood in the drainage to intra-abdominal hemorrhage, which could be fatal in some cases. This is mainly true in early postoperative period, but selective thrombolysis *via* the hepatic artery presents several advantages, such as a smaller thrombolytic dose, a highly localized concentration and little influence on systemic coagulation<sup>[17,20]</sup>. Endoluminal IAT with restoration of flow should be associated with underlying anatomic defects treatment if present, including reduction of kinking, treatment of an anastomotic stenosis and often requires balloon angioplasty and/or stent placement<sup>[16,20]</sup>. Association of IAT with PTA and/or stenting showed better efficacy and survival rates when compared to IAT alone. In summary, PTA and stent placement are currently tried first to resolve the problem in many centers<sup>[10,20]</sup>. Open surgical revascularization of thrombosed liver transplant is considered a viable option to save the transplant and to avoid retransplantation. Open surgical revascularization can be performed in various ways depending on the length and on the integrity of the recipient and on the graft arterial stumps. The procedure in its simplest form can be a Fogarty thrombectomy and a primary resuture of the end-to-end hepatic artery anastomosis<sup>[16]</sup>. Duffy *et al*<sup>[10]</sup> evaluated 4234 LT from 1984 to 2007: 203 (5%) developed HAT including 133 early and 70 late HAT; the occurrence of HAT was 3.9% in adults. Overall 90 patients were treated with surgical exploration, thrombectomy, or anastomotic revision. Nine patients were treated with catheter-based thrombolysis and 13 patients received anticoagulation. Of the patients with early HAT who underwent thrombectomy and anastomotic revision, only 9 (10.5%) had graft salvage, and the remaining patients needed re-transplantation. Overall, re-transplantation was necessary in 153 (75%) patients with HAT. Therefore, retransplantation after HAT has a better survival rate compared with revision or thrombolysis<sup>[5,10]</sup>.

In contrast, some patients with late HAT survive without revascularization or retransplantation by developing a collateral circulation distal to the thrombosis. The mean time between the diagnosis of HAT and the neovascularized liver is 4.1 mo (range: 3-5.5 mo). Four factors are associated with the development of a neovascularized liver: Late HAT, early HAS, site of thrombosis, and Roux-en-Y anastomosis<sup>[24,39]</sup>. These results confirm that a slow arterial obstruction process allows for the formation of arterial substitute pathways, but this striking neoangiogenesis capacity, only significant in cases of chronic ischemia, is insufficiently rapid in the case of early HAT. Given the improved outcome of the conservative treatment of liver transplant recipients, in whom late HAT develops without revascularization or retransplantation, revascularization in this condition is controversial. Based on two limitations (the relative

lack of utility of revascularization of late HAT and the contraindication to early postoperative thrombolysis), Saad *et al*<sup>[16]</sup> (2007) proposed that the clinical window of the applicability of transcatheter thrombolysis should be most likely from 1 to 3 wk to 1 to 3 mo post-transplantation, respecting contraindications to avoid fatal bleeding complications. However, successful and safe pharmaceutical thrombolysis was described by Figueras *et al*<sup>[11]</sup> (1995) 3 d after OLT. In the literature, the time interval between the transplant and thrombolysis procedures ranges from 2 to 120 d (mean, 53 d)<sup>[11,16,27,49-51]</sup>.

**Prognosis:** At the time of revascularization, survival rates is 40% in symptomatic vs 82% in asymptomatic patients<sup>[17]</sup>. The incidence of HAT has a significant impact on transplant and recipient survivals. Indeed, Silva *et al*<sup>[27]</sup> (2006) reported an overall mortality rate of 23% in those developing HAT post-OLT. In the meta-analysis reported by Bekker *et al*<sup>[28]</sup> (2009) HAT was a major cause of graft loss (53.1%) and mortality (33.3%) in the early postoperative period.

**Conclusion:** HAT is rare but it represents the most common vascular complication following LT. A definitive diagnosis is achieved by angiography, which may detect predisposing anatomical anomalies. Moreover, it allows prompt therapeutic management in the same time. IAT can be performed alone and an eventual anatomical anomaly may then be corrected by endovascular procedures such as balloon angioplasty and/or stent placement, or a surgical intervention. Currently, it seems reasonable to propose endovascular treatment first, mainly due to organ shortage and the high mortality related to retransplantation, considering the highly individualized outcome and depending of the competence of the transplant center. However, in the early post-transplant period, it is widely accepted that symptomatic patients with severe allotransplant dysfunction and symptoms related to arterial thrombosis need retransplantation.

### Hepatic artery stricture/HAS

**Definition:** HAS following OLT is defined as a narrowing of the transverse diameter of the HA, more or less extended, resulting in graft ischemia mainly revealed by elevated liver function tests<sup>[2,16,52-56]</sup>. Significant HAS is usually defined as a narrowing of the transverse diameter > 50% on angiogram associated with clinical suspicion and a RI < 0.5 (defined by peak systolic flow-end diastolic flow/peak systolic flow) and a peak systolic velocity > 400 cm/s detected by DUS<sup>[16,57,58]</sup>. HAS and HAT are the most common hepatic arterial complications, with high rates of morbidity and mortality<sup>[56,58]</sup> (Table 3).

**Incidence:** HAS occurs in 2% to 13% of transplants and has been suggested to progress to HAT implicating, at least in part, that HAS and HAT are two contiguous components of the broader allotransplant ischemic spectrum<sup>[2,16,30,52,53,55,56,58-60]</sup>. Wozney *et al*<sup>[2]</sup> (1986) reported three cases in which untreated anastomotic

**Table 3** Hepatic artery stenosis highlights**Summary of the clinical characteristics about HAS**

Significant HAS is defined as a narrowing of the transverse diameter > 50% on the angiogram associated with clinical suspicion, with a resistive index < 0.5 and a peak systolic velocity > 400 cm/s detected by DUS

HAS occurs in 2% to 13% of transplants, at the level of the anastomosis (59% of cases), graft HA (41%) or recipient HA (2.6%)

HAS has been speculated to progress to HAT in 65% of cases at 6 mo for untreated HAS

The median time to diagnosis is 100 (range: 1-1220) d following OLT

Most of patients with HAS are asymptomatic and most commonly present only with abnormal liver function tests and in rare cases with graft failure

Routine screening by DUS during the postoperative period is mandatory because of the insidious clinical presentation

The risk factors are not really known, but among these, technical and surgical factors (vascular injury such as clamp injury, intimal dissection, faulty placement of anastomotic sutures, excessive length with kinking and angulation, differences in the vessel caliber that require and oblique anastomosis, vasa vasorum disruption) or acute cellular rejection

DUS is a non-invasive method for the assessment of HA patency, but a contrast-enhanced CT scan and angiography are required to confirm the diagnosis

Radiological endovascular intervention by PTA with or without stent placement is often used to treat post-transplant HAS and are both efficacious, with 7% to 12% of complications including dissection and arterial rupture, restenosis or thrombosis (25%) and 12% failed attempts

Surgical revision and retransplant showed a high rate of success, but the overall mortality rate was as high as 20%. In some case, HAS may be an early sign of chronic rejection

DUS: Doppler ultrasound; HA: Hepatic artery; HAT: Hepatic artery thrombosis; HAS: Hepatic artery stenosis; OLT: Orthotopic liver transplantation; PTA: Percutaneous transluminal angioplasty; CT: Computed tomography.

strictures of the hepatic artery progressed to HAT. Saad *et al*<sup>[52]</sup> (2005) emphasized the correlative progression of untreated significant HAS to HAT with an incidence rate of 65% at six months for untreated HAS<sup>[2,16,52]</sup>. Abbasoglu *et al*<sup>[57]</sup> (1997) reported an incidence of 4.8% in a cohort of 857 consecutive OLT from 1988 to 1995. The median time to diagnosis was 100 d (range: 1-1220 d) following OLT, which was also reported by Denys *et al*<sup>[60]</sup> (2002) with a mean time to diagnosis at 94 d post-OLT<sup>[57,60]</sup>. Similar to HAT, HAS may be divided in two groups: HAS occurring within 30 d after OLT (early HAS), and HAS occurring more than 30 d after OLT (late HAS). Chen *et al*<sup>[61]</sup> (2009) reported an overall HAS incidence of 2.8%, with an early HAS incidence of 40% vs a late HAS incidence of 60% (mean time elapsed between transplantation to diagnosis: 91 d; range: 1-430 d). Abbasoglu *et al*<sup>[57]</sup> (1997) reported that stenosis occurred in 59% of cases at the level of the anastomosis with a median time of diagnosis at 75 d post-OLT, in 41% of cases at the level of the graft HA with a median time of diagnosis at 160 d post-OLT, and in 2.6% at the level of the recipient HA<sup>[57]</sup>. Saad *et al*<sup>[52]</sup> (2005) did not confirm these results. Indeed, the literature has established that the anastomotic stenosis is the most common place for the development of HAS within three months after LT<sup>[10,62]</sup>.

**Clinical presentation:** The clinical presentation of HAT range from normal liver function to transplant failure secondary to ischemia or necrosis. Moreover, HAS can lead to an insidious form of graft disorder, both in the early and later postoperative stages. Many patients with HAS are asymptomatic and most commonly present only with abnormal liver function tests (LFT)<sup>[16,52,57,58,60,63,64]</sup>. Indeed, Abbasoglu *et al*<sup>[57]</sup> (1997) reported that an elevation in LFT was the main clinical presentation. Most asymptomatic patients are detected during routine DUS screening. In fact, the non-specific and insidious clinical presentation of HAS mandates to perform routine

screening DUS at regular time intervals. In contrast, it is obvious that DUS screening should be highly required for OLT asymptomatic patients presenting elevated LFT.

Compared with HAT, the risks of developing biliary complications, including biliary strictures and bile leaks, are less frequent with HAS. Ideally, HAS should be diagnosed before the occurrence of biliary complications, because of the significant impact on both graft and patient survival<sup>[10,19,57]</sup>. Indeed, incidence of biliary complications is reported to be as high as 67% in liver transplant recipients with HAS<sup>[52,63,64]</sup>.

**Risk factors:** The risk factors of HAS are not really known and seem to have a multifactorial origin<sup>[60]</sup>. Many authors suggest perioperative factors (technical) of vascular injury (clamp injury, intimal dissection, faulty placement of anastomotic sutures), donor and recipient factors (excessive length with kinking and angulation, differences in vessel caliber that require oblique anastomosis), and others, such as extrinsic compression and microvascular injury, *i.e.*, vasa vasorum disruption or acute cellular rejection<sup>[52]</sup>. Abbasoglu *et al*<sup>[57]</sup> (1997) demonstrated that a low mean initial HA flow (less than 400 mL/min) after OLT is a risk factor for developing anastomotic HAS, but they did not identify a risk factor. Moreover, they showed that the presumed immunological bases, such as autoimmune hepatitis, primary biliary cirrhosis and primary sclerosing cholangitis for their OLT, were not risk factors for HAS<sup>[57]</sup>.

**Diagnosis:** DUS is a well-established non-invasive method for the assessment of HA patency, and its efficiency in the early diagnosis of HAS has been reported in several studies<sup>[52,57]</sup>. Abbasoglu *et al*<sup>[57]</sup> (1997) showed a DUS sensitivity of 85% in detecting HA stenosis. DUS showed a sensitivity of 100%, a specificity of 99.5%, a positive predictive value of 95% and a negative predictive value of 100%, and an overall accuracy of 99.5% in early HAS diagnosis<sup>[10,57,62,65]</sup>.

**Figure 2** Arteriography showing an anastomotic hepatic artery stenosis after orthotopic liver transplantation. Stenosis (arrow).

Many teams also use MDCTA and standard angiography to confirm the diagnosis, which is the gold standard for HAS diagnosis<sup>[10,62,65]</sup>.

**Therapeutic management:** The therapeutic management of HAS includes either surgical revision, retransplant or percutaneous endovascular interventions, such as PTA with or without stent placement<sup>[52,57,60,63,64,66]</sup> (Figures 2 and 3). Abbasoglu *et al*<sup>[57]</sup> (1997) reported 35 cases of surgical revision, including aortohepatic iliac artery graft (from banked donor vessels), autologous saphenous vein patch angioplasty and resection of the stenotic segment either with primary reanastomosis or with interposition of a banked iliac artery or saphenous vein graft. In this group, HA flow was reestablished successfully in all patients. At a mean follow-up of 25 mo, 67% of patients were asymptomatic with normal liver function. Six patients were treated with PTA. Five of them were found to be asymptomatic at a mean follow-up of 25 mo<sup>[57]</sup>. Indeed, balloon angioplasty can be an effective treatment option in these cases<sup>[10,19]</sup>. Similar to Abbasoglu *et al*<sup>[57]</sup> (1997), Saad *et al*<sup>[52]</sup> (2005) also reported 81% successful treatment of cases in a series of 42 cases of significant HAS treated by PTA, with an incidence of immediate complication of 7% including dissection and arterial rupture<sup>[52,57]</sup>. Delayed complications (*i.e.*, HAT) within 30 d of PTA occurred in 5% of cases, yielding a total complication rate of 12% and 12% total failed attempts without consequences. In this treatment modality, very different rates of restenosis have been reported from no restenosis to rates as high as 75%<sup>[60,63,64,67,68]</sup>. Denys *et al*<sup>[60]</sup> (2002) reported a low rate of HAT among 13 HAS patients treated by HA stent placement, which may be attributed to anticoagulation and/or antiplatelet regimens that were routinely given to their patients<sup>[52,60]</sup>. In their study, they also reported a post-HA stent placement HAT in one patient, and four patients with intra-stent restenosis in whom restenosis was dilated successfully. Other teams showed that primary stenting of the HA is feasible and offers a low complication rate with an acceptable one-year patency rate<sup>[60,69]</sup>. Ueno *et al*<sup>[69]</sup> (2006) reported an incidence of restenosis of 25% after stent placement, which is

**Figure 3** Contrast-enhanced-multidetector-row computed tomography-scan showing a hepatic artery pseudoaneurysm following orthotopic liver transplantation. Pseudoaneurysm (arrow).

significant, but Sommacale *et al*<sup>[56]</sup> (2013) demonstrated that repeated endovascular treatment of recurring HA stenosis carries a high rate of success<sup>[56,69]</sup>. However the best time for the earliest endovascular intervention after liver transplant is currently still discussed. Boyvat *et al*<sup>[66]</sup> (2008) reported endovascular intervention performed within seven days after transplant in nine patients, with a mean intervention time of 34.6 d (range: 6 h-210 d). They experienced extravasation or HAR in five patients and used graft-covered stents to solve this issue in all patients. They suggested that this technique should allow for safer endovascular intervention with no restriction time after surgery and with an acceptable benefit/risk ratio<sup>[66]</sup>. Finally, a recent published meta-analysis of case series has reported that interventional radiological procedures are often used to treat post-transplant HAS, and that PTA with balloon dilation alone or associated to stent placement are both efficacious and show similar complication rates and decrease the retransplantation rate<sup>[55]</sup>.

**Prognosis:** In the study by Abbasoglu *et al*<sup>[57]</sup> (1997) the overall mortality was 20%, mainly in the surgical revision group. Nineteen percent of patients with HAS had retransplantation with a median time of four months (range: 11 d-21 mo). It is interesting to note that among these, five had chronic rejection not diagnosed prior to HA revision, suggesting that HA stenosis should be an early sign of chronic rejection<sup>[57]</sup>. Therefore, Abbasoglu *et al*<sup>[57]</sup> (1997) recommended that every HAS patients should be screened for chronic rejection. The patient and graft survival rates at four years in the revised HA group were 65% and 56%, respectively; these rates were not significantly different from those of the control group<sup>[57]</sup>.

**Conclusion:** To conclude, HAS requiring revision is an uncommon condition after OLT. Early diagnosis by means of systematic DUS in the postoperative period and prompt revascularization procedures, with percutaneous endovascular methods with or without stent placement first, are usually successful with long-term graft and patient survival<sup>[56]</sup>. Individualized therapeutic regimens

**Table 4** Hepatic artery pseudoaneurysm highlights

Summary of the clinical characteristics about HAP
The reported incidence of HAP is ranging from 0.27% to 3% following OLT
In most cases, HAP is localized extra-hepatic and occurred in the early postoperative period around 1 mo post-OLT (69% within 20 d and 81% within 35 POD)
Clinical presentation varies from the asymptomatic state and incidental diagnosis to abdominal pain with fever and gastrointestinal bleeding (25% of cases, massive bleeding through the abdominal drain or acutely with hemorrhagic shock)
Risk factors include peritoneal infection, biliary leak, bilio-digestive anastomosis and digestive leak
Diagnosis of HAP is confirmed by DUS (with lower performance), contrast-enhanced CT scan, magnetic resonance angiography or angiography
Treatment of HAP includes reoperation (urgent laparotomy for HA ligation: Mortality rate 60%; HAP excision and immediate revascularization with a cryopreserved arterial allograft: Mortality rate 28%) or interventional radiology (HA embolization with a coil or HAP exclusion with a covered stent)
HAP has a worse prognosis with an overall mortality of more than 50% (ranging from 53% to 100%)
Early recognition of HAP in the population at high risk is mandatory and allows for a successful therapeutic outcome in 100% of cases

DUS: Doppler ultrasound; HA: Hepatic artery; HAP: Hepatic artery pseudoaneurysm; OLT: Orthotopic liver transplantation; CT: Computed tomography.

should be applied to treat HAS according to the technical platform available within transplant centers. When endovascular intervention fails to rescue arterial blood inflow, surgical revascularization should be attempted, especially if HAS is associated with biliary complications before considering retransplantation, which carries a higher mortality rate<sup>[70]</sup>. Finally, a meticulous arterial anastomosis suture with careful attention of a sufficient arterial flow into the liver transplant seems prevent this complication.

### HAP

**Definition:** HAP is defined as a dilated hepatic artery, which occurs after iatrogenic injury in most cases, causing blood to leak and pool outside the artery wall into surrounding tissue, with a persistent communication between the HA and the resultant adjacent cavity (Table 4). This is a very unusual event, with a reported incidence of 0.27%-3%<sup>[26,30,71-80]</sup>.

**Incidence:** In the retrospective cohort studied by Volpin *et al*<sup>[81]</sup> (2014) on 787 LT performed between January 1990 and 31 December 2005, a HAP incidence of 2.5% was reported, uniformly distributed over the 16-year period. The authors showed that this complication did not significantly affect any specific indication for liver transplantation. In the 16 patients that were concerned, the anatomical localization of HAP was extra-hepatic and occurred after the first liver transplant. In fact, most HAP occurred in the early postoperative period around one month post-OLT: 69% presented within 20 d and 81% within 35 d following LT. The median time of presentation of HAP was 13 d. This corresponds to the median time reported by many authors, varying from 13.4 to 29 d post-LT<sup>[26,30,78,80,81]</sup>.

**Clinical presentation:** The clinical presentation of HAP varies from the asymptomatic state and incidental diagnosis upon imaging to abdominal pain associated with fever, gastrointestinal bleeding (25% of cases), massive bleeding through the abdominal drain in the very early post-LT period (31% of cases) and acutely with hemorrhagic shock (81% of cases, the most frequent in

the series of Volpin *et al*<sup>[81]</sup>, 2014). These imply additional investigations, such as emergent abdominal imaging.

**Risk factors:** Several predisposing factors have been suggested, including peritoneal infections, technical difficulties during the completion of arterial anastomosis and biliary leak<sup>[26,30,71-83]</sup>. The rate of patients with extra-hepatic HAP and with bacterial or fungal organisms isolated from the peritoneal fluid or from the arterial wall is very high. In the series of Volpin *et al*<sup>[81]</sup> (2014), these patients accounted for 81% of the total (microorganisms cultured from the HAP wall: 50% of cases; cultured from the abdominal fluid: 31% of cases), and other authors report a rate varying from 66% to 100%<sup>[26,30,71,73-81,84,85]</sup>. Four patients of the Volpin series had a biliary leak discovered before or at the same time as HAP. Indeed, bile leak and bilio-digestive anastomosis were found to be risk factors for HAP, suggesting that enterotomy, bile and digestive leaks could be a source of peritoneal contamination, be considered very seriously and treated promptly because of the risk of HAP formation. In contrast, LDLT, reduced size, split, auxiliary LT and retransplantation were not risk factors for HAP.

**Diagnosis:** In the study by Volpin *et al*<sup>[81]</sup> (2014), the diagnosis of HAP was made by DUS, contrast-enhanced CT scan or angiography (Volpin *et al*<sup>[81]</sup>, 2014) (Figure 4).

**Therapeutic management:** Treatment of HAP can be achieved by reoperation or interventional radiology<sup>[26,75,78,81,86]</sup>. In the series of Volpin *et al*<sup>[81]</sup> (2014), five patients underwent urgent laparotomy for HA ligation; three of them died in the immediate postoperative course with a mortality rate of 60%. The two survivors had biliary complications<sup>[81]</sup>. Among patients treated by HA ligation, other authors confirmed this unfavorable outcome: 28% mortality in the series of Madariaga *et al*<sup>[73]</sup> (1992), 75% in the series of Marshall *et al*<sup>[78]</sup> (2001) and 85% in the series of Bonham *et al*<sup>[74]</sup> (1999). Moreover, this treatment exposes survivors to impaired liver function, graft loss and finally retransplantation<sup>[81,85]</sup>. Despite these poor outcomes, Boleslawski *et al*<sup>[26]</sup> (2013) reported that HA ligation without revascularization is

**Figure 4** Arteriography showing a hepatic artery stenosis due to a kinking following orthotopic liver transplantation. Kinking stenosis (arrow).

regarded as a reasonable option, with no early mortality in 10 patients with HAP rupture treated by ligation without revascularization. Six of them were still alive without retransplantation after a median follow-up of 70 mo<sup>[26]</sup>; seven patients underwent HAP excision and immediate revascularization. The arterial continuity was directly restored in five cases and cryopreserved arterial allograft conduits were interposed in two cases. In three cases, concomitant biliary complication was treated simultaneously by bilio-enteric anastomoses. Two patients died postoperatively (mortality rate of 28%). In this subgroup of treated patients, 66% of cases had an uneventful outcome, which seems to offer the best outcome in an emergency setting. Finally, two patients were treated by interventional radiology. One patient underwent embolization with a coil for deliberate HA occlusion; at 10.5 years of follow-up, this patient has good liver function without biliary complications. Another patient had HAP excision with a covered stent inserted into the HA; this patient has good liver function at 10 years of follow-up<sup>[81]</sup>.

**Prognosis:** Volpin *et al*<sup>[81]</sup> (2014) reported an overall mortality of 50%. Among patients who presented with HAP rupture, the mortality rate was 53%. The three patients treated before HAP rupture occurred are still alive after 10 years of follow-up<sup>[81]</sup>. In the literature, HAP is associated with a high mortality rate, ranging from 69% to 100%<sup>[26,30,71-81]</sup>.

**Conclusion:** To conclude, the early recognition of HAP in a high risk population (patient presenting with a documented peritoneal infection, bacteremia, bile and/or digestive leak, or bilio-digestive anastomosis) is crucial to expressly carry out diagnostic assessment and therapeutic management by percutaneous endovascular techniques first. Surgical intervention for HAP excision should be followed by immediate revascularization, even in an infected field, if endovascular management has failed. Recognition before rupture should allow a successful outcome in 100% of cases. Keeping in mind that HAP is usually asymptomatic before rupture, that

it occurs most often within the first five weeks post-LT and the poor performance of DUS<sup>[87]</sup>, Volpin *et al*<sup>[81]</sup> (2014) suggested that a contrast-enhanced CT scan or magnetic resonance angiography should be performed.

## HAR

**Definition, incidence and risk factors:** HAT is defined as a severe hemorrhage from the trunk or from a main branch of the HA. It is a very serious complication that results in the disruption of the arterial blood supply of the transplant. This is a very exceptional but a dramatic complication after OLT which carries very high incidence of liver transplant loss and high mortality rate. In most cases, this condition complicates a pseudoaneurysm of the HA, leading to major bleeding that requires emergency operation. Many reports reported the role of infectious pathogens as the cause in the development of pseudoaneurysms. Diagnosis of pseudoaneurysms is accessible with various radiological techniques, but in half of cases, HAP is not recognized before rupture, requiring immediate surgery<sup>[26]</sup> (Table 5).

In cases of acute bleeding, many therapeutic possibilities are available: endovascular intervention with embolization with or without stenting, surgical intervention for anastomotic revision, aorto-hepatic grafting, HA ligation or emergency/elective retransplantation. In case of HAR, mortality remains very high and currently there is no consensus on the indications for these procedures<sup>[26,73,78,80,88]</sup>. Boleslawski *et al*<sup>[26]</sup> (2013) published the largest series of ruptured post-transplant HAP; they highlighted the efficacy of primary HA ligation on both early and late survival. They reported an HAR incidence of 0.64% (17 patients out of 2649 OLTs from 1997 to 2007). The mean age was 47.9 years (range: 27-65 years; 13 men and 4 women). The median time between transplant and HAR occurrence was 29 d (range: 2-92 d), but the distribution of events was bimodal with only four late HA ruptures occurring after two months<sup>[26]</sup>.

**Clinical presentation and diagnosis:** In the study by Boleslawski *et al*<sup>[26]</sup> (2013), clinical presentation was always sudden hemorrhage: Hemoperitoneum in ten patients, gastrointestinal bleeding in five patients, hematoma in one patient and hemobilia in one patient. The presence of a fungal infection in the arterial wall was confirmed in six patients. Biliary leak was observed in seven patients<sup>[26]</sup>.

**Therapeutic management:** In the study by Boleslawski *et al*<sup>[26]</sup> (2013), immediate treatment included urgent laparotomy (15 patients) with definitive ligation of the HA (10 patients), anastomotic revision (3 patients) and aortohepatic grafting (2 patients). One patient had a percutaneous embolization and one patient died before treatment. Treatment of the associated biliary leak was performed either synchronously or after the first surgery in seven patients. In this series, the early mortality rate was 35% (0-80 d from HAR and 16-172 d from

**Table 5 Hepatic artery rupture highlights**

Summary of the clinical characteristics about HAR
HAT is defined as a severe hemorrhage from the trunk or from a main branch of the HA, resulting in disruption of graft arterial blood supply
This is a very rare (incidence of 0.64%) but a dramatic complication following OLT with a high mortality rate
In most cases, HAR complicates a pseudoaneurysm of the HA
The median time of HAR is 29 d (range: 2-92 d) following OLT
The clinical presentation is always a sudden hemorrhage: Hemoperitoneum, gastrointestinal bleeding, hematoma and hemobilia
Treatment comprises urgent laparotomy with definitive ligation of the HA, anastomotic revision and aortohepatic grafting or interventional radiology with percutaneous embolization

HA: Hepatic artery; HAT: Hepatic artery thrombosis; OLT: Orthotopic liver transplantation; HAR: Hepatic artery rupture.

transplantation) because of hemorrhagic relapse or sepsis<sup>[26]</sup>.

**Prognosis:** Boleslawski *et al*<sup>[26]</sup> (2013) also studied the effect of HA ligation on survival. They compared patients with ( $n = 10$ ) and without ( $n = 6$ ) HA ligation treatment. Of the 6 patients that received percutaneous embolization or revascularization, only 1 survived beyond 90 d (mortality rate: 83%). The 10 patients with HA ligation survived after postoperative day 90. Additionally, the one- and three-year graft survival rates for patients without HA ligation were 14% and 14%, respectively, vs 80% and 70%, respectively, in patients with HA ligation. The one- and three-year overall survival probabilities were 14% and 14%, respectively, in patients without HA ligation vs 100% and 80%, respectively, in patients with HA ligation<sup>[26]</sup>.

**Conclusion:** Finally, in this retrospective study, Boleslawski *et al*<sup>[26]</sup> (2013) recommended that HA revascularization should be avoided, especially when mycotic pseudoaneurysm is suspected (*i.e.*, if there was a gastrointestinal wound during liver procurement, documented systemic candidiasis prior to HAR, or if HAR occurred several weeks after transplant with associated lesions, such as biliary leak or gastroduodenal perforation). In contrast, HA ligation seems to be a reasonable life-saving option because it prevents hemorrhagic recurrence and should achieve a successful long-term outcome, with or even without retransplantation. Expected biliary complications, such as ischemic cholangitis, following HA ligation could be managed afterward by percutaneous and/or endoscopic interventions<sup>[26]</sup>.

## VENOUS COMPLICATIONS

Compared to arterial complications, venous complications are less frequent with an estimated overall incidence of less than 3%<sup>[4,5,8,9,62,89-91]</sup>. They can be potentially devastating and lead to graft failure, and therefore represent an important source of morbidity and mortality after OLT, especially if they occur in the early post-operative period<sup>[9,90,91]</sup>. Numerous literature reports have demonstrated that the incidence of venous complications in pediatric transplants is higher than in adult transplants<sup>[9,62,92,93]</sup>. Venous complications

following OLT include: Portal (1%-3%) and caval (< 2%) problems<sup>[5,8,9,91]</sup>. The etiology underlying most of these involves the anastomosis, including: (1) PVT: < 3% (the most pejorative), portal vein stenosis (PVS): 2%-3%; and (2) caval and hepatic veins with specific complications depending to the type of anastomosis either end to end caval anastomosis: Thrombosis, stenosis (< 2%); or piggyback: Thrombosis, stenosis, kinking < 2%<sup>[4,5,8,9,91,94,95]</sup>. In the same fashion as HACs, they can be classified into two categories (Table 1): Early (< 1 mo) or late (delayed, *i.e.*, > 1 mo). In the recent years, the literature has been in favor of endovascular intervention management of venous complications, with very good outcomes<sup>[8,9,10,62,91]</sup>.

### Portal vein complications

The incidence of portal vein complications (PVCs) following liver transplantation is relatively uncommon, occurring in 1% to 3% of patients<sup>[4,5,8,9,89-91,96]</sup>. These complications are associated with high morbidity and graft loss<sup>[8,9]</sup>. An another important fact to mention is that PVCs are more common with split liver and LDLT and also in pediatric transplantation<sup>[91,97]</sup>. Regarding PVCs, DUS, contrast enhanced ultrasound (CEUS) and contrast-enhanced CT are the usual tools for diagnosis; more recently, magnetic resonance venography using the gadofosveset trisodium agent has been proposed<sup>[8,9,98]</sup>. Therapeutic PVCs management ranges from thrombectomy and anastomosis revision to retransplantation depending to the delay of occurrence after OLT. Nowadays, except early PVT, endovascular procedures are now considered to be the first line treatment for post-transplant PVCs, and many studies have shown highly successful results<sup>[62,93,99,100]</sup>.

**PVT:** The incidence of PVT in OLT ranges from 0.3%-2.6%<sup>[1,90]</sup> (Table 6). From the UCLA experience, Duffy *et al*<sup>[5]</sup> (2009) reported a PVT incidence of 2% in more than 4200 patients. However, the incidence of PVT is close to 4% in adult LDLT due to technical difficulties in PV reconstructions, mainly related to a shorter vessel pedicle and limited vessel graft<sup>[101]</sup>. In LDLT, PVT occurs more frequently in the early period, defined as within 3 mo by Kyoden *et al*<sup>[101]</sup> (2008) (73% of cases from Kyoden's series; median, 58 d; range, 1-68 d).

The clinical presentation depends on the time the

**Table 6 Portal vein thrombosis highlights****Summary of the clinical characteristics about PVT**

The incidence of PVT is uncommon and ranges from < 3% following OLT  
 PVT incidence is higher in pediatric transplantation, LDLT and split liver transplantation  
 Early PVT is more frequent than late PVT with a median time to diagnosis of 5 d following OLT (range: 1 to 15 d)  
 The clinical presentation of early PVT ranges from portal hypertension manifestations (abdominal pain, ascites, gastrointestinal bleeding, splenomegaly) to severe allograft dysfunction and multiorgan failure  
 The most common causes leading to PVT are technical errors and anatomic complications such as venous redundancy, kinking and/or stenosis of the anastomosis  
 Risk factors are the presence of portal thrombosis prior OLT, small diameter of the portal vein, previous splenectomy, large portosystemic collaterals and the use of cryopreserved venous conduits for PV reconstruction  
 DUS, CEUS, contrast-enhanced CT, MRI and portography are imaging tools used for a positive diagnosis  
 PVT treatment includes systemic anticoagulation therapy, catheter-based thrombolytic therapy by percutaneous radiological intervention (transhepatic or transjugular access depending of the coagulation state) with or without stent placement to portosystemic shunting (TIPS) to retransplantation in highly unresolvable cases  
 PVT is associated with poor survival without treatment, but with prompt management, outcomes in terms of morbidity and mortality are satisfying

DUS: Doppler ultrasound; PVT: Portal vein thrombosis; OLT: Orthotopic liver transplantation; LDLT: Living donor liver transplantation; CEUS: Contrast enhanced ultrasound; MRI: Magnetic resonance imaging; CT: Computed tomography; TIPS: Transjugular intrahepatic portosystemic shunt.

thrombosis occurs. When it occurs early, severe acute liver insufficiency or graft failure predominates. If it occurs late, clinical symptoms depend of the portocaval collateral circulation existence. Portal hypertension manifestations including upper gastrointestinal bleeding due to esophagogastric varices and ascites are the most frequent clinical presentations. In contrast, liver failure is rare<sup>[30,90,96]</sup>. Langnas *et al.*<sup>[30]</sup> (1991) reported a mean diagnosis time of 5 d following OLT (range: 1 to 15 d), which was confirmed by Kyoden *et al.*<sup>[101]</sup> (2008), who reported that PVT occurred more frequently in the early period, *i.e.*, 8/11 cases (72%).

The most common causes of PVT are technical errors related to venous redundancy and kinking and/or stenosis of the anastomosis<sup>[90]</sup>. Other reported risk factors include prior surgery on the portal or splanchnic venous system or a pre-transplant portal thrombosis requiring thrombectomy during the operation, a small diameter of the portal vein (< 5 mm), previous splenectomy, hypoplastic portal vein, large portosystemic collaterals and the use of venous conduits for portal vein reconstruction<sup>[90,96]</sup>. Specific risk factors found in adult LDLT are: Small PV size, liver graft position and the type of venous conduits used to connect the PV of the donor to the recipient such as a cryo-preserved vein, the use of which is discouraged by Kyoden *et al.*<sup>[101]</sup> (2008)<sup>[30,90,96,102-105]</sup>.

DUS should be the first imaging tool used and is easily employed to evaluate vascular patency. It allows, in most cases, for an immediate non-invasive diagnosis and provides a rapid evaluation of vascular flow patency. DUS protocols vary widely worldwide among liver transplant centers, but most teams recommend performing DUS daily (some authors recommend twice daily) in the immediate post-operative period until POD 5 or in the presence of abnormalities of liver function tests or a clinical suspicion of the diagnosis<sup>[106-109]</sup>. Recently, other authors have proposed the use of CEUS to avoid frequent false-positive results after DUS<sup>[108,110]</sup>. CEUS may help in assessing the severity of portal insufficiency,

based on evidence of parenchymal perfusion status. It allows to show small thrombus in a peripheral portal branch<sup>[108,110]</sup>. In a retrospective evaluation of 23 patients, CEUS was used as an additional diagnostic method to DUS, CT and magnetic resonance imaging<sup>[110]</sup>. The authors reported new clinically relevant findings in 52% of cases, such as PVT confirmed during surgery or other radiological results.

Therapeutic options for PVT range from systemic anticoagulation to catheter-based thrombolytic therapy, to surgical revision until retransplantation. The three percutaneous options presented in the literature include transhepatic portal vein angioplasty (with or without stent placement), percutaneous thrombolytic therapy *via* transjugular intrahepatic portosystemic shunt (TIPS) creation and the transsplenic approach<sup>[111-114]</sup>. In practice, three different therapeutic situations that require specific care may be distinguished: (1) complete PVT within the first 48 h post-OLT; (2) PVT (complete or partial) at 48 h and not more than at 30 d (early PVT); and (3) after more than at 30 d (late PVT).

Early complete PVT within the first 72 h post-LT: In a patient who shows signs of multiorgan failure, surgical revision of the anastomosis is mandatory. In the presence of kinking or twisting that caused the thrombosis, anastomotic revision and systemic anticoagulation are sufficient to resolve this condition. If this procedure is unsuccessful in obtaining satisfactory portal transplant revascularization, emergent retransplantation should be indicated.

Early PVT (PVT > 72 h and < 30 d): Independently of PVT presentation (partial or complete), non-surgical treatment should be reasonably attempted. The most frequent procedure is percutaneous thrombolysis associated with stent placement<sup>[111,113,115-117]</sup>. Cherukuri *et al.*<sup>[113]</sup> (1998) reported the necessity that thrombolytic doses should be relatively low and maintained for only a few hours for efficacy and safety. Concerning the modality for stent placement, two different possibilities are described in the literature: The classical percutaneous

**Table 7 Portal vein stenosis highlights****Summary of the clinical characteristics about PVS**

The true incidence of PVS is not really known, but is thought to be < 3%  
 The major complication of PVS is the evolution to PVT if not treated  
 The majority of patients with PVS are asymptomatic and the diagnosis of stenosis is an incidental finding detected on routine DUS screening  
 Risk factors of PVS are almost exclusively represented by technical errors, particularly if a tapered anastomosis is required in the case of a vessel size mismatch between donor and recipient  
 Pre-OLT radiotherapy is another major predisposing factor of PVS  
 DUS with the finding of a stenosis ratio > 50% or a portal velocity ratio > 3:1 defines PVS. Contrast-enhanced CT and portography are used to confirm the diagnosis  
 If PVS is asymptomatic, no therapeutic intervention with close surveillance is possible, but anticoagulation therapy is recommended  
 In patients with clinical manifestations, percutaneous radiological intervention is the method of choice by transhepatic or transjugular access to perform angioplasty with or without stent placement; this prevents recurrence with a high rate of success and low rate of complications

PVT: Portal vein thrombosis; PVS: Portal vein stenosis; DUS: Doppler ultrasound; OLT: Orthotopic liver transplantation; CT: Computed tomography.

transhepatic approach and the transjugular approach. It is obvious that the latter should be preferred in patients with a coagulopathy or ascites, to minimize the risk of bleeding from transhepatic puncture<sup>[118-120]</sup>. This method has already been used in transplanted patients in the presence of decompensated cirrhosis, veno-occlusive disease or portal hypertension. The success rate with different endovascular methods ranges from 68%-100% and the mortality and morbidity rates are between 0% and 11%, respectively<sup>[121]</sup>.

Late PVT (PVT > 30 d): Two clinical presentations should be distinguished. Late PVT involving or not the superior mesenteric vein and normal liver function tests develop *de novo* hepato-portal collaterals and cavernoma formation. In these cases, observation may be justified, because of the appropriate venous inflow from the splenic circulation<sup>[19]</sup>; Late PVT with symptomatic manifestations such as acute gastroesophageal bleeding or ascites that should be treated with percutaneous or transjugular transhepatic procedures. Regarding the transjugular experience, Lodhia *et al.*<sup>[122]</sup> (2010) reported 3 cases of acute PVT occurring years following LT treated with an approach combining a TIPS and mechanical thrombectomy. To reduce the risk of periprocedural pulmonary emboli, the authors performed direct PV thrombolysis prior to placing the TIPS stent in order to allow time for clot dissolution<sup>[122]</sup>. Another possibility reported by Guckelberger *et al.*<sup>[123]</sup> (1999) was described for cases of late PVT with complete recanalization using a systemic low dose recombinant tissue plasminogen activator (rt-PA). The authors reported their experience with late PVT 45 mo after LT and justified the use of systemic low dose rt-PA lysis continuously for 10 d, along with 25000 IU heparin per day to adjust the partial thromboplastin time to favorable administration<sup>[123]</sup>. In fact, although, streptokinase (SK) and urokinase (UK) have been shown to be largely effective for thrombolytic therapies, both are characterized by limited thrombolytic potencies and major clinical disadvantages compared to rt-PA<sup>[124]</sup>. While streptokinase has a high antigenicity, both SK and UK, unlike rt-PA, lack fibrin-specific action which results in systemic consumption of plasminogen and decreased thrombolytic efficacy. Furthermore, it

may increase bleeding complications<sup>[124]</sup>.

PVT is associated with poor survival without treatment, but in cases of prompt diagnosis and adequate management, the literature shows good results in terms of morbidity and mortality.

To conclude, PVT is a rare but serious complication when it occurs in the early post-operative period. Diagnosis is mandatory as soon as possible by DUS screening protocols or with suspicious clinico-biological findings including abnormal abdominal pain and/or elevated liver enzymes and unexpected decrease PT. Surgical thrombectomy is traditionally required in the early post-operative period, but percutaneous radiological intervention has progressively become the best therapeutic option with good outcomes and safety.

**PVS**

The true incidence of PVS after LT is not really known, and the only data reported in the literature concerning the incidence of venous complications is < 3%<sup>[91]</sup> (Table 7).

When PVS occurs, it can be present with graft failure or the complication of portal hypertension<sup>[125]</sup>. In practice, the majority of patients with PVS are asymptomatic and the diagnosis of stenosis is an incidental finding detected on routine screening ultrasound. Conversely, when the patients are symptomatic, they may present with signs of portal hypertension, which include upper gastrointestinal tract bleeding from gastroesophageal varices, ascites and splenomegaly. Abnormal liver function tests are not constant, and are therefore not a reliable sign for PVS diagnosis<sup>[91]</sup>.

Regarding the risk factors of PVS, similar to PVT, it is well-established that the major concern is surgical technical errors<sup>[91]</sup>. Classically, the portal anastomosis is end-to-end and is usually simple in OLT, though a tapered anastomosis may be required when a significant size mismatch exists between the recipient and the donor, which constitutes a risk factor of stenosis. It explains in part why the pediatric population represents a population highly at risk to PVS<sup>[91]</sup>. In most cases, early PVS is the consequence of a surgical mistake due to technical difficulties in the anastomosis and could

evolve into an early thrombosis if not treated promptly. In contrast, it is assumed that late PVS is secondary to fibrosis or intimal hyperplasia<sup>[126]</sup>. Schneider *et al*<sup>[125]</sup> (2011) reported some cases of PVS after neoadjuvant radiotherapy for cholangiocarcinoma, and highlighted radiotherapy as a predisposing factor in venous complications; 21% of the patients who received a LT following the Mayo protocol for cholangiocarcinoma developed PVCs<sup>[125,127]</sup>.

Concerning a positive diagnosis, although DUS is the first screening morphological tool to use, its definition is still controversial because of the lack of definite and objective criteria. Moreover, DUS is sensitive for PVS but it is not specific. The PVS criteria for diagnosis include portal caliber size, velocities at the anastomotic site, as well as the preanastomotic and postanastomotic gradients. Recently Huang *et al*<sup>[107]</sup> (2010) reported a formula that can estimate the portal stenosis ratio in LDLT: They calculated the portal stenosis ratio (SR) = PRE-AS/PRE > 50% [anastomotic stenosis (AS); pre-stenotic stenosis (PRE)]; significant PVS was defined as a PVS with an SR > 50%. The portal velocity ratio (VR) was also calculated between AS and PRE, such that > 3:1 is defined as a significant VR value correlating with the SR evaluation. If these are confirmed, the patient should undergo contrast-enhanced CT to confirm the diagnosis<sup>[107]</sup>. Some authors consider the pressure gradient between the pre- and post-stenosis site. Wei *et al*<sup>[126]</sup> (2009) considered a gradient of > 5 mmHg to initiate treatment, while Shibata *et al*<sup>[128]</sup> (2005) used a significant gradient of > 3 mmHg. Other authors did not measure gradients if the stenosis was noted to be greater than 75% of the main portal vein diameter.

Surgical treatment, including anastomotic revision or retransplantation, is usually preferred for early portal inflow abnormalities following OLT<sup>[129]</sup>. In cases of asymptomatic patients with normal hepatic function test results, PVS may be solely observed with no therapeutic intervention<sup>[102]</sup>. In these particular cases, and in view of the possible evolution to PVT, it is reasonable to screen regularly by DUS to check for the patency of the PV. Moreover, in this condition, the use of anticoagulant therapy is still discussed and there is no international consensus or recommendation on this issue. In patients with clinical manifestations and radiological confirmation of significant stenosis, therapeutic intervention is mandatory to avoid graft loss, retransplantation and mortality. Interventional radiology has become widely recognized as the first choice for treatment for PVS after LT<sup>[103-105,111,125,126,128-132]</sup>. Regarding PVS management, it is possible to use the transhepatic access or transjugular access<sup>[133]</sup>, but most authors choose a transhepatic approach, usually from the right side. Shibata *et al*<sup>[128]</sup> (2005) reported that a single balloon dilatation was sufficient to maintain patency in 77.7% of patients, with a mean follow-up of 24.8 mo. In some series, stent placement associated with PTA was used to prevent recurrence. However, problems related to stent placement have been reported by Zajko *et al*<sup>[130]</sup> (1994),

*i.e.*, a thrombus that developed around the stent that could not be lysed, requiring retransplantation. However, Ko *et al*<sup>[129]</sup> (2007) reported on their experience in PVS management by percutaneous transhepatic primary stent placement after LDLT. In this series, technical and clinical success was obtained in 77.8% by using this method with a complication rate of 33% (including hemoperitoneum caused by blood oozing from the transhepatic tract and intrahepatic pseudoaneurysms)<sup>[129]</sup>. Finally, regarding the recurrence rate, this ranges between 0%-100%. Shibata *et al*<sup>[128]</sup> (2005) reported the most important series in the literature where the recurrence rate was 28.6%. Some authors recommend the use of anticoagulant therapy for the prevention of recurrent PVT<sup>[134]</sup>. Recently, Sanada *et al*<sup>[134]</sup> (2010) concluded that the use of three anticoagulant therapies, *i.e.*, low-molecular-weight heparin, warfarin and aspirin, significantly reduced the recurrence of thrombosis with a median follow-up of three months<sup>[134]</sup>. Additionally, some authors have coupled endovascular treatment with surgical PV access<sup>[106]</sup>.

To conclude, PVS represents an uncommon venous complication following OLT. This condition is more specific to pediatric LT and LDLT. As described earlier, a DUS screening protocol is an important diagnostic tool to help the clinician because the majority of asymptomatic cases can progress until PVT if not promptly treated, with negative effects on the prognosis of the graft and ultimately patient survival. Currently, it is obvious that percutaneous transhepatic radiological intervention with stent placement is the method of choice to address this complication with a high rate of success and a low rate of recurrence and/or complications.

### Caval vein complications

Currently, transplant outflow obstruction by kinking, stenosis or thrombosis of the inferior vena cava (IVC) or hepatic vein, especially in LDLT, are relatively uncommon complications following liver transplantation with an reported incidence of less than 3%<sup>[94,95]</sup> (Table 8 and Figure 5).

Clinical presentation ranges from lower limb edema, hepatomegaly, ascites, pleural effusions, Budd-Chiari syndrome, liver and renal failure to hypotension leading to allograft loss and multiorgan failure<sup>[4,89,135]</sup>.

The main risk factor leading to caval anastomosis complications (CACs) is represented by technical errors in the connection of caval anastomoses, which lead to kinking or thrombosis in the early post-operative course. In the late post-operative period, chronic stenosis in the anastomotic area is the result of fibrosis, hyperplasia and/or extrinsic compression from the enlarged liver graft<sup>[2,136,137]</sup>.

Diagnosis should be achieved by DUS, contrast-enhanced CT, and finally by cavography which allows for providing treatment.

Many techniques for caval anastomosis connection can avoid these complications, such as piggyback (PB) and subsequently modified-PB, first described by Starzl

**Table 8 Caval anastomosis complication highlights****Summary of the clinical characteristics about CAC**

The incidence of CAC is not known and is thought to be less than 3%  
 CAC is represented by stenosis, thrombosis and kinking depending on the type of caval anastomosis (cava resection or PB)  
 Clinical presentation of CAC ranges from lower limb edema, hepatomegaly, ascites, pleural effusions, Budd-Chiari syndrome, liver and renal failure, and hypotension, leading to allograft loss and even death  
 The main risk factor is a technical error in the creation of the anastomosis, which leads to kinking stenosis and thrombosis  
 Modified-PB with the three-hepatic vein seems to offer better outcomes because it has been demonstrated to be an efficient and safe method  
 Diagnosis tools include DUS, contrast-enhanced CT and cavography  
 Percutaneous radiological intervention is the method of choice *via* a transjugular approach or transhepatic approach if the anastomosis cannot be catheterized  
 It includes angioplasty by balloon dilatation and recurrences should be prevented by stent placement

CAC: Caval anastomosis complication; DUS: Doppler ultrasound; CT: Computed tomography; PB: Piggyback.

**Figure 5** Contrast-enhanced-multidetector-row computed tomography-scan showing median and left thromboses hepatic veins following orthotopic liver transplantation (arrow).

*et al.*<sup>[138]</sup> (1968). The method described by Starzl *et al.*<sup>[138]</sup> (1968) consists of a complete resection of the recipient IVC and interposition of the donor intrahepatic part of the vena cava with two end-to-end anastomoses<sup>[138-144]</sup>. The preservation of the recipient IVC with the PB technique has been associated with an increased risk of suprahepatic IVC thrombosis or stenosis, leading to acute or chronic Budd-Chiari syndrome in 0% to 1.6%, venous congestion of the liver allograft in 1%, and with an increased incidence of post-transplant ascites<sup>[89,135]</sup>. To avoid such complications, techniques for optimizing outflow with the piggyback technique have been described; the main of these in undoubtedly the width of the caval anastomosis, while other authors have reported methods using either the two-vein or the three-vein technique for anastomosis with a low rate of CACs<sup>[89,94,135,145-149]</sup>. Finally, several studies have demonstrated the superiority of modified-PB with the three-hepatic vein technique, which should be routinely used in OLT because it is safe and efficient and involves few surgical complications<sup>[89,94,143]</sup>. Hepatic venous stenosis is specific to LDLT with an incidence of 2% to 4%, because of the different techniques of donor graft outflow venoplasty, leading to Budd-Chiari syndrome or outflow block syndrome after LDLT<sup>[150]</sup>.

Therapeutic management of CACs depends on the time of the presentation and the delay following OLT. In

the case of severe allograft dysfunction or multiorgan failure, retransplantation is always indicated. Beyond this particular situation, percutaneous radiological intervention is the method of choice, where mortality after interventional transplant salvage procedure is 11.1% as compared with 41.6% mortality for those patients managed by retransplantation<sup>[121,137]</sup>. Treatment can be performed by transjugular approach, but percutaneous transhepatic access may be necessary when the anastomosis cannot be catheterized from the jugular access. Angioplasty by balloon dilatation can restore anastomotic patency in almost 100% of cases, but recidive of stenosis is frequent and repeat angioplasties may be applied<sup>[137]</sup>. PTA associated with stent placement may be the better solution with a high rate of success ranging from 73% to 100% in the literature; this technique is safe and apparently durable<sup>[121,130,136,137,151-157]</sup>.

To conclude, the incidence of CACs is very low, and particular attention should be paid to the caval anastomosis connection. Currently, modified-PB using the three-hepatic vein technique seems to show better outcomes. As with other VCs, prompt diagnosis and management are required if the patient is clinically symptomatic. The percutaneous endovascular method should be attempted to rescue the outflow patency, reserving surgical revision in unresolvable cases and ultimately retransplantation in patients presenting multiorgan failure.

## CONCLUSION

VCs continue to be a major problem following transplantation with a relatively frequent incidence (7%). They carry a high rate of morbidity and mortality, especially if they occur in the immediate post-operative period (first month) and if diagnosed late. The only solution to reduce their gravity is to prevent it by controlling risk factors and, if this is not possible, to diagnose them as early as can be, even in asymptomatic or paucisymptomatic patients. Many transplant teams worldwide advocate the routine use of complementary explorations such as DUS and, if in doubt, a contrast-enhanced CT scan or classical arteriography, which is

the reference. Currently, if recognized promptly, and if there is no graft or multiorgan failure, endovascular treatment should be attempted first if a technical plateau is available, because this has demonstrated efficacious and safe outcomes. Conversely, if there are severe liver repercussions, the most efficient therapeutic procedure is an emergency retransplant which shows better outcomes in terms of efficacy and survival, but the organ shortage dramatically limits this therapeutic option.

### Abstract

The aim of liver transplantation (LT) for hepatocellular carcinoma (HCC) is to ensure a rate of disease-free survival similar to that of patients transplanted due to benign disease. Therefore, we are forced to adopt strict criteria when selecting candidates for LT and prioritizing patients on the waiting list (WL), to have clarified indications for bridging therapy for groups at risk for progression or recurrence, and to establish certain limits for downstaging therapies. Although the Milan criteria (MC) remain the standard and most employed criteria for indication of HCC patients for LT by far, in the coming years, criteria will be consolidated that take into account not only data regarding the size/volume and number of tumors but also their biology. This criteria will mainly include the alpha fetoprotein (AFP) values and, in view of their wide variability, any of the published logarithmic models for the selection of candidates for LT. Bridging therapy is necessary for HCC patients on the WL who meet the MC and have the possibility of experiencing a delay for LT greater than 6 mo or any of the known risk factors for recurrence. It is difficult to define single AFP values that would indicate bridging therapy (200, 300 or 400 ng/mL); therefore, it is preferable to rely on the criteria of a French AFP model score > 2. Other single indications for bridging therapy include a tumor diameter greater than 3 cm, more than one tumor, and having an AFP slope greater than 15 ng/mL per month or > 50 ng/mL for three months during strict monitoring while on the WL. When considering the inclusion of patients on the WL who do not meet the MC, it is mandatory to determine their eligibility for downstaging therapy prior to inclusion. The upper limit for this therapy could be one lesion up to 8 cm, 2-3 lesions with a total tumor diameter up to 8 cm, or a total tumor volume of 115 cm<sup>3</sup>. Lastly, liver allocation and the prioritization of patients with HCC on

the WL should take into account the recently described HCC model for end-stage liver disease, which considers hepatic function, HCC size and the number and the log of AFP values. This formula has been calibrated with the survival data of non-HCC patients and produces a dynamic and more accurate assessment model.

**Core tip:** This article aims to provide clinicians who treat patients with hepatocellular carcinoma, in whom liver transplantation may be indicated, with an actualized tool that considers a combination of morphological (size and number of tumors) and biological data (alpha fetoprotein value) and that facilitates the process of selecting candidates, predicts the indication of and response to neoadjuvant therapy prior to transplantation and also aids in the prioritization of patients once they are on the waiting list.

Selection of patients with hepatocellular carcinoma for liver transplantation: Past and future. *World J Hepatol* 2016; 8(1): 58-68 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i1/58.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i1.58>

## INTRODUCTION

Hepatocellular carcinoma (HCC) is a major global health problem. It is the sixth most common cancer worldwide<sup>[1]</sup> and the third most common cause of cancer death<sup>[2]</sup>. Without treatment, the 5-year survival rate is 10%-12%<sup>[3,4]</sup>. In the early stages, curative treatment includes resection, radiofrequency ablation and liver transplantation (LT). The latter technique remains the most effective treatment method in cases of early HCC because it jointly eliminates the tumor and the underlying disease and shows 1- and 5-year survival rates of 85% and 70%, respectively<sup>[5]</sup>. However, LT does not completely eliminate the possibility of recurrence, which is still a serious problem; therefore, it is discussed in this review.

## DIAGNOSIS

In the last decade, great improvements in HCC diagnosis<sup>[6]</sup> have occurred, which are mainly based on imaging tests. In recent years, HCC has been diagnosed earlier<sup>[7]</sup>, and due to the improvements in imaging tests, a progressive decline in the use of alpha fetoprotein (AFP) levels for the surveillance of HCC in cirrhotic patients<sup>[6,8,9]</sup>

has occurred owing to their lack of appropriate sensitivity and specificity<sup>[8]</sup>.

For lesions less than 1 cm, ultrasonography is repeated every three months, and for lesions larger than 1 cm, a typical image (arterial hypervascularity and venous delayed phase wash out) can be used to confirm the diagnosis<sup>[8]</sup> because this method is 100% specific, with a very high predictive value<sup>[10]</sup>. When a surveillance test is positive, a more definitive noninvasive imaging exam is recommended. Recent guidelines endorse multiphasic computerized tomography (CT) and magnetic resonance imaging (MRI) with hepatobiliary agents as first-line modalities for this purpose. Both modalities provide excellent sensitivity for nodular HCCs larger than 2 cm, modest sensitivity for 1-2-cm HCCs, and poor sensitivity for HCCs smaller than 1 cm. However, MRI is emerging worldwide as a leading method for the diagnosis and staging of HCC, and it is the most sensitive method for the detection of small HCCs<sup>[11]</sup>. However, the combination of dual-phase CT-angiography in the arterial and portal phase with positron emission tomography (PET) imaging using (18)F-fluorodeoxyglucose [(18)FDG] appears to be a sensitive method for the detection of HCC with the alternative presence of hypervascularity or hyperaccumulation of (18)FDG<sup>[12]</sup>.

If the radiological pattern is not typical, the test should be repeated. If the result does not meet the criteria for HCC, a biopsy of the lesion can be performed while taking into account that a negative finding after a biopsy does not exclude HCC<sup>[1]</sup>, and the possible complications of a biopsy such as hemorrhage and needle track tumoral implant should be considered<sup>[13]</sup>. Although in a recent, long retrospective series the incidence of HCC was only 0.2%<sup>[14]</sup>, in a meta-analysis the incidence was 2.7% overall or 0.9% per year<sup>[15]</sup>.

## STAGING

The TNM classification, which is widely accepted for the staging of cancer, for HCC has a lower capacity to predict long-term survival<sup>[16]</sup>. For this reason, the Barcelona Clinic Liver Cancer (BCLC) staging and treatment strategy is most often used<sup>[9,17]</sup> because it includes information concerning the tumor, hepatic function and the general clinical status<sup>[18]</sup>. However, in spite of these facts, the TNM classification is used as the reference for pathological studies of surgical specimens.

## SELECTION OF CANDIDATES WITH HCC FOR LT

The aim of LT for HCC is to obtain a level of disease-free survival (DFS) similar to that of patients who are transplanted for benign disease; therefore, we are obliged to adopt strict selection criteria for candidates, with the intention of obtaining the maximum survival with the minimum possible recurrence.

**Table 1 Isolated biological criteria for the selection of candidates with hepatocellular carcinoma for liver transplantation**

### Isolated biological criteria for the selection and prognosis of patients with HCC for LT

More than a decade ago, several authors noted the importance of the isolated AFP value in predicting mortality and/or posttransplant recurrence. High AFP values may be a marker for vascular invasion or extra hepatic disease that has escaped detection by conventional imaging techniques. It has been observed that a pretransplant AFP level higher than 300 ng/mL is the only factor independently associated with mortality after LT<sup>[19]</sup>, and a level higher than 1000 ng/mL is a significant predictor of reduced survival<sup>[16]</sup>. In general, HCC patients on the waiting list (WL) with a baseline serum level of AFP > 200 ng/mL display significantly worse outcomes<sup>[20]</sup>; however, several detrimental cut-off values for AFP levels have been reported recently. Xu *et al*<sup>[21]</sup> found that pre-transplant AFP levels > 400 ng/mL were associated with higher tumor recurrence. Mailey *et al*<sup>[22]</sup> classified patients into low ( $\leq 20$  ng/mL), medium (20-399 ng/mL), or high ( $\geq 400$  ng/mL) AFP level groups. In a multivariate analysis, the medium and high AFP groups were associated with higher mortality. Another study<sup>[23]</sup> correlated the DFS and 5-year recurrence rate to the AFP level. Normal AFP values between 10-150 ng/mL, those from 150-500 ng/mL and those > 500 reduce DFS from 71% to 57%, 46% and 28%, respectively, and increase the recurrence rate from 4% to 10%, 24% and 62%, respectively. Recently, it was shown once again that an AFP level > 1000 ng/mL is a reason for exclusion from the WL<sup>[24,25]</sup>, confirming data reported in 2001<sup>[16]</sup>. However these data have not been taken into account by programs using expanded criteria that only consider an AFP level greater than 10000 ng/mL as a reason for exclusion<sup>[26]</sup>. This matter will be further examined when discussing the indications for downstaging of HCC prior to LT (Table 1).

In Japan, des-gamma carboxy prothrombin (DCP) is well established as a biomarker and is reported to

**Table 2 Selection criteria base on radiological/morphological tumor characteristics**

Ref.	Parameters	Importance
Bismuth <i>et al</i> <sup>[30]</sup>	Up to 3 nodules Each < 3 cm	Best results
Mazzaferro <i>et al</i> <sup>[31]</sup>	Single lesion < 5 cm	DFS > 75%
	< 3 lesions, each < 3 cm	Recurrence < 15%
	No macrovascular invasion	
	No extrahepatic disease	
Löhe <i>et al</i> <sup>[34]</sup>	Single tumor with size > 5 cm	Reduction in DFS
Yao <i>et al</i> <sup>[16]</sup>	Single lesion $\leq 6$ cm	DFS > 75%
	2-3 lesions each $\leq 4.5$ cm	Recurrence < 15%
	Total tumor diameter $\leq 8$ cm

	Abscissas: Tumor size	
Mazzaferro <i>et al</i> <sup>[42]</sup>	Up to 7, as the sum of: Largest tumor in centimeter and <i>n</i> of tumors	71.2% 5 yr survival
Jang <i>et al</i> <sup>[46]</sup>	10 as the sum of: Largest tumor in cm and <i>n</i> of tumors	If >: Decreased DFS

DFS: Disease-free survival.

correlate with post-LT recurrence of HCC<sup>[27,28]</sup>. We cannot predict whether new molecular markers of HCC such as PIVKA-II, a protein induced by the absence of Vit K, will have widespread use, but Japanese studies suggest that it is correlated with microvascular invasion<sup>[29]</sup>.

### Selection criteria based on radiological/morphologic tumor characteristics

Some criteria include the number and size of the tumors and the tumor volume.

**Criteria based on number and size:** In 1993, Bismuth *et al*<sup>[30]</sup> noted that patients transplanted for HCC with up to 3 nodules (each < 3 cm) exhibited the best results. In 1996, the Milan criteria (MC)<sup>[31]</sup> set clear limits on the selection of HCC patients for LT, consisting of a single lesion < 5 cm or fewer than three lesions, each < 3 cm and without macrovascular invasion or extrahepatic disease, which resulted in 5-year DFS > 75% and a recurrence rate < 15%<sup>[31]</sup>. Since that time, these standard selection criteria for LT due to HCC have been accepted worldwide<sup>[20,32,33]</sup>. Other authors have confirmed that a single tumor with a size > 5 cm causes a reduction in DFS<sup>[34]</sup>. The MC have received criticism because the radiological studies used for evaluations are not very accurate<sup>[35]</sup> and highly variable between centers. In addition, some authors have argued that these criteria are strict<sup>[20]</sup>, with tumor size and tumor number cut-offs that are somewhat arbitrary and too restrictive, and that they deprive patients of the possible benefit of LT<sup>[36]</sup> and therefore should be extended<sup>[16,37,38]</sup> (Table 2).

Thus, in 2001 the so-called expanded criteria of the University of San Francisco, California (UCSF) were proposed by Yao *et al*<sup>[16]</sup>, which set the limit for LT to a single lesion  $\leq 6.5$  cm in diameter or 2-3 lesions each  $\leq 4.5$  cm with a total maximum diameter  $\leq$

8 cm, thus obtaining similar survival after LT to that obtained with the MC. These criteria were criticized because in this study, only 24% of the patients did not meet the MC<sup>[39]</sup>, and because it was a retrospective study based on the histology of explants<sup>[40]</sup>. By that time, Mazzaferro<sup>[41]</sup> had introduced the concept of the Metroticket calculator, a system of orderly Cartesian ordinates (number of tumors) and abscissa (tumor size) in which the progressive reduction of 5-year survival is graphically represented as these parameters increase, leading to the expression “the longer the trip, the higher the price”. In 2009, Mazzaferro *et al*<sup>[42]</sup> found that a total tumor diameter greater than 7 cm resulted in an increase in the percentage of recurrence and proposed a new MC (the so-called up-to-seven), using seven as the sum of the size of the largest tumor (in centimeter) and the number of tumors, which yielded 5-year overall survival of 71.2%. Many groups have validated these criteria<sup>[43,44]</sup>, but after 5 years, they have not been accepted as widely as the MC. Other authors have made similar suggestions<sup>[45]</sup>, however, others have placed this limit at 10 cm, which results in a decrease in DFS<sup>[46]</sup>. This value should be universally accepted as the upper limit<sup>[26]</sup>. The expanded criteria require further validation because recurrence could be less often reported, increasing the risk of vascular invasion, microsatellites and poorly differentiated tumors<sup>[35,47,48]</sup>.

**Morphological criteria based on the total tumor volume:** Toso *et al*<sup>[37]</sup> calculated the total tumor volume (TTV) as the sum of the volumes of all tumors using the formula  $(4/3) \pi r^3$ , where  $r$  is the maximum radius of each tumor. The radiological accuracy of this formula was greater, and based on the risk of recurrence, a threshold of 115 cm<sup>3</sup> was established, which allowed the selection of more patients for LT with results similar to those of the MC and UCSF criteria<sup>[37]</sup>. According to this mathematical formula, the largest tumor has the maximum importance. As a result, the possibility of correct staging increases because larger tumors are evaluated more accurately than smaller ones.

Expansion of the MC may be justified in regions with less organ shortage, but this will require demonstrating high survival rates for the newly eligible patients<sup>[49]</sup>. Regional variation in survival does not facilitate a national policy<sup>[50]</sup>, but it is undeniable that in the USA, 97% of patients transplanted for HCC meet the MC<sup>[51]</sup>,

and although this number has changed somewhat recently, the number of inclusions for patients for LT that do not meet the MC is still less than 5%<sup>[52]</sup>. It should be mentioned that until very recently, the criteria used in the United Kingdom for LT for HCC considered a maximum tumor diameter up to 15 cm (up to 5 tumors all  $\leq 3$  cm), which is well beyond the limit of the MC and UCSF criteria<sup>[26]</sup>.

### Selection criteria based on functional/radiological features of the tumor:

Dynamic MRI may constitute a non-invasive and promising method to assess the biology of HCC due to its greater avidity of contrast uptake, which implies a higher degree of microscopic vascular invasion and greater aggressiveness<sup>[53,54]</sup>. Tumors that are heterogeneously hyperintense in the hepatobiliary phase on gadoteric acid-enhanced MRI have more malignant potential than other types of HCC<sup>[55]</sup>. Other authors<sup>[56]</sup> have used 18F-fluorodeoxyglucose positron emission tomography/computed tomography (18F-FDG PET/CT) not only for detection<sup>[12]</sup> but also as a prognostic factor, which distinguishes between well and poorly differentiated HCC<sup>[12]</sup>. High positivity of HCC increases the risk of early recurrence after curative resection<sup>[56]</sup>, and the maximum standardized uptake value (mSUV) of 18F-FDG PET/CT reflects the existence of distant microsatellites; therefore, it can be a useful tool in the treatment protocol of HCC<sup>[57]</sup>. In a comparison of two groups of transplanted patients who did not meet the MC, other authors<sup>[58]</sup> found that patients with positive PET findings had significantly lower survival than PET negative patients (Table 3).

### Combined morphological and biological tumor parameters:

Adequate patient selection should be based on tumor biology assessed *via* serum or pathological parameters rather than on the macro morphology of HCC<sup>[59]</sup>. In fact, the aggressiveness of a tumor can be determined by a higher histological grade and greater microscopic vascular invasion, and a biopsy can be used to predict DFS. The Toronto criteria<sup>[60]</sup> select patients with HCC for LT who do not meet the MC by biopsy exclusion of poorly differentiated tumors, resulting in 5-year overall survival (OS) and DFS values of 70% and 66%, respectively, which are similar to those of the MC (72% and 70%, respectively). However, there is little correlation between the biopsy and

**Table 4 Combined morphological/biological selection criteria**

Ref.	Parameters	Importance

TTV: Total tumor volume; AFP: Alpha fetoprotein; MC: Milan criteria; LT: Liver transplantation.

histology of an explant due to tumor heterogeneity and because, in multifocal disease, the dominant lesion is not always the most biologically representative. For these reasons, currently, the biopsy has a limited role in pre-LT staging<sup>[61]</sup> (Table 4).

In 2009, Toso *et al*<sup>[52]</sup> found that only the TTV and AFP levels predicted survival and established a composite score with a TTV > 115 cm<sup>3</sup> or AFP > 400 ng/mL as limits for indication for transplantation because patients with greater values for these parameters had 3-year survival rates < 50%.

Using a multivariate analysis, Lai *et al*<sup>[62]</sup> found that an AFP level > 400 ng/mL and a total tumor diameter > 8 cm were the strongest predictors for recurrence.

Recently, Duvoux *et al*<sup>[63]</sup> generated an improved prognostic model for predicting recurrence in LT candidates with HCC. A prognostic score was developed and validated prospectively. The AFP level independently predicted tumor recurrence and was correlated with vascular invasion and differentiation. A model combining the log10 value of the AFP, tumor size and number of tumors was highly predictive of tumor recurrence and death. Using a simplified version of the model with untransformed AFP values, a cut-off value of 2 was identified. In the validation cohort, a score greater than 2 predicted a marked increase in 5-year risk of recurrence and decreased survival. Among patients who exceeded the MC, a score of 2 or lower identified a subgroup of patients with AFP levels less than 100 ng/mL and a low 5-year risk of recurrence. In contrast, for patients who met the MC, a score greater than 2 identified a subgroup of patients with AFP levels greater than 1000 ng/mL and a high risk of recurrence. We will refer to this as the French model.

Our group<sup>[64]</sup>, based on our previous experience with LT for patients with HCC and cirrhosis, has performed an analysis of the risk factors for HCC relapse and applied the French AFP model to LT for HCC and cirrhosis patients who met the MC<sup>[65]</sup>. We were able to confirm the predictive value for tumor relapse of the French AFP model both pre- and postoperatively.

Berry *et al*<sup>[66]</sup> established that the AFP level, rather than the tumor burden, was most strongly associated with posttransplant survival. Thus, patients with HCC and AFP levels < 15 ng/mL at the time of transplantation

did not exhibit excess posttransplant mortality; increases in AFP (16-65 ng/mL; 66-320 ng/mL and > 320 ng/mL) result in progressively worse posttransplant mortality than similar increases in recipients without HCC. Patients who did not meet the MC showed excellent survival if their AFP level was < 15 ng/mL. In contrast, patients who met the MC exhibited poor survival if their serum AFP level was substantially elevated (serum AFP ≥ 66 ng/mL). AFP changes while on the WL closely corresponded to changes in posttransplant mortality. Not only the absolute serum AFP level but also changes in this level strongly predicted posttransplant survival independently of tumor burden.

These models, combining data related to the tumor (size and number of tumors) with preoperative levels of AFP, had previously been studied by Japanese authors<sup>[67]</sup> in living-donor liver transplant (LDLT) patients (Table 5). In these models, a value of 1 to 4 points (p) was assigned to each of the following parameters: tumor size: ≤ 3 cm (1 p), 3.1-5 cm (2 p), 5.1-6.5 cm (3 p), > 6.5 cm (4 p); number of tumors: 1 (1 p), 2-3 (2 p), 4-5 (3 p), > 5-6 nodules (4 p); AFP: ≤ 20 ng/mL (1 p), 20.1-200 ng/mL (2 p), 200.1-1000 ng/mL (3 p), and > 1000 ng/mL (4 p). Candidates with 3-6 total points were "transplantable" and those with 7-12 points were "non-transplantable". In Japan and other Asian countries, due to the severe organ shortage, LDLT comprises the majority of LT<sup>[68]</sup>. Each center has developed and proposed expanded selection criteria based on institutional and regional experience, which vary from the model of Tokyo University<sup>[68]</sup>, which only considers morphological tumor parameters, *i.e.*, up to 5 nodules with a maximum diameter ≤ 5 cm, without taking into account any biological markers. The Kyoto group<sup>[69]</sup> considers patients with less than 10 nodules, all less than 5 cm, with a DCP level < 400 mAU/mL, and the Kyushu group<sup>[70]</sup> also use extended criteria without limiting the number of nodules but require a maximum tumor diameter less than 5 cm and DCP levels under 300 mAU/mL.

## ORGAN ALLOCATION FOR LT

The allocation of organs for LT follows criteria of prioritization that have varied throughout the history

**Table 5** Japanese combined morphological/biological selection criteria for living-donor liver transplant

Ref.	Parameters					Importance: Limits for LDLT
	Value	1p	2p	3p	4p	
Yang <i>et al</i> <sup>[67]</sup>	T size (cm)	≤ 3	3.1-5	5.1-6.5	> 6.5	Patients with 3-6 points are transplantable Those with 7-12 points are not transplantable
	<i>n</i> of tumors	1	2-3	4-5	> 5 or 6	
	AFP (ng/mL)	< 20	20-200	200.1-1.000	< 1.000	
Akamatsu <i>et al</i> <sup>[68]</sup>	Up to 5 nodules					Upper limit for LDLT
Kaido <i>et al</i> <sup>[69]</sup>	Maximum diameter ≤ 5					Upper limit for LDLT
	Less that 10 nodules, all < 5 cm					
	DCP < 400 mAu/mL					
Shirabe <i>et al</i> <sup>[70]</sup>	<i>n</i> of nodules: No limit					Upper limit for LDLT
	Maximun diameter: < 5 cm					
	DCP < 300 mAu/mL

of LT, from prioritization of the more serious patients based on the Child-Turcotte-Pugh score and the time of inclusion on the WL to the more recent model for end-stage liver disease (MELD) score. However, because this method does not consider the risk of neoplastic growth while on the WL, HCC patients are prioritized based on their exception points and the MELD exception, with the goal of obtaining similar WL mortality for neoplastic and non-neoplastic patients. Exception points are assigned every 3 mo<sup>[36]</sup> because progression of HCC can produce a 15% increase in mortality<sup>[71]</sup>. Paradoxically, several years later, it was found that the likelihood of undergoing transplantation was higher for HCC candidates than for other patients<sup>[72]</sup>, which produced a clear disadvantage for non-HCC patients<sup>[73]</sup>. For this reason, the "HCC-MELD" equation ( $1.27/\text{MELD} - 0.51/\log\text{AFP} + 4.59$ ) has been proposed<sup>[74]</sup>, which takes into account hepatic function and the log of the AFP value, and has been calibrated to the survival of non-HCC patients. This formula gives additional points to patients with HCC, not arbitrarily, but based on a calculation of the benefits of transplantation, in a manner similar to that for patients without HCC. Other authors<sup>[73]</sup>, with a similar aim, have studied and validated a new and promising model for allocation of patients using a large cohort in the United States and United Kingdom that includes: HCC size, HCC number, AFP value, and the classic MELD score calculated according to the following formula:  $\text{New MELD} = -37.8 + 1.9 \times \text{MELD} + 5.9$  (if HCC number  $\geq 2$ ) + 5.9 (if AFP level > 400 ng/mL) + 21.2 (if HCC size > 1 cm). This new model provides a dynamic and more accurate assessment of dropout than the use of the MELD exception, showing a distribution similar to that of the MELD for non-HCC patients. Both scores could be used in parallel for the management of WL patients with and without HCC.

## NEOADJUVANT TREATMENT OF PATIENTS ON THE WL (BRIDGING AND DOWNSTAGING TREATMENTS)

HCC patients who meet the MC and are included on the

WL should be monitored every 3 mo by CT/MRI and AFP level evaluation for the identification of those at high risk of dropout<sup>[75]</sup>. AFP progression while on the WL<sup>[66]</sup>, and more specifically an AFP increase of > 15 ng/mL per month, is the most relevant preoperative prognostic factor for low OS and DFS<sup>[76]</sup>. For patients with changes in tumor size and/or an increase of in the AFP level > 50 ng/mL, locoregional therapy (LRT) or removal of the patient from the WL should be performed, if necessary<sup>[77]</sup>.

### Bridging therapy

Bridging therapy is used for patients with HCC who meet the MC and are included on the WL but have the possibility of a delay in LT > 6 mo. Its purpose<sup>[78]</sup> is to prevent tumor progression<sup>[79]</sup>, reduce the recurrence of HCC after LT and increase posttransplant survival. As the waiting time for LT has progressively increased<sup>[79]</sup>, treatment of HCC in patients awaiting LT has become routine<sup>[80]</sup>. Bridging is not indicated for tumors that meet the current MC, except for those with a diameter greater than 3 cm or patients with more than 1 tumor, because these patients are more likely to have recurrence after LT<sup>[81]</sup>.

The most employed method of LRT for bridging therapy is percutaneous ablation<sup>[1]</sup>, which is frequently performed by radiofrequency (RF) and less often performed by ethanolization (ET) or surgery. ET and RF have similar effectiveness for tumors less than 2 cm, but with increased tumor size, RF is more effective and shows similar results to surgery. In lesions > 3 cm, ET failures increase; therefore, it is rarely used as bridging therapy<sup>[82,83]</sup>.

Patients with small solitary tumors and very well preserved liver function are the best candidates for surgical resection<sup>[1]</sup>, but tumor recurrence complicates 70% of cases at 5 years<sup>[6]</sup>. Certain favorable locations, such as peripheral tumors and left hepatic lobe location, may allow laparoscopic resection, which avoids the greater complexity of transplantation after laparotomic surgery. Resection may offer improved local tumor control and allows full microscopic analysis, with subsequent study of its biological aggressiveness, which

could lead to subsequent elective LT. Subsequent tumor recurrence after resection is an absolute indication for LT; this so-called salvage transplantation was first described by Majno *et al.*<sup>[84]</sup> in 2000. This procedure requires fewer donors and allows better management of the WL.

### Downstaging

Downstaging<sup>[78,79]</sup> is used to convert tumors that initially do not meet the transplant criteria, usually intermediate multinodular asymptomatic tumors (stage B of the BCLC)<sup>[6]</sup>, into tumors that meet the MC (the most frequent endpoint), UCSF criteria or the up-to-seven criteria, with the aim of including the patients on the WL once the tumor has decreased in size. Tumors with more favorable histology are more likely to respond to treatment and exhibit a good outcome after LT<sup>[85]</sup>. The eligibility criteria for downstaging should have an upper limit, which can be set as follows<sup>[85]</sup>: (1) one lesion > 5 cm and up to 8 cm; (2) two to three lesions with at least one lesion > 3 cm and not exceeding 5 cm, with a total tumor diameter up to 8 cm; or (3) four to five lesions with none > 3 cm, and a total tumor diameter up to 8 cm.

The LRT technique depends on each center, and the response is evaluated by the Response Evaluation Criteria in Solid Tumors (RECIST) or the modified RECIST (mRECIST)<sup>[86]</sup>, which we will further discuss later. Once the treatment is completed, it is mandatory to follow the "ablate and wait policy"<sup>[81]</sup>, with close monitoring for at least 3 mo before inclusion on the WL<sup>[50,85]</sup> to evaluate the tumor's behavior and exclude aggressive tumors from LT; therefore, a total of six months will elapse until transplantation<sup>[81]</sup>.

Some authors<sup>[87]</sup> have attempted to perform a meta-analysis of HCC downstaging, which has been impossible due to many factors such as the great variability of the inclusion criteria protocols<sup>[79]</sup>, variability of post-treatment response assessment and absence of histological information on tumor biology<sup>[87]</sup>. At the moment, there is no evidence that patients submitted to downstaging followed by LT have a worse prognosis than those who initially meet the MC. Therefore, we must assume that those patients should be eligible for LT, as if they had been from the start<sup>[87]</sup>, and will show an excellent posttransplantation outcome<sup>[85]</sup>, reaching 5-year survival rates comparable to those of patients who meet the MC or UCSF criteria and do not require downstaging<sup>[75,88]</sup>.

Trans-arterial chemoembolization (TACE) is the form of LRT most often used for downstaging<sup>[75]</sup>, followed by RF ablation<sup>[89]</sup>. Chemoembolization improves the survival of stringently selected patients with unresectable HCC<sup>[90]</sup>. Posttransplant survival has shown a marked benefit in response to TACE, but this benefit was only seen in patients whose disease meets, but does not exceed, the MC<sup>[91]</sup>. TACE can reduce the percentage of posttransplant recurrence (17% with treatment vs 36% without treatment)<sup>[92]</sup>, and it is possible to verify its effectiveness using (18)FDG PET/CT to compare the

SUV before and after treatment<sup>[93]</sup>.

At the present time, there is no evidence demonstrating the superiority of one form of LRT over another, but merging the techniques of drug eluting beads-TACE and trans-arterial radio-embolization with Yttrium-90 and external beam conformal radiotherapy<sup>[78]</sup> is generally better tolerated than conventional techniques.

### Response criteria following downstaging with LRT

The efficacy of neo-adjuvant treatments should be evaluated<sup>[79]</sup> by the rate of dropout from the WL and, methodologically, with a 3-mo interval mRECIST<sup>[86]</sup> reassessment that considers not only the reduction in size, but the amount of tumor necrosis and the disappearance of any intratumoral arterial enhancement in conjunction with the initial and post-treatment AFP levels.

Patients presenting with an AFP level > 1000 ng/mL submitted to downstaging are a special problem because such high levels predict a greater risk of tumor recurrence and are considered the only factor in treatment failure<sup>[85]</sup>.

In these cases, a stable decrease in the AFP level to < 500 ng/mL is necessary in subsequent determinations until LT to consider the downstaging effective<sup>[50,94]</sup>. However, other authors<sup>[48]</sup> state that the level should be < 400 ng/mL because levels > 400 ng/mL in the immediate pretransplant period are a unique risk factor for recurrence after LRT<sup>[36]</sup>. This is because patients who did not show a reduction of the AFP level to ≤ 400 after downstaging had less intent-to-treat survival, and only the last pretransplant AFP value, not the original value (even if it was originally > 1000 ng/mL) or changes in the AFP level, independently predicted posttransplant survival<sup>[95]</sup>. Others have set the level to 100 ng/mL<sup>[96]</sup>, but in general, the mean AFP levels are higher in patients who do not achieve successful downstaging<sup>[97]</sup>. AFP levels are considered to play an important role in monitoring the response and/or tumor progression after LRT<sup>[25,98]</sup>.

Combined radiological and biological modifications permit documentation of the response to LRT in patients waiting for LT and are essential elements for further refining the selection criteria for potential liver recipients with HCC<sup>[94]</sup>. An AFP level ≥ 100 ng/mL, a maximum tumor size ≥ 7 cm and a lack of complete necrosis at LT after TACE were found to be independent predictors of HCC recurrence<sup>[46]</sup>. However, patients with maximum tumor size < 7 cm who achieve complete necrosis together with AFP levels < 100 ng/mL at LT may be the best candidates for LT following downstaging<sup>[46]</sup>.

In addition, an AFP slope > 15 ng/mL per month and mRECIST progression are unique independent risk factors for HCC recurrence and patient death regardless of whether the patient meets the MC<sup>[94]</sup>.

## CONCLUSION

Although the MC remain by far the standard and the most employed inclusion criteria for LT for HCC, in the

coming years, criteria will be consolidated that take into account not only data regarding the size/volume and number of tumors but also their biology, including AFP value and some of its published logarithmic models. Additionally, the AFP value will be considered in the allocation and prioritization of patients in the WL with the aforementioned new reform of the MELD-HCC system. Furthermore, the number of tumors, their volume and AFP levels will be important determinants for bridging and downstaging therapy and to evaluate the patient response. AFP values > 1000 ng/mL must be considered a sign of a bad prognosis and a questionable indication for LT unless the value can be reduced to < 400 ng/mL. Organ scarcity and the probability of recurrence following LT for HCC necessitate that all of these facts should be taken into account.

### Abstract

Hepatitis C virus (HCV)-related liver disease is the leading indication for liver transplantation (LT) worldwide. However, HCV is an independent predictor of lower survival following LT, and recurrence of HCV post-LT is virtually universal. The historic standard of care during the interferon era of HCV therapy was expectant management-initiation of antiviral therapy in the setting of documented disease progression following LT. With the advent of new direct acting antiviral (DAA) therapies for HCV, the paradigm of expectant treatment for recurrent HCV infection post-LT is shifting. The safety, tolerability, and efficacy of DAAs, even among the sickest patients with advanced liver disease, enables treatment of HCV in the pre-transplant setting among LT waitlist registrants. Finally, emerging data are supportive of preemptive therapy with DAAs in liver transplant recipients as the preferred approach. Expectant management of HCV following LT can rarely be justified in the modern era of HCV therapy.

**Key words:** Hepatitis C virus; Liver transplantation; Direct acting antivirals; Sustained virologic response

## INTRODUCTION

Hepatitis C virus (HCV) infection afflicts an estimated 180 million people worldwide, or nearly 3% of the global population<sup>[1,2]</sup>. HCV results in 8000 to 13000 deaths annually in the United States<sup>[3]</sup>. To date, HCV remains the leading indication for liver transplantation (LT) in developed nations and represents 33% of patients currently on the LT waitlist<sup>[3,4]</sup>.

## NATURAL HISTORY OF HCV INFECTION BEFORE LT

Among 70% to 75% of patients, acute HCV infection is asymptomatic. The remaining minority of patients develops systemic symptoms, including weakness, malaise, anorexia, and, rarely, jaundice. Eighty-five percent of patients with acute HCV infection do not clear the infection without treatment and instead develop chronic infection<sup>[5]</sup>. Progression to cirrhosis or hepatocellular carcinoma occurs in between 15% to 40% of patients with chronic HCV<sup>[1]</sup>. Accelerated development of cirrhosis and end-stage liver disease ensue under certain conditions. Rate of progression to cirrhosis is impacted by age at exposure - higher risk with HCV exposure at advanced age; route of transmission - blood transfusion portends greater risk than injection drug use; duration of infection; HCV genotype; and coexisting illnesses, including human immunodeficiency virus infection, hepatitis B virus (HBV) infection, and alcoholic liver disease<sup>[6-10]</sup>.

## TREATMENT OF HCV INFECTION BEFORE LT

Although 5-year survival among patients with compensated cirrhosis due HCV ranges from 84% to 91%, there is a 20% risk of decompensation and a 10% risk of HCC<sup>[11,12]</sup>. Attainment of sustained virologic response (SVR) is associated with lower rates of hepatic

decompensation, HCC, and all-cause mortality<sup>[13]</sup>. Indeed, an international multicenter study demonstrated that patients with chronic HCV who achieve SVR have long-term survival comparable to that of the general population<sup>[14,15]</sup>. Moreover, recent data reveal improved long-term survival following LT among patients in whom HCV was eradicated prior to LT<sup>[16]</sup>. As a third of LT in the United States are performed for HCV-related liver disease<sup>[4]</sup> and HCV-positive recipients have worse outcomes following LT<sup>[17]</sup>, attaining pre-transplant SVR may yield significant improvements in patient outcomes. In the interferon era, HCV therapy was instituted with caution in patients with advanced liver disease due to the potential risk of hepatic decompensation. Now, with the advent of safe, well-tolerated, and efficacious direct acting antivirals (DAAs), a paradigm shift toward pre-transplant treatment of HCV is warranted. The shortage of donor livers in the United States, which results in substantial liver transplant waitlist mortality and dropout<sup>[18]</sup>, underscores the importance of treating HCV prior to LT. The significance of this shift is even greater in regions where the availability of LT is limited to only very sick patients<sup>[19]</sup>. Treatment of HCV pre-transplant stands not only to improve post-LT outcomes but also reduce the overall societal need for LT. Viral suppression in HBV has been shown to lead to regression of fibrosis<sup>[20,21]</sup>. Likewise, emerging data now reveals histological regression of fibrosis among patients with HCV who have achieved SVR<sup>[4]</sup>. As such, long-term virologic suppression of HCV may lead to disease reversal.

## LT FOR HCV

LT is optimal therapy for decompensated cirrhosis due to chronic HCV, but HCV reinfection poses challenging management issues that may arise either early or late after transplantation<sup>[22,23]</sup>.

## DONOR LIVER ALLOCATION FOR LT

In 2002, the model for end-stage liver disease (MELD) score shown to predict LT waitlist mortality was implemented as an allocation criterion for donor livers<sup>[24]</sup>. The goal is to improve survival and quality of life among patients with end-stage liver disease. LT has proven to be effective at achieving these goals. The benefits of LT are most established for patients with MELD scores of at least 15 or higher<sup>[25]</sup>. The MELD score necessary to receive a donor liver varies widely by United Network for Organ Sharing region. While patients with MELD scores in the mid-20s receive offers in some regions, MELD scores in the high-30s are commonly needed in other regions. Because offers are allocated to patients with higher MELD scores, concern has emerged about the possibility of a so-called "MELD purgatory" with pre-transplant treatment of HCV. Concern exists that certain patients may have delayed progression of liver disease after achieving SVR without substantial reversal or improvement in quality of life<sup>[26]</sup>. Proponents of this view

contend that post-LT treatment of HCV would alleviate this concern. We should be cognizant of the fact that up to 3000 potential liver transplant candidates are removed from the waitlist annually in the United States - half develop contraindications for LT while the wait for a potential donor and the other half die from complications of end-stage liver disease<sup>[27]</sup>. Therefore, necessitating changes in allocation policies to reduce waitlist mortality<sup>[28]</sup>. Therefore, deferring antiviral therapy from pre- to post-LT phase may not be safe. Morbidity and mortality associated with LT are low, but should be ignored with emerging DAA data supporting instituting treatment in the pre-transplant phase. Furthermore, most experts agree that fibrosing cholestatic hepatitis and compensated recurrent HCV infection following LT demonstrates relatively lower efficacy with DAA therapy<sup>[29,30]</sup>. The concerns regarding the use of HCV-positive allografts have been alleviated with more recent data suggesting that transplant outcomes for recipients who accept HCV-positive donor allografts may be comparable with those who receive HCV-negative allografts<sup>[31]</sup>. Emerging treatments to eradicate HCV have further improved the course of HCV-positive individuals, with improved efficacy and reduced side-effects. HCV-positive donors constitute 4.8% of HCV-positive LT recipients<sup>[32]</sup>. The use HCV-positive donor in HCV-negative recipients with the availability of DAAs needs to be studied further. Lastly, if LT is imminent in a Child-Turcotte-Pugh class C patient with MELD score > 35 or hepatocellular carcinoma patient with exception MELD points - it may be pragmatic to wait and institute antiviral therapy following LT<sup>[33]</sup>.

## NATURAL HISTORY OF HCV INFECTION FOLLOWING LT

Studies demonstrate worse outcomes post-LT among patients with recurrent HCV infection compared to patients transplanted for other causes of cirrhosis<sup>[23,34]</sup>. The natural history of HCV infection in liver transplant recipients is typically accelerated, partially due to concomitant administration of post-LT immunosuppression. Up to 20% of HCV-infected patients develop cirrhosis by 5 years following LT<sup>[23]</sup>. Recurrent disease ranges from asymptomatic mild hepatitis to severe chronic hepatitis and cirrhosis. Reinfection with HCV post-LT is virtually universal, occurring in over 95% of cases<sup>[22]</sup>.

## PREEMPTIVE TREATMENT OF HCV FOLLOWING TRANSPLANTATION

Historically, preemptive use of antiviral therapy post-LT was not advisable because of the increased rate of acute allograft rejection associated with interferon therapy<sup>[35]</sup>. However, with the emergence of safe and efficacious DAAs, the previous concern of interferon-related immunomodulation with allograft rejection and

poor tolerance due to anti-HCV therapy following LT is abating. None of the new DAAs have yet been approved by the United States Food and Drug Administration for use among patients following LT, but the powerful body of emerging literature suggests that approval may be expected in the near future<sup>[29,30]</sup>. Preemptive treatment of HCV in the post-LT setting may alleviate the need for re-transplantation.

## EXPECTANT TREATMENT OF HCV FOLLOWING TRANSPLANTATION

Despite being the previous standard of care in the interferon era, expectant management of HCV does not seem to have a role for the vast majority of patients in the era of DAAs. Delaying HCV therapy post-LT is not advisable due to the rapid progression of HCV-related liver damage and promising data regarding the use of DAAs.

## CONCLUSION

Advances in peri-transplant management of liver transplant recipients in the setting of chronic hepatitis C have resulted in long-term post-transplant survival rates approaching 90%<sup>[36]</sup>. Nevertheless, survival following LT remains lower among patients with HCV compared to those undergoing LT for liver disease related to other etiologies<sup>[17]</sup>. Attaining SVR pre-transplant reduces all-cause mortality, may decrease the need for LT, and may improve survival following LT<sup>[14,15]</sup>. The improvements in the efficacy of antiviral therapy against HCV infection with DAAs argue against the interferon-era paradigm of expectant use of antiviral therapy following LT. The decision between treating patients pre-transplant or preemptively in the early post-transplant setting should be individualized for each patient in the context of the regional waitlist trends and exception policies for LT. Despite advancements in LT, there remains a shortage of donor livers to meet the demands for LT in the United States. Treatment of patients on the LT waiting list may ultimately decrease the number of patients needing LT and help address the imbalance in supply and demand.

### Abstract

**AIM:** To identify patients with or without liver steatosis and its severity in treatment-naïve patients affected by hepatitis C virus (HCV) infection.

**METHODS:** We included 56 HCV infected patients, and assessed the amount of liver fat by histomorphometry, and its relationships with fat and lean mass at different parts of the body (by densitometry), hormones [insulin, homeostatic model assessment (HOMA)], adipokines (resistin, adiponectin, leptin), and cytokines (tumor necrosis factor  $\alpha$ , interleukin-6).

**RESULTS:** Although the intensity of liver steatosis is related to trunk fat mass and HOMA, 33% of patients showed no liver steatosis, and this finding was not related to body mass index or genotype. Besides trunk

fat mass, no other factor was related to the presence or not of liver steatosis, or to the intensity of it, by multivariate analysis. Lean mass was not related to liver steatosis. Adiponectin levels were lower among patients. No differences were observed in leptin and resistin.

**CONCLUSION:** Steatosis in HCV infection is common (67.2%), and closely related to trunk fat, and insulin resistance, but not with leg fat mass or adipokines.

**Key words:** Resistin; Adiponectin; Insulin resistance; Proinflammatory cytokines; Leptin; Hepatitis C virus; Liver steatosis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Pathogenesis of liver steatosis in hepatitis C virus (HCV) infection is complex and is not fully understood. For unknown reasons some patients, despite having a high body mass index (BMI), do not develop liver steatosis, whereas others with normal BMI develop intense liver fat deposition. We analyse if body fat and lean mass composition, insulin resistance and adipokine profile may help to identify patients with or without liver steatosis and its severity in treatment-naïve HCV patients. Multivariate analysis showed that only trunk fat mass and insulin resistance were independently related to liver steatosis assessed on histomorphometrical grounds and its severity.

## INTRODUCTION

Non-alcoholic steatohepatitis is observed in several clinical conditions, especially diabetes and obesity. In steatohepatitis hepatocytes become laden with fat droplets that elicit an inflammatory response which may evolve to liver cirrhosis and hepatocarcinoma. In diabetes and obesity insulin deficiency and/or resistance lead to increased mobilization of fatty acids from adipose tissue to liver. In chronic hepatitis C virus (HCV) infection, steatosis and steatohepatitis are also observed and the pathogenesis is based on complex mechanisms: although HCV by itself especially genotype 3 may lead to liver steatosis, obesity and concomitant alcohol abuse are the main factors involved<sup>[1]</sup>. However, many HCV infected patients do not drink alcohol at all, but they may develop liver steatosis. Cytokine activation and increased lipid peroxidation may contribute both to liver steatosis and to the progression of simple liver steatosis

to steatohepatitis<sup>[2]</sup>.

The main source of liver fat accumulation is body fat stores<sup>[3]</sup>. In this scenario, fat tissue is not only the source of fatty acids, but also produces several proinflammatory cytokines which are of paramount importance in the progression of liver disease. However, adipose tissue is heterogeneous. For instance, trunk fat is associated with increased insulin resistance and an increased vascular risk<sup>[4]</sup>, whereas leg fat exerts opposite effects<sup>[5]</sup>, probably due to secretion of a different cytokine profile.

The association of liver steatosis with distribution of fat stores at different parts of the body in chronic HCV infection is not well known. This is an important issue, since the heterogeneous nature of fat tissue may lead to different adipokine secretion<sup>[6]</sup>. In fact, notable controversy exists regarding serum levels of different adipokines, such as adiponectin<sup>[7-9]</sup> or leptin<sup>[10,11]</sup> and their relationship with histological changes in chronic HCV infection. In a previous report which analysed a series of patients (different from those included in this study) we found that an increased waist circumference (> 102 cm for men and > 88 cm among women) was related to increased liver fat, but we also found that 38.8% of non-obese patients also showed intense fatty infiltration<sup>[12]</sup>, a result in accordance with other researchers, who have reported fatty liver among lean individuals<sup>[13]</sup>. Conversely, some HCV infected patients do not show liver steatosis, regardless of their body mass index. The mechanisms that underlie the lack of association in some cases between liver fat and body fat stores are unclear.

On the other hand, in a recent Indian study in a cohort of patients with steatohepatitis, 13% were lean patients<sup>[14]</sup>, and sarcopenia has been described as an independent risk factor for steatohepatitis<sup>[15]</sup>. In addition it has been shown that interleukin-6 (IL-6) a protean cytokine also produced by muscle<sup>[16]</sup> strongly modulates liver fat accumulation<sup>[17]</sup>. Therefore, given these observations, it is important to also analyse the relationship between lean mass and liver steatosis.

Based on these facts, in the present study we analyse the association of the degree of liver steatosis with fat and lean mass stores at different parts of the body, insulin resistance, and serum adipokine levels, in treatment-naïve patients affected by HCV infection. Since we have assessed liver steatosis on histological grounds, we also look for differences in cytokine and adipokine profile, fat and lean mass distribution among HCV patients who did not show liver steatosis and those who did, in order to shed light on the reasons why some HCV patients do not develop liver steatosis.

## MATERIALS AND METHODS

### Patients

We included 56 patients with (19 women) HCV infection, aged  $41.54 \pm 9.57$  years. Diagnostic criteria for HCV infection were the following: (1) presence of anti-HCV and/or HCV RNA by reverse transcriptase polymerase

**Table 1** Differences in biochemical variables, body mass index and total lean and total fat area between patients and controls

	Patients		Controls		
	<i>n</i>	<i>X</i> ± <i>SD</i> , median ( <i>IQ</i> range)	<i>n</i>	<i>X</i> ± <i>SD</i> , median ( <i>IQ</i> range)	
Insulin (μU/mL)	44	12.48 ± 15.65, 7.89 (4.63-14.32)	10	8.34 ± 4.34, 7.15 (5.08-10.63)	<i>Z</i> = 0.43; NS
Resistin (ng/mL)	44	4.97 ± 1.76, 4.90 (3.98-5.60)	10	4.28 ± 1.42, 4.97 (3.32-5.29)	<i>Z</i> = 0.88; NS
Adiponectin (ng/mL)	44	11.99 ± 8.30, 9.54 (6.04-17.16)	16	24.92 ± 21.84, 19.05 (13.53-21.58)	<i>Z</i> = 3.18; <i>P</i> = 0.001
Leptin (ng/mL)	44	12.25 ± 15.83, 4.23 (1.15-17.78)	10	18.41 ± 16.03, 12.89 (4.65-34.42)	<i>Z</i> = 1.78; NS
Tumor necrosis factor-α (pg/mL)	56	10.65 ± 4.14, 10.18 (7.15-13.08)	19	6.05 ± 1.90, 5.20 (4.40-8.00)	<i>Z</i> = 4.56; <i>P</i> < 0.001
Interleukin-6 (pg/mL)	53	4.28 ± 4.75, 2.0 (2.0-4.29)	19	5.90 ± 1.64, 5.0 (5.0-6.60)	<i>Z</i> = 2.97; <i>P</i> = 0.003
Body mass index (kg/m <sup>2</sup> )	56	24.19 ± 3.44	19	25.20 ± 3.42	<i>t</i> = 1.02; NS
Total fat mass (g)	50	19929 ± 11944	19	21443 ± 6393	<i>t</i> = 0.54; NS
Total lean mass (g)	50	48284 ± 8848	19	50131 ± 15796	<i>t</i> = 0.64; NS

Comparisons were made using non-parametric tests, such as Mann-Whitney's *U* test (*Z*) or parametric ones (Student's *t*-test). NS: Not significant.

chain reaction; and (2) Histology consistent with HCV. Most patients (43) were infected by HCV type 1 genotype, 5 by type 3 genotype, and 8 by type 4. All patients were recruited before treatment for virus C hepatitis was administered, and none of them were active drinkers. Liver function was still preserved: Liver function tests were normal, and none of them showed ascites or encephalopathy.

### Nutritional evaluation

After informed consent was obtained, 51 patients underwent assessment of fat and lean mass at different parts of the body, such as right and left arm, trunk, right and left leg, and total body, with a LUNAR PRODIGY ADVANCE device, General Electric, Piscataway, NJ, United States. We further calculated (using the protocol established by other authors<sup>[18]</sup>) the trunk fat/(right leg + left leg fat) index, as well as the indices fat mass/lean mass at each of the body compartments mentioned before. Body mass index [BMI, as weight (kg)/height (m)<sup>2</sup>] was also recorded.

### Biochemical assessment

Blood samples were taken at 8:00 am in fasting conditions. Routine laboratory evaluation was performed and these analyses included, among others, prothrombin activity, serum albumin and bilirubin. Samples were immediately frozen at -20 °C. We determined the following parameters-IL-6, by chemiluminescent assay interassay variation coefficient ranging 5.3%-7.5%, recovery = 85%-104%, diagnostic products corporation (DPC), Los Angeles, CA, United States; tumour necrosis factor α (TNF-α) by immunometric chemiluminescent assay (intra-assay variation coefficient ranging 4%-6.5%, interassay variation coefficient ranging 2.6%-3.6%, recovery 92%-112%, DPC, Los Angeles, CA, United States). We also determined serum insulin, by immunoanalysis (Chemiflex); interobserver variation coefficient = 1.9%-5.2%; intraobserver variation coefficient = 1.7%-4.2%; sensitivity = 1 μU/mL; recovery = 91.1%-101.6%; (Architect system, Abbott, Wiesbaden Germany), serum resistin, by ELISA (sensitivity = 0.033 ng/mL; intra-assay variation coefficient = 2.8%-3.4%; interassay variation coefficient ranging 5.1%-6.9%,

recovery = 85.2%-99.2%, Biovendor, Heidelberg, Germany), serum leptin, by ELISA (sensitivity = 0.2 ng/mL; intra-assay variation coefficient = 4.2%-7.6%; interassay variation coefficient ranging 4.4%-6.7%, recovery = 85.7%-98.0%, Biovendor, Heidelberg, Germany); serum adiponectin by ELISA (sensitivity = 26 ng/mL; intra-assay variation coefficient = 3.9%-5.9%; interassay variation coefficient ranging 6.3%-7%, recovery = 92.4%-102.9%, Biovendor, Heidelberg, Germany); insulin resistance was estimated by the homeostatic model assessment (HOMA).

Cytokine values were compared with those of a control group composed of 19 healthy hospital workers, seven of them women, aged 40.45 ± 3.57 years. As shown in Table 1, not all the variables were determined in all patients and controls.

All these data were recorded the day at which the patients underwent a liver biopsy before receiving active treatment against HCV infection.

### Histological assessment

The degree of liver steatosis was determined using software based on histomorphometry (LEICAQWin, version 3.0, Wetzlar, Germany). The specimens were stained with haematoxylin-eosin and Masson trichromic and were viewed at 40 ×. This protocol has been previously described<sup>[12]</sup>. The proportion of fatty area to total area in specimens was recorded. The Knodell index and the total amount of fibrous tissue determined by histomorphometry (using Masson trichromic stain) were also measured.

The study protocol was approved by the local ethical committee of our Hospital. All patients included gave their informed consent prior to their inclusion in the study, and the study conforms to the ethical guidelines of the 1975 Declaration of Helsinki.

### Statistics analysis

We tested for normal distribution using the Kolmogorov-Smirnov test. In order to compare means between two groups or between three or more groups, we used Student's *t* test and ANOVA, respectively. If the variables did not show a normal distribution, Mann-Whitney's *U* and Kruskal-Wallis tests were used to compare

**Figure 1** Fat amount among the three hepatitis C virus genotypes included in this study. Patients with genotype 1 (the most frequent) show significantly less amount of fat than patients affected by genotype 3 or 4 (solid circles are outliers, and hollow circle, extreme values). HCV: Hepatitis C virus.

means. Correlations between quantitative variables were established using Spearman's *r* and Pearson's *r*. The  $\chi^2$  test was used to compare qualitative variables. We performed stepwise multiple regression analysis to establish which parameters liver steatosis depends on. All statistical analyses were performed using SPSS software (Chicago, Ill., United States).

## RESULTS

Liver steatosis was observed in 42 patients out of 56; in the remaining 14 patients, no steatosis at all was observed, and in 4 more, only very few small isolated fat droplets could be observed (fat amount < 0.05%). Median value of liver fat area was 0.20%, but 14 patients showed more than 5% of fat in their biopsies. Patients with genotype 1 showed significantly less steatosis than those with genotype 3 or 4 ( $Z = 2.17$ ;  $P$

= 0.03; Figure 1). Indeed, as shown in Figure 1, patients with genotype 3 or 4 showed higher values of liver fat (fat proportion = 6.66% ± 8.42%) when compared with those with genotype 1 (fat proportion = 1.40% ± 2.78%). Only 1 (out of 5) genotype 3 patient showed no steatosis at all, compared with 13 (out of 51) affected by non-3 genotype infection, but this association was not statistically significant ( $\chi^2 = 0.07$ ). No differences in liver fat were observed when HIV-coinfected patients were compared with non-co-infected ones ( $Z = 0.40$ ;  $P = 0.694$ ). Seven patients were diabetics, but although they showed a trend to more intense liver steatosis (6.66% ± 9.68%) than non-diabetics (2.05% ± 3.97%), this difference was not significant ( $Z = 1.31$ ;  $P > 0.20$ ). None of the diabetics showed no fat in their livers, but association between diabetes/no diabetes and presence or not of liver steatosis was not significant ( $P = 0.17$  by exact Fisher's test). No association was observed between viral load and proportion of liver fat.

Median proportion of fibrosis was 5.75% (interquartile range = 3.53%-8.88%). Twenty-one patients showed a Knodell index higher than 5, whereas 35 showed a Knodell index below 6.

### Relationship of liver steatosis with nutritional status

Patients with marked steatosis (over the median) showed increased BMI and greater fat mass, especially at the trunk ( $t = 3.01$ ,  $P = 0.004$ ), as shown in Table 2. In addition to the finding of a significantly higher BMI among those with liver steatosis over the median (Table 2), we also found that patients with BMI over 25 kg/m<sup>2</sup> had significantly more liver fat ( $Z = 2.25$ ;  $P = 0.031$ ). Only 22 patients were overweight, and only 3 of them were obese (BMI > 30 kg/m<sup>2</sup>). Three patients who were overweight showed no fat at all in their liver biopsies, vs 11 out of 33 with normal weight. This association was not statistically significant. Significant relationships were observed between fat parameters and liver steatosis, especially with trunk fat ( $r = 0.42$ ;  $P = 0.002$ ), right

Comparisons were made using non-parametric tests, such as Mann-Whitney's *U* test (*Z*). NS: Not significant.

arm fat ( $r = 0.31$ ;  $P = 0.029$ ), left arm fat ( $r = 0.30$ ;  $P = 0.033$ ), and total fat ( $r = 0.34$ ;  $P = 0.016$ ). The significant relationship between liver steatosis and trunk fat was observed both among women ( $r = 0.50$ ;  $P = 0.04$ ) and men ( $r = 0.41$ ;  $P = 0.016$ ). In a similar way, BMI was related to liver steatosis both among women ( $r = 0.53$ ;  $P = 0.02$ ) and men ( $r = 0.36$ ;  $P = 0.032$ ). However, while liver steatosis was related to arm and leg fat mass among both women and men, the correlations were not statistically significant, possibly due to the relatively low number of cases. No relationship was observed between parameters related to lean mass and liver steatosis, but when the indices fat mass/lean mass were compared with liver steatosis, the results were similar to those obtained with fat parameters ( $r = 0.39$ ;  $P = 0.006$  for the trunk,  $r = 0.34$ ;  $P = 0.017$  for the left arm,  $r = 0.32$ ;  $P = 0.026$  for the right arm, and  $r = 0.34$ ;  $P = 0.016$  for total fat). Remarkably, no association was observed when leg fat mass was compared with liver steatosis. The ratio trunk fat/legs fat was not significantly different among patients with liver steatosis below or above the median. A significant correlation was observed between liver steatosis and BMI ( $r = 0.41$ ;  $P = 0.002$ ).

Trunk fat was the only variable that was selected ( $P = 0.011$ ) when a logistic regression analysis was done searching for the factors related to liver fat over or below the median values.

Similar results relative to fat mass at different parts of the body were observed when patients without liver steatosis (including those 4 with minimal steatosis) were compared with the remaining patients, although differences were less significant ( $t = 2.73$ ,  $P = 0.009$  for trunk fat,  $t = 2.34$ ,  $P = 0.023$  for left arm fat,  $t = 2.31$ ;  $P = 0.025$  for right arm fat) than when patients were classified according to the median values of liver fat. BMI was also significantly lower among those without liver steatosis ( $t = 2.43$ ;  $P = 0.023$ ). No differences at all were observed regarding lean mass variables. As with steatosis below or above the median, the only selected variable was trunk fat ( $P = 0.015$ ) when a logistic regression was performed to discern which

variables were independently related to the presence or absence of liver fat infiltration.

No associations were observed between the proportion of fibrosis in liver biopsy and any of the nutritional variables, but Knodell index was related both to fat mass variables (total fat,  $r = 0.37$ ;  $P = 0.007$ ; trunk fat,  $r = 0.32$ ;  $P = 0.024$ ); left arm and right arm fat,  $r = 0.47$  and  $r = 0.45$ ; respectively,  $P < 0.001$ ; left leg and right leg, ( $r = 0.31$  and  $r = 0.28$ , respectively,  $P < 0.05$  in both cases), as well as to some lean mass variables (trunk lean mass,  $r = 0.35$ ;  $P = 0.012$ ; left leg lean mass,  $r = 0.30$ ,  $P = 0.034$ ).

#### Relationship of liver steatosis with insulin resistance and adipokines

No differences were observed in any of the adipokines, HOMA, insulin, TNF-α, or IL-6 among patients with or without liver steatosis. Only HOMA, out of these parameters, was significantly higher among patients with liver fat over the median compared with those with liver fat below the median ( $Z = 2.15$ ;  $P = 0.032$ ); a similar trend that was not statistically significant ( $P = 0.059$ ) was observed with insulin (Tables 3 and 4, Figure 2).

Significant relationships were observed between liver steatosis (proportion of fat) and HOMA index ( $r = 0.30$ ;  $P = 0.046$ ). Serum insulin ( $r = 0.44$ ;  $P = 0.003$ ) and HOMA ( $r = 0.36$ ;  $P = 0.017$ ) were directly related to Knodell index, whereas no associations were observed between any of the adipokines and cytokines and the amount of fibrosis in the liver biopsies. Selecting only those patients with liver steatosis, a significant correlation was observed between IL-6 and amount of liver fat ( $r = 0.49$ ;  $P = 0.003$ ).

After introducing in a multiple regression analysis the fat variables which showed a significant relationship with liver steatosis in the univariate analysis, only trunk fat (beta = 0.37;  $P = 0.026$ ) was independently related to the amount of liver fat. In a similar way, trunk fat was the only selected variable when a logistic regression analysis was done searching for the factors related to liver fat over or below the median values (Table 5).

**Table 4** Correlations between body composition parameters and adipokines, proinflammatory cytokines and insulin resistance

	Leptin	Adipo-nectin	Insulin	HOMA	TNF- $\alpha$	IL-6	Resistin

### Relationships of nutritional variables with insulin resistance and adipokines

Leptin, insulin and HOMA were strongly and directly related to fat parameters, as shown in Table 4 ( $r > 0.40$  in all the cases;  $P < 0.006$ ), but not to lean mass. On the contrary, adiponectin and TNF- $\alpha$  were inversely related to most of the lean mass parameters. Adiponectin was also inversely related to the trunk fat mass/leg fat mass index ( $r = -0.33$ ;  $P = 0.037$ ).

The fat/lean indices were also strongly related to leptin, insulin and HOMA, and also, to IL-6, in this last case only with the trunk fat/trunk lean mass index. No associations were observed between serum resistin and nutritional parameters (Table 4).

## DISCUSSION

We have found that liver steatosis is frequent among

**Figure 2** Serum insulin levels among patients with liver steatosis over the median (left) and below the median (right). Differences are not statistically significant, but there is a trend to higher values among patients with intense steatosis ( $P = 0.059$ ). Solid circle represents an outlier.

patients with HCV infection (67.86%), even surpassing the prevalence data (about 50%) reported by other authors<sup>[19]</sup>. This high proportion of patients with steatosis was observed despite a BMI that was not different - even slightly lower- than that of a control population. However, as expected, liver steatosis showed a significant relationship with BMI, but it is noteworthy that

**Figure 3** Scattergram showing the relation of body mass index with the amount of liver steatosis. Despite a significant relationship between both variables ( $\rho = 0.41$ ;  $P = 0.002$ ), as shown, some patients with BMI over 30 show no steatosis at all or only minimal amount of liver fat, in contrast with some others with BMI below 25 and marked steatosis in their livers. BMI: Body mass index.

some cases showed only minimal steatosis despite the fact that the patient was overweight. Some other cases showed considerable liver fat accumulation despite low BMI values (Figure 3), suggesting that factors other than BMI are involved in liver fat accumulation. This result is similar to that obtained by our group six years ago, in a different cohort of patients, in whom adiposity was assessed by waist circumference, triceps skinfold measurement, and BMI<sup>[12]</sup>.

We have also shown that liver steatosis in HCV-infected patients is associated with trunk fat. This has been also reported by other authors<sup>[20,21]</sup>, since, as mentioned above, it is generally accepted that trunk fat is associated with a more “noxious” adipokine secretion profile that is able to cause insulin resistance and a proinflammatory state. The opposite happens with peripheral fat. In this sense, we failed to find any relationship between liver steatosis and leg fat mass, as shown in Table 2. Therefore, in sharp contrast with trunk fat, which was clearly related to liver steatosis, liver fat accumulation seems to be independent of leg fat mass.

Regarding adipokines, adiponectin levels were significantly lower among patients than among controls, despite a similar BMI. Adiponectin was inversely related to lean mass, but not to fat mass or liver steatosis. However, it is important to highlight the inverse relationship between the trunk fat/leg fat ratio and adiponectin, fully in accordance with the observation of an inverse relationship between visceral fat and adiponectin levels in other settings<sup>[22]</sup>. Although there is little doubt about the protective role of adiponectin in steatohepatitis (it has been described that adiponectin antagonizes the effects of  $\text{TNF-}\alpha$ <sup>[23]</sup>), in the present study, there seems to be no association between adiponectin levels and liver steatosis, despite the fact that their serum levels are lower in HCV patients in comparison to controls.

This is not a universal finding. The studies on the levels of adiponectin in HCV-related steatohepatitis had been controversial<sup>[7-9,24-28]</sup>. It is also remarkable that we found, in accordance with the protective effect of adiponectin on vascular risk, a significant correlation between adiponectin and high density lipoprotein cholesterol ( $\rho = 0.56$ ;  $P < 0.001$ ), as other authors also did<sup>[29]</sup>.

We also failed to find differences in resistin and leptin between patients and controls, or when these adipokines were compared among patients with intense or less intense steatosis. Leptin, a fat derived cytokine, may promote fibrogenesis through up-regulation of  $\text{TGF-}\beta$ <sup>[30]</sup>, but also protects the liver from fat accumulation, by lowering the expression of SREBP-1<sup>[31]</sup>. These nearly opposite effects may explain, perhaps, disparate findings in relation to leptin levels in chronic HCV infection<sup>[32]</sup>. Indeed, there is also controversy regarding the levels of leptin in HCV-related steatohepatitis<sup>[10,11,33-35]</sup>.

Hyperinsulinaemia decreases synthesis of apoB-100, thus preventing very low density lipoproteins formation and leading to liver steatosis. Moreover, transcription of lipoprotein lipase is decreased by  $\text{TNF-}\alpha$ , leading to hypertriglyceridaemia<sup>[36]</sup>. Most of the results observed in this study sustain this hypothesis: We did find hyperinsulinemia and increased HOMA index in patients with more intense steatosis. This result is fully in accordance with the current knowledge, since insulin resistance leads to an ongoing lipolysis that overwhelms the liver capacity to metabolize them.

Genotype 3 infected patients usually show a more intense degree of steatosis, and it has been shown that it exerts a direct cytopathic effect on liver cell leading to steatosis<sup>[37]</sup>. Concordant with this, patients infected with genotype 3 showed a more intense liver steatosis than those genotype non-3 infected ones, but no significant differences were observed in nutritional anthropometric parameters among them. Also, although the number of patients infected with genotype 3 HCV was low, in one case no fat at all was observed in the liver, and this proportion was similar in HCV genotype non-3 patients. In fact, we have failed to find any difference in adipokine and/or cytokine profile between patients without fat and with fat in the liver. The only independent variable related to the intensity of liver steatosis or to the presence of liver steatosis was trunk fat. Lean mass parameters seem to play no role at all, and insulin resistance, assessed by HOMA, and IL-6 levels were also related to liver fat stores in the univariate analysis, being displaced by trunk fat mass in the multivariate analysis.

Therefore, we conclude that steatosis in chronic hepatitis C is a common event (67.86%), and is closely related to trunk fat, but not with leg fat mass; to insulin resistance, and to IL-6. The main factor involved is trunk fat, despite the normal BMI of the patients included in this study, and also despite the fact that at least 12 patients with BMI over 25 kg/m<sup>2</sup> showed no liver steatosis, or minimal amount of it, as shown in Figure 1. The reasons for this finding are unclear, and suggest that

factors other than BMI, HOMA or fat mass should be involved. The results here presented also do not support the hypothesis that lean mass plays a role in liver fat accumulation.

Authors are indebted to the nurses and staff of the Internal Medicine Unit and Infectious Diseases Section of the Hospital Universitario de Canarias.

## COMMENTS

### Background

Hepatitis C virus (HCV) infection is a common disease, ultimately leads to liver cirrhosis and hepatocarcinoma. Liver steatosis is an early finding in these patients. Mechanisms are poorly understood, although it is known that HCV genotype 3 may lead to steatosis. Possibly, trunk fat and some adipokines may be also involved.

### Research frontiers

There is a lot of controversy regarding the association of main adipokines, such as adiponectin or leptin, with liver steatosis, and their role in the progression of simple steatosis to liver inflammation. In addition, although there is general agreement in the association between obesity and liver steatosis, the relationship between fat distribution at different body compartments is not well defined. Moreover, there are some studies that also suggest a role of lean mass in liver steatosis.

### Innovations and breakthroughs

In this study the authors report that liver steatosis in chronic HCV infection is a common, but not universal event (67.86%). It is closely related to trunk fat and to interleukin (IL)-6, a cytokine that may be produced by trunk fat, but not with fat at the legs, and also to insulin resistance. However, there are still some unexplained results: The relationship between liver steatosis and trunk fat was observed despite the normal body mass index (BMI) of the patients included in this study, and also at least 12 patients with BMI over 25 kg/m<sup>2</sup> showed no liver steatosis, or minimal amount of it. In addition, their results also do not support the hypothesis that lean mass plays a role in liver fat accumulation.

### Applications

This study provides new data relative to the association of liver steatosis with several adipokines and inflammatory cytokines in HCV-infected patients. As mentioned above there is considerable controversy regarding levels of some of these cytokines in HCV-infected patients, and even opposite results have been reported by several groups. In addition, this study underscores the role of trunk fat in liver steatosis, despite normal BMI, and does not support to the hypothesis that lean mass could play a role.

### Terminology

Cytokines are small molecules with protean effects on inflammation and immune response, among many other effects on most organs. Tumor necrosis factor alpha is one of the first cytokines described, initially as the factor responsible for tumor-induced cachexia. IL-6 is a proinflammatory cytokine, that also bears an immunomodulatory effect. Adipokines are cytokines secreted by adipose tissue.

### Peer-review

In this manuscript, the authors described about effects of adipokines, cytokines, and body fats on liver steatosis in hepatitis C patients. The key results are very interesting to the readers of HCV and other hepatic diseases.

## Contents

Three issues per month Volume 8 Number 2 January 18, 2016

### TOPIC HIGHLIGHT

- 83 Hepatitis C virus infection and thyroid autoimmune disorders: A model of interactions between the host and the environment

*Pastore F, Martocchia A, Stefanelli M, Prunas P, Giordano S, Toussan L, Devito A, Falaschi P*

- 92 Chronic hepatitis C: This and the new era of treatment

*Bertino G, Ardiri A, Proiti M, Rigano G, Frazzetto E, Demma S, Ruggeri MI, Scuderi L, Malaguarnera G, Bertino N, Rapisarda V, Di Carlo I, Toro A, Salomone F, Malaguarnera M, Bertino E, Malaguarnera M*

### REVIEW

- 107 Hepatitis C virus and non-Hodgkin's lymphomas: Meta-analysis of epidemiology data and therapy options

*Pozzato G, Mazzaro C, Dal Maso L, Mauro E, Zorat F, Moratelli G, Bulian P, Serraino D, Gattei V*

### MINIREVIEWS

- 117 Hepatitis E virus infection in the liver transplant recipients: Clinical presentation and management

*Aggarwal A, Perumpail RB, Tummala S, Ahmed A*

- 123 Ribavirin: Past, present and future

*Loustaud-Ratti V, Debette-Gratien M, Jacques J, Alain S, Marquet P, Sautereau D, Rousseau A, Carrier P*

- 131 Hepatitis C and insulin action: An intimate relationship

*Knobler H, Malnick S*

## Contents

*World Journal of Hepatology*  
Volume 8 Number 2 January 18, 2016

### ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Jochen Mattner, MD, Associate Professor, Molecular Microbiology and Infection Immunology, University Clinic of Erlangen, 90154 Erlangen, Germany

### AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### INDEXING/ ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed Central, PubMed, Digital Object Identifier, Directory of Open Access Journals, and Scopus.

### Abstract

The hepatitis C virus (HCV) infection is an important

public health problem and it is associated with hepatic and extrahepatic manifestations. Autoimmune thyroid diseases are common in HCV infected patients and the standard interferon-based treatment is associated with an increase of the immune-mediated thyroid damage. Recent evidence in the literature analyzed critical points of the mechanisms of thyroid damage, focusing on the balance between the two sides of the interaction: The environment (virus infection with potential cross-reaction) and the host (susceptibility genes with consistent immune response). The spectrum of antiviral treatment for chronic HCV infection is rapidly expanding for the development of dual or triple therapy. The availability of interferon-free combined treatment with direct antiviral agents for HCV is very promising, in order to ameliorate the patient compliance and to reduce the development of thyroid autoimmunity.

**Key words:** Hepatitis C virus; Thyroid autoimmunity; Interferon; Antiviral agents; Self-tolerance

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This review examines the relationship between the hepatitis C virus (HCV) infection and the thyroid autoimmunity, on the basis of recent evidence of the literature about the mechanisms of self tolerance and thyroid damage related to HCV. The advances in the HCV infection treatment have been discussed in the paper, with relevant clinical results.

Hepatitis C virus infection and thyroid autoimmune disorders: A model of interactions between the host and the environment. *World J Hepatol* 2016; 8(2): 83-91 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/>

## INTRODUCTION

Hepatitis C virus (HCV) infection is a liver disease that may be associated with extra hepatic manifestations (EHM) (autoimmune disorders or malignant tumors), defining the HCV syndrome as result of multifactorial process with significant genetic predisposition and/or environmental triggering cofactors<sup>[1]</sup>.

More than 50% of HCV-positive patients have symptoms of at least one EHM during the course of the disease that can be the first and only clinical signs of a chronic hepatitis C<sup>[2]</sup>.

The loss of tolerance is the main mechanism that promotes autoimmune diseases and, particularly, autoimmune thyroid disorders (AITD)<sup>[3,4]</sup>, with autoantibodies (Abs) or T lymphocytes (humoral or cellular response) reacting with self-antigens (Ags) (Figure 1).

The clinical spectrum of AITD includes hyper- [Graves' disease (GD)] or hypo-function [Hashimoto's thyroiditis (HT)] of the gland. The Abs against the thyroglobulin (Tg) and the thyrotropin-stimulating hormone (TSH)-receptor (TSH-r) in patients with GD were firstly identified 50 years ago<sup>[5,6]</sup>. The Abs bind and activate the TSH receptor in GD, whereas antibody-dependent cellular cytotoxicity to thyroglobulin and thyroid peroxidase (TPO) and T cells mediated injury in HT. An immune-mediated mechanism is present in painful subacute thyroiditis (without significant anti-thyroid autoantibodies) and in drug-induced thyroiditis (interferons).

T cells CD4<sup>+</sup> are divided into regulatory T (Treg) cells and conventional T helper (Th) cells (with Th1 and Th2 lineages controlling cell-mediated and humoral immunity, respectively)<sup>[7-11]</sup>. In the central event of the immune response, the antigen-presenting cell (APC) presents the Ag bound to the human leukocyte antigen (HLA) class II to the CD4<sup>+</sup> T cell, through the T cell receptor and additional costimulations (engagement of B7 with CD28 and CD40 with CD40 ligand). The Ag recognition for CD8<sup>+</sup> T cells requires linear peptides that are processed and bound to HLA class I. The CD4<sup>+</sup>/CD8<sup>+</sup> ratio, the HLA system and the costimulation have been involved in initiation, progression, and maintenance of AITD<sup>[12]</sup>. Since activated T cells stimulate B cells to proliferate and secrete antibodies (IgG), B cell tolerance mechanisms are considered as a secondary mechanism<sup>[13]</sup>. Tregs suppress immune responses against self or non-self Ags, producing immunosuppressive cytokines [interleukin-10 (IL-10), and transforming growth factor  $\beta$  (TGF- $\beta$ )] and Tregs are dysfunctional in AITD patients<sup>[14,15]</sup>. Programmed death-1 negative co-stimulatory pathway mediate Treg activity, that is characterized by the expression of forkhead box protein 3 (FoxP3) and cytotoxic T-lymphocyte antigen 4 (CTLA-4).

At the peripheral site of chronic inflammation, the Th17 cells produce proinflammatory cytokines

(IL-17, IL-21 and IL-22), as it has been demonstrated in AITD<sup>[16,17]</sup>. Local immunosuppressive regulatory cytokines (TGF- $\beta$  and IL-10) may be involved in the maintenance of tolerance and prevention of AITD<sup>[18,19]</sup>. A decreased apoptosis of activated T cells, like in defects of interaction of Fas (CD95) and Fas ligand (Fas-L), has been studied in AITD<sup>[20]</sup>. The proportion of intrathyroidal natural killer T cell subset has been found lower in GD than in the peripheral blood of the same patients and of controls, contributing to the incomplete regulation of autoreactive T cells<sup>[13]</sup>.

## HOST-DEPENDENT FACTORS IN THYROID AUTOIMMUNITY

The aetiology of the AITD is unknown, but endogenous agents may predispose to the development to autoimmunity.

A genetic influence (the susceptibility genes) has been reported in the development of autoimmunity<sup>[21,22]</sup>. As matter of fact, the association with HLA class II molecules, the concordance studies in twins, the association with CTLA-4 and protein tyrosine phosphatase nonreceptor-type 22 and CD40 polymorphism (A/G49 and 1858C/T and CC genotype, respectively), the association of a microsatellite inside the *FoxP3* gene, the linkage with chromosomal locations (14q31, 18q21, 20q11, Xp11, Xq21, 6p, 13q32 and 12q22) and the presence of anti-thyroid Abs in siblings of probands with AITD have been observed<sup>[23-32]</sup>. Moreover, the HLA class II (DRB1\*0301) is also associated with chronic HCV infection<sup>[33]</sup>. Genome-wide association studies of autoimmune disease recently revealed multiple associations with the major immune cell subsets and uncovered insights into the control for regulatory Tregs<sup>[34]</sup>.

AITD clearly increases with age, resulting from changes in immune regulation (endogenous factor). A sexual dimorphism in AITD has been described<sup>[3]</sup>, with the highest ratio in females with HT (F:M = 4-10:1), suggesting an immunomodulatory role of sex steroids (respectively for androgens, estrogens and progesterone), mediated by specific receptor<sup>[35]</sup>. Males have an increased risk of advanced liver disease (cirrhosis and hepatocellular carcinoma) during HCV infection, in association with polymorphisms in sex steroid hormone synthesis and signaling<sup>[36,37]</sup>.

A blunted hypothalamic-pituitary-adrenal axis may be associated to susceptibility to autoimmune/inflammatory disease<sup>[38]</sup>, but no evidence of pituitary or adrenal involvement was present in a recent histopathologic study in HCV patients with thyroid disorders<sup>[39]</sup>.

The main targets of the immune response in AITD are the Tg (two 330-kDa monomers, with the highest "immunogenicity score"), the TSH-r (60 kDa for the A subunit) and the TPO (homodimer of two 107-kDa subunits); no supporting data, at the moment, for the sodium/iodide symporter (NIS) and the pendrin<sup>[9]</sup>. Specific Tg peptides (representing major T-cell epitopes

**Figure 1** Potential mechanisms for self-tolerance control. AIRE: Autoimmune regulator gene; DCs: Dendritic cells; TGF: Transforming growth factor; IL: Interleukin; Ab: Antibody; NKT cells: Natural killer T cells.

that can bind to the HLA-DRB-Arg74 pockets) and intron 1 polymorphism in the *TSH-r* gene (altering its splicing) has been associated with GD<sup>[40,41]</sup>. Cytotoxic CD8<sup>+</sup> T cells recognized Tg or TPO peptide epitopes associated to HLA-A2 molecules in patients with HT<sup>[11]</sup>.

Epigenetic modifications (including DNA methylation, histone modifications, and RNA interference by microRNA) can amplify a risk conferred by an inherited polymorphism resulting in a combined high risk for disease<sup>[42]</sup>.

## ENVIRONMENT AND VIRUS-DEPENDENT FACTORS IN THYROID AUTOIMMUNITY

Environmental risk factors include pollution, iodine intake (as in the cases of Jod-Basedow and Wolff-Chaikoff effect) and smoking. Stressful situations are well known inducers of AITD and, in particular, of hyperthyroidism<sup>[43]</sup>. Allostatic load during stress conditions is a well-known environmental factor favouring the development of AITD. A high number of drugs (lithium, amiodarone, interferons, anti-CD52 monoclonal antibody Campath-1H) may induce AITD<sup>[44-47]</sup>. In the past years, leukocyte-derived interferon (IFN) contaminated with  $\gamma$ -IFN demonstrated "*in vivo*" potent inducing properties of AITD in humans<sup>[48]</sup>.

The HCV is one of the most important viruses associated with autoimmune diseases (both chronic liver inflammation and EHM). HCV may interfere with the functions and mechanisms of self-recognition both on the immune system and thyroid cells<sup>[49,50]</sup>, where HCV may directly destroy thyroid tissue or mimic the structure of some components of thyroid gland, starting the autoimmune disease (Figure 2).

The HCV prevalence is about 5%, strongly associated with health inequity<sup>[51,52]</sup>. HCV structure consists of three structural (core, E1 and E2) and seven non-structural proteins (p7, NS2, NS3, NS4A, NS4B, NS5A and

NS5B) and six main HCV-RNA genotypes<sup>[53]</sup>. HCV has a significant lymphotropism: In fact, the lymphoid tissue is a site for the persistence of the infection and chronic immune stimulus<sup>[54,55]</sup>. The chronic stimulation results in: AutoAbs production (clonal B lymphocyte expansion and Th2 response), anti-apoptotic effects (translocation with Bcl-2 activation and prolonged survival of lymphocytes), drive for autoimmunity (binding of protein E2 to CD81, that mediate attachment on hepatocytes), increased cytokine and chemokine secretion (IFN- $\gamma$  and Th1 response with IFN- $\gamma$  inducible chemokines such as C-X-C motif chemokine 10 or CXCL10, in order to stop viral spread; IL-8) and upregulation of CXCL10 by NS5a<sup>[56-59]</sup>. However, no association has been found between chronic hepatitis C with increased CXCL10 and AITD<sup>[60]</sup>.

## DEVELOPMENT OF AITD DURING THE $\alpha$ -IFN TREATMENT FOR HCV CHRONIC HEPATITIS

The AITD during the  $\alpha$ -IFN treatment for viral chronic hepatitis is an interesting clinical model for autoimmunity, since it includes both environmental and endogenous factors, together interacting. The mechanisms responsible for AITD in HCV patients have not been elucidated.

In the autoimmune model, initiating (susceptibility genes/environmental stimuli) and modulating factors (sex hormones/neuroendocrine influences) are involved in the whole complex of the autoimmune processes.

Age, female gender and pre-existing positive Abs are well-known risk factors for the development of AITD in the IFN-treated HCV patients<sup>[61-64]</sup>.

HCV is associated with AITD (10%) and thyroid dysfunction (3%, with a hypothyroidism/hyperthyroidism ratio of about 2:1)<sup>[49,61-63,65-70]</sup>. AITD in patients with HCV are more frequent than in viral hepatitis B (5%) and in

**Figure 2** Development of thyroid autoimmunity in patients with chronic hepatitis C virus infection during interferon- $\alpha$  treatment. Ab: Antibody; Ag: Antigen; APC: Antigen presenting cell; CD: Cluster of differentiation; CTLA-4: Cytotoxic T-lymphocyte antigen 4; CXCL10: C-X-C motif chemokine; DC: Dendritic cell; HCV: Hepatitis C virus; HLA: Human leukocyte antigen; I-: Iodide; IFN: Interferon; IL: Interleukin; NIS: Sodium/iodide symporter; PTPN22: Protein tyrosine phosphatase nonreceptor-type 22; T3 and T4: Thyroid hormones; TCR: T cell receptor; Tg: Thyroglobulin; TGF: Transforming growth factor; Th: T helper; TPO: Thyroid peroxidase; Tregs: T regulatory cells.

controls (2%-4%)<sup>[11,66]</sup>.

The standard antiviral therapy with  $\alpha$ -IFN for HCV-related chronic hepatitis may exacerbate or induce underlying latent thyroid disorders, increasing the incidence of AITD and dysfunction to 20%-40% and 11%-15%, respectively<sup>[49,61-63,65,67,68,70-72]</sup>. The "de novo" appearance of anti-thyroid Abs and overt dysfunctions in euthyroid subjects have been demonstrated after the  $\alpha$ -IFN therapy, suggesting that this cytokine is a direct inducer of AITD<sup>[49,61,62,67,68,70,71]</sup>.

Recombinant  $\alpha$ -IFN administration induces an increase of endogenous  $\gamma$ -IFN and IL-6, supporting a sequence in the cytokine cascade that modulate the immune system and the neuroendocrine axis secretion<sup>[73]</sup>. At the thyroid level, IFNs ( $\alpha$ ,  $\beta$  and  $\gamma$ ) are inhibitors of iodide uptake and hormone release on thyrocytes<sup>[74]</sup>. At the pituitary level,  $\gamma$ -IFN and IL-6 do not change TSH release<sup>[75]</sup>, whereas at the hypothalamic level,  $\gamma$ -IFN stimulates somatostatin release<sup>[76]</sup> that suppresses TSH secretion. We examined the effect of  $\alpha$ -IFN (3 million IU i.m. 3 times a week) on hypothalamic-pituitary-thyroid (HPT) axis in patients with viral chronic hepatitis and negative anti-thyroid Abs

from a neuroendocrine point of view and we did not find a statistically relevant modification of thyroid hormones and TSH levels<sup>[77]</sup>.

A case of De Quervain's thyroiditis during  $\alpha$ -IFN therapy for HCV-related chronic hepatitis, with persisting negative anti-thyroid Abs after  $\alpha$ -IFN therapy, has been reported<sup>[78]</sup>. The common viral infections (Coxsackie virus, mumps, Epstein-Barr virus, adenovirus, cytomegalovirus) were negative, but we found an association with HLA-Bw35<sup>[79,80]</sup>. The patient presented the HCV, the typical HLA class I predisposition for the thyroid disease and an exogenous accelerating factor ( $\alpha$ -IFN therapy). During viral infections, APCs present antigens to Th cells, in the presence of cytokines (*i.e.*,  $\alpha$ -IFN, IL-12), inducing them to differentiate towards the Th1 phenotype that causes cell damage<sup>[81]</sup>.

In a second case report, a patient with HCV infection and negative anti-thyroid Abs before treatment but with the typical association for HT (HLA-DR5 antigen or HLA-DRB1.11/HLA-DRB1.12 alleles) in Caucasian developed HT during  $\alpha$ -IFN treatment<sup>[82]</sup>.

In a preliminary longitudinal (range 12-54 mo)

study in patients with chronic hepatitis C and absence of thyroid disorders at the baseline ( $n = 15$ ), the relationship between the HLA antigen susceptibility and the thyroid disorders during the  $\alpha$ -IFN treatment was evaluated, with respect to control subjects ( $n = 107$ )<sup>[83]</sup>. The HCV genotype was 1b (20%), 2a (60%) and 3a (20%), with the distribution (1b:2a:3a) of 1:3:1 and absence of mixed genotype. It is well known that the HLA-B35, -DR3 (DRB1.03 allele) and -DR5 (DRB1.11/HLA-DRB1.12 alleles) are commonly associated with De Quervain's thyroiditis, thyrotoxicosis/hyperthyroidism and hypothyroidism, respectively<sup>[80,84-92]</sup>. Arginine at position 74 of HLA-DRB1 chain (DRB-Arg74) may permit autoAg peptides to fit into the binding pocket, to be presented more efficiently to T cells<sup>[93]</sup>. On the other side, the HLA-A2 has been aspecifically associated with thyroid disorders (either hyper- or hypothyroidism) in patients with chronic hepatitis C during  $\alpha$ -IFN therapy<sup>[30]</sup>. The HLA-A2 antigen (class I molecule) is involved in the restricted presentation of HCV peptides by the APC to the CTL (response strongly increased by  $\alpha$ -IFN, with final outcome of target cell disruption both at the liver and thyroid gland level)<sup>[94-97]</sup>.

Forty percent of HCV patients presented a double positive HLA result (HLA-A2/B-35, HLA-A2/DRB1.03, HLA-A2/DRB1.11 or HLA-B35/DRB1.11) before the treatment and five patients with double positive HLA received the  $\alpha$ -IFN therapy. Four double positive HLA treated females developed clinical thyroid disorders, with the HLA system specifically associated with the particular kind of the thyroid disorder ( $P < 0.05$ ). The HLA-A2 was not specific for thyroid disorder, being present in hypothyroidism, in thyrotoxicosis as well as in thyroiditis. The relationship between the thyroid disorders and the HCV genotype did not reveal significant association. In our group with 40% double positive HLA pre-treatment, the overall development of thyroid disorders after  $\alpha$ -IFN was 36% (33% in patients with pre-treatment negative anti-thyroid Abs).

Previous studies have showed the association of AITD with female gender, older age and pre-existing positive anti-thyroid Abs, in  $\alpha$ -IFN treated patients with HCV-related chronic hepatitis<sup>[26,49,61,66,69,70]</sup>. Our results suggest that the HLA system is a strong susceptibility factor to the development of AITD, in particular, in the patients with two Ags together (the double association of HLA class I and/or II). Therefore, the examination of HLA (HLA-A2, -B35, -DRB1.03, -DRB1.11) in HCV patients before  $\alpha$ -IFN treatment may be a useful predictive tool to detect the predisposition to develop the specific AITD.

HCV virion attachment and entry in thyrocytes are mediated by CD81 (host) and E2 (virus), activating the local inflammatory response (as well as it occurs for hepatocytes). Moreover, HCV also replicates within the infected human thyroid cells *in vitro*<sup>[98]</sup>. The HCV infection of thyroid cells can trigger the autoimmune thyroiditis by induction of changes in self Ag expression, exposing of cryptic epitopes or molecular mimicry and

leading to production of the proinflammatory IL-8 (a contributor to bystander activation)<sup>[11]</sup>.

Even if important host effector molecules (such as the interferon-induced transmembrane proteins IFITM family of proteins) may act against HCV in the liver, restricting infection by targeting the endocytosed virion for lysosomal degradation<sup>[99]</sup>, at the moment, no data in the literature describe the role of IFITM in AITD.

The molecular mimicry is the mainly investigated mechanism of induction of autoimmunity and we analyzed the frequency of the sequence homology between the thyroid and the HCV. We found 62.5%-100% homology, when the conservative substitutions were included in the analysis (ten out of ten identical/conservative amino acids in the sequence), between the HCV polyprotein and five thyroid Ags (Tg, TPO, TSHr, NIS and pendrin). The homology was not restricted to a single HCV genotype, with the highest degree between the NIS and the HCV1a-NS4a protein. The Tg had the highest number of homologies with the different HCV genotypes. The length of ten amino acids is consistent with the presentation of the self/viral Ags with the HLA class I to CD8<sup>+</sup> lymphocytes (the HLA class II usually bind longer peptides)<sup>[100]</sup>.

The aberrant expression of HLA class II on thyroid cells (with costimulation) and the local inflammation (with cytokine release) result in activation of autoreactive T cells by bystander mechanisms. Systemic inflammation (cytokines and chemokines, like IL-8) plays an important role in the immunopathogenesis of thyroiditis and antagonize the antiviral effects of IFN, facilitating HCV persistence in thyrocytes. The absence of HCV clearance from thyrocytes perpetuates the chronic inflammation and autoimmunity.  $\alpha$ -IFN triggers AITD through an epigenetic mechanism involving variant of Tg and TSHr gene promoter<sup>[101,102]</sup>. Moreover,  $\alpha$ -IFN locally enhances the expression of TSH-r, Tg, TPO and HLA class I molecules on thyrocytes and the secretion of the potent proinflammatory IL-2 cytokine<sup>[11]</sup>.

$\alpha$ -IFN treatment for HCV-related chronic hepatitis acts an enhancer of AITD in susceptible patients. The standard dual therapy with pegylated  $\alpha$ -IFN (pegIFN)/ribavirin has been recently increased to a triple therapy, based on new direct-acting antiviral drugs [NS3/4A serine protease inhibitor (PI), such as telaprevir or boceprevir].

The monitoring of the patients during the treatment avoids the side effects (typically flu-like symptoms with pegIFN or anemia with ribavirin, or irritability, allergic reactions, severe fatigue, bacterial infections)<sup>[103,104]</sup>. Thyroid function tests should be examined every 3 mo during the  $\alpha$ -IFN based treatment<sup>[105,106]</sup>. Recently,  $\alpha$ -IFN-free combined treatment with direct antiviral agents for HCV has been developed with or without ribavirin, ameliorating the patient compliance and reducing the risk for thyroid autoimmunity development. These agents are second generation PI (simeprevir, grazoprevir), NS5A inhibitor (daclatasvir, ledipasvir, ombitasvir, elbasvir) and NS5B polymerase inhibitor (sofosbuvir,

paritaprevir, dasabuvir, beclabuvir, asunaprevir) that are strongly efficacious to eradicate the HCV infection (undetectable HCV-RNA after 24 wk from the beginning of therapy)<sup>[53,107-109]</sup>.

## CONCLUSION

In conclusion, the development of AITD in patients with chronic HCV-infection is a complex model for autoimmunity in which every component (the host and the environment) has a significant role.

The new approach with  $\alpha$ -IFN-free combined treatment for chronic HCV-infection with direct antiviral agents is very promising in order to ameliorate the patient compliance and to reduce the risk of development of AITD.

## Abstract

Over the last years it has started a real revolution in the treatment of chronic hepatitis C. This occurred for the availability of direct-acting antiviral agents that allow to reach sustained virologic response in approximately 90% of cases. In the near future further progress will be achieved with the use of pan-genotypic drugs with high efficacy but without side effects.

**Key words:** Direct-acting antiviral agents; Nucleoside inhibitors; Boceprevir; Sofosbuvir; Telaprevir; Hepatitis C; Simeprevir; Daclatasvir; Ledipasvir; Faldaprevir; Ritonavir; Ombitasvir; Dasabuvir

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This review analyzes the current therapies for chronic hepatitis C and the future challenges of the research. So it tries to give an update on the research of hepatitis C virus (HCV) infection, providing a critical view of the emerging therapies and their impact on the future management of HCV infection. Since novel

treatments for HCV infection are highly efficacious but costly, priority should be given to patients with advanced hepatic fibrosis, which is a disease that cannot be deferred.

Chronic hepatitis C: This and the new era of treatment. *World J Hepatol* 2016; 8(2): 92-106 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i2/92.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i2.92>

## INTRODUCTION

The hepatitis C virus (HCV), identified in the 70s but cloned in 1989, is a single-stranded RNA virus belonging to the family *Flaviviridae*.

HCV is the main cause of progressive liver diseases and a public health problem worldwide. It is estimated that approximately 150-180 million people in the world are living with chronic hepatitis<sup>[1,2]</sup>, 350 million of whom die each year from liver damage associated with the infection<sup>[3]</sup>.

About 80% of people infected with HCV develop chronic hepatitis, of which 20%-40% will develop liver cirrhosis or hepatocellular carcinoma (HCC) 20-30 years after infection.

As a consequence, chronic HCV infection is the major reason of liver transplantation in developed countries<sup>[4-7]</sup>.

According to the Global Burden Disease Study in Europe, the death rate for viral hepatitis is significantly higher than that for human immunodeficiency virus (HIV) and acquired immune deficiency syndrome; in particular in 2010, the number of deaths from viral hepatitis have been ten times bigger than that attributed to HIV. It is reasonable to think that this difference is due to the lack of effective therapies for HCV until a few years ago<sup>[8]</sup>.

HCV is also one of the main causes of death<sup>[9]</sup>. The virus causes both liver damage and extra-hepatic manifestations, many of these syndromes are associated with the ability of HCV to replicate in peripheral blood mononuclear cells (PBMCs); an example is the mixed cryoglobulinemia, which is by far the most common extrahepatic disease closely connected with the infection.

Recently it was shown that antiviral treatment is associated with improved renal and cardiovascular outcomes in patients with cryoglobulinemia<sup>[4,6,10,11]</sup>. Newly approved oral anti-HCV drugs are very safe and effective, but unfortunately their cost will force to choose a priority of treatment. The intent should therefore be to identify and treat patients with a higher risk of morbidity and mortality due to HCV.

The availability of these new oral treatments can definitely heal patients and consequently it will cause a significant reduction in health care costs<sup>[2]</sup>. The aim of

this review article is to give an update on the research of HCV infection, providing a critical view of the emerging therapies and their impact on the future management of HCV infection.

## Natural history of chronic hepatitis C

The natural history of chronic hepatitis C is partly defined. The primary HCV infection is completely asymptomatic in 60%-70% of cases, but in 80% of patients the infection becomes chronic and is characterized by the persistence of the viral genome in the blood for at least 6 mo from the onset of acute infection. In a variable proportion of people carrying the virus, especially in the presence of strong necro-inflammation and/or co-factors of liver damage, the disease can evolve from the condition of chronic hepatitis to cirrhosis and HCC.

There are several factors that can change the course, severity and progression of the disease, including age at the time of infection, route of infection, viral load, co-infection with other hepatitis viruses or HIV, alterations of immune status, and the coexistence of other hepatotoxic factors such as consumption of alcohol, iron overload, obesity, type 2 diabetes, resistance to insulin and genetic factors<sup>[12-14]</sup>.

Chronic HCV infection in about 20% of cases progresses up to hepatic cirrhosis, end-stage liver disease and HCC, generally after 20-30 years from primary infection.

The progression of chronic disease leads, through a mechanism of chronic damage, to the loss of organ function, for progressive deposition of fibrotic tissue and disruption of the parenchymal structure, and results in liver fibrosis and cirrhosis.

Cirrhosis changes the normal liver architecture, and furthermore itself represents the most important risk factor for the development of HCC, in part by acting as a cofactor accelerating the process triggered by a primary carcinogen (HCV), and specially by increased hepatocyte regeneration. Once HCV infection progresses to cirrhosis, there is a 1%-5% annual risk of HCC<sup>[12]</sup>.

The probability that a patient with compensated cirrhosis can evolve towards the decompensated form increases progressively over time.

Liver cirrhosis and its complications (portal hypertension and therefore esophageal varices, splenomegaly, ascites, hepatic encephalopathy, spontaneous bacterial peritonitis, hepatorenal syndrome, hepato-pulmonary syndrome and HCC) are burdened with high morbidity and mortality.

It is also known that different variables influence the progression of the disease, for which the prognosis changes individually and is very hard to define<sup>[12-14]</sup>.

Several studies have concluded that the eradication of HCV infection slows the progression of the disease, improves the survival, and reduces the incidence of liver failure and the risk of developing liver cancer<sup>[12-28]</sup>. The understanding of the natural history of chronic hepatitis C and its long-term consequences is essential to enable appropriate decisions on treatment, but unfortunately

the natural history of HCV infection is still the subject of much controversy. In fact, according to some authors the disease is relentlessly progressive, with a high probability to evolve to cirrhosis and HCC, while according to others the course is variable, and most patients die as a consequence of co-morbidities, not the infection itself.

Because the infection has a significant role in causing chronic hepatitis, cirrhosis and HCC, the goal of treatment is to cure HCV infection, and consequently to prevent its complications.

Although the viral RNA genome does not integrate into the host genome, the infection becomes persistent in the majority of patients, and about 70%-90% of the infected people fail to clear the virus once acquired.

It is widely known that the antiviral treatment and the achievement of a sustained virological response (SVR - defined as an absence of detectable HCV-RNA 12 mo after therapy is complete) are associated with regression of fibrosis and clinical improvement. However, despite treatment, HCV may persist in liver tissue and extrahepatic locations like PBMCs, leading to late relapse, defined as reappearance of viremia after SVR has been achieved<sup>[29,30]</sup>.

### **Treatment and SVR - what is the real purpose of antiviral therapy?**

As mentioned above the primary goal of HCV therapy is the complete eradication of the virus, which is the SVR.

SVR was traditionally defined as HCV-RNA undetectable in serum for at least 24 wk after the end of treatment (SVR24); however, recent data suggest that the assessment at 12 wk after treatment (SVR12) is sufficient for defining this result.

Follow-up studies document that more than 99% of patients who achieve an SVR remain HCV-RNA negative 4-5 years after the end of treatment, and no signs of hepatitis have been documented.

SVR represents the main goal of antiviral therapy, indeed once achieved, the SVR is considered effective in the long term because late recurrences are rare; the SVR is associated with long-term health benefits, including improved quality of life.

SVR reduces risk for progression to cirrhosis, HCC, liver transplantation and liver-related mortality, and also decreases extra-hepatic manifestations of HCV infection (for example, cryoglobulinemic vasculitis).

Moreover it seems reasonable to assume that a lasting biochemical and virological response induced by treatment can also lead to improved liver fibrosis<sup>[31-39]</sup>.

For decades the antiviral therapy of chronic HCV infection was based on the administration of interferon (IFN), initially as monotherapy and subsequently in combination with ribavirin (RBV). Dual therapy with "pegylated IFN (PEG-IFN) and RBV" achieves SVR rates of 40% to 50% in patients with genotype 1, and about 80% in those with genotypes 2, 3, 5 and 6; the results for genotype 4 are intermediates.

In 2011, the first direct-acting antivirals boceprevir

and telaprevir have been approved in combination with PEG-IFN and RBV. These drugs are protease inhibitors (PIs) and increase SVR rates in both naive patients and in experienced patients, compared to dual therapy<sup>[40-46]</sup>; however, they were dropped due to their significant toxicity.

With the advent of new oral antiviral regimens, with better efficacy and tolerability, and a shorter treatment duration, the number of patients that can be treated is expected to increase significantly, and also the SVR rates will improve to approximately 95% or plus<sup>[47]</sup>.

### **HCV and host: The HCV replication cycle and mechanisms of action of the new direct acting antiviral agents**

HCV is classified within the *Flaviviridae* family, as the only member of a distinct genus called *Hepacivirus*<sup>[48]</sup>.

The lack of detailed information on the viral replication cycle has significantly prevented the development of direct acting antivirals.

For decades the antiviral therapy of chronic HCV infection was based on the administration of IFN, initially alone and then in combination with RBV, but this regimen was effective in only 50% of patients with genotype 1, with significant side effects<sup>[49-54]</sup>.

In the last decade the development of *in vitro* models of viral replication has thus represented a turning point for the understanding of the different stages of the replication cycle, and quickly has led to the design and introduction of direct acting antivirals (DAAs)<sup>[55]</sup>.

However, because of huge variability of the virus, new drugs cannot be administered as monotherapy because it would quickly lead to the selection of drug-resistant viral variants.

HCV indeed is characterized by an extremely high degree of variability. The genetic heterogeneity of HCV gives an adaptive advantage as the simultaneous presence of multiple genomic variants allows rapid selection of mutants that better adapt to environmental changes (for example resistance to drugs or the immune response); this genetic heterogeneity is the basis of chronic infection, and is probably involved in the phenomena of evasion of the immune response and in the limited efficacy of treatment<sup>[56-59]</sup>.

The HCV replication cycle occurs in the cytoplasm, and can be summarized as follows: (1) entry into the host cell and release of viral genomic RNA into the cytoplasm; (2) translation of RNA, processing of the viral polyprotein and formation of a replication complex associated with intracellular membrane; (3) using positive RNA for the synthesis of an intermediate negative RNA for the production of new positive RNA molecules with different destination; and (4) release of viral progeny into circulation from infected cells. The infectious viral structure is comprised of envelope glycoproteins in a lipid bilayer, that contain the viral core protein and RNA<sup>[60-63]</sup>.

After cell entry, the viral RNA is translated through the host machinery into a polyprotein, which is cleaved

**Figure 1** Hepatitis C virus replicative cycle and main targets for direct acting antiviral agents. Modified from Manns and Cornberg. *Lancet Infectious Diseases* 2013. PIs: Protease inhibitors; NPIs: Nucleoside polymerase inhibitors; NNPIs: Non-nucleoside polymerase inhibitors.

during and after translation by both host and viral-encoded proteases into 10 mature viral proteins, including several non-structural (NS) proteins. One of the viral proteases involved in this post-translational processing is a heterodimeric complex of the NS3 and NS4A proteins (NS3/NS4A). NS3 has the proteolytic activity and NS4A is a membrane protein that acts as a cofactor. Synthesis of new viral RNA occurs in a highly structured replication complex that consists of NS3, NS4A, NS4B, NS5A, and NS5B. NS5B is an RNA-dependent RNA polymerase that is essential for viral replication. NS5A has a presumptive role in the organization of the replication complex and in regulating replication. It is also involved in assembly of the viral particle that is released from the host cell (Figure 1)<sup>[64-69]</sup>.

### Therapies

Increased knowledge of the HCV replication cycle and genomic diversity has driven the development of antiviral agents specifically targeting well-conserved proteins required for efficient viral replication. Aside from PEG-IFN, HCV-specific therapeutic agents that have gained widespread use or reached late-stage clinical trials include NS3 PIs, nucleoside and nucleotide analogues, and other NS5B polymerase inhibitors.

### DAAs

After year of IFN-based therapy, the introduction of DAAs has increased the number of patients who respond to treatment, and has changed radically the treatment of chronic HCV genotype-1 infection<sup>[43,70-72]</sup>.

Thanks to the discovery of key viral replication targets such as the NS3/4A protease, NS5A, and the NS5B RNA polymerase, other potent antiviral inhibitors were licensed in 2014.

These new regimens include the addition of simeprevir (SMV) (a second-generation PI), daclatasvir (an NS5A inhibitor), and sofosbuvir (an uridine nucleotide prodrug NS5B polymerase inhibitor), in combination with PEG-IFN and RBV for 12-24 wk<sup>[73,74]</sup>.

The main targets of the DAAs are the HCV-encoded proteins that are vital to the viral replication. The DAAs have a high barrier to resistance and ideally, they should also be active against all HCV genotypes. Furthermore, these drugs are well tolerated and have few drug interactions.

There are four classes of DAAs, which are defined by their mechanism of action and therapeutic target<sup>[75]</sup> (Figure 2 and Table 1): (1) NS3/4A PIs; (2) NS5B nucleoside polymerase inhibitors (NPIs); (3) NS5B non-NPIs (NNPIs); and (4) NS5A inhibitors.

### NS3/4A PIS

NS3/4A PIs are drugs that inhibit the NS3/4A serine protease, an enzyme involved in post-translational processing and replication of HCV<sup>[76]</sup>.

There are two generation of PIs.

#### First-generation PIs (telaprevir and boceprevir)

The first-generation PIs telaprevir and boceprevir were the first DAAs available for the treatment of CHC<sup>[77]</sup>.

**Figure 2 Direct acting antiviral agents.** Modified from Alexopoulou *et al.*<sup>[121]</sup>. Interferon-based combination treatment for chronic hepatitis C in the era of direct acting antivirals. *Annals of Gastroenterology* 2015; 28: 55-65. NPIs: Nucleoside polymerase inhibitors; NNPIs: Non-nucleoside polymerase inhibitors; DAA: Direct acting antiviral.

The addition of PIs to PEG-IFN and RBV has become the new standard of care for the treatment of genotype 1 infection, and so, in 2011, has increased the efficacy of PEG-IFN and RBV in patients with chronic HCV genotype 1 infection.

Telaprevir and boceprevir were approved for the treatment of chronic HCV genotype 1 infection by the Food and Drug Administration (FDA) and European Medicines Agency in combination with PEG-IFN- $\alpha$  and RBV in adults with compensated liver disease, including cirrhosis, who are previously untreated or who have failed previous IFN and RBV therapy<sup>[78]</sup>.

Telaprevir and boceprevir are NS3/4A PIs, and they both have the same molecular target: The HCV NS3/4A serine protease.

They have an high antiviral potency only against genotypes 1 and 2, but a low barrier to resistance<sup>[79]</sup>.

Monotherapy with these agents resulted in the selection of drug resistant variants, so they should always be used in triple combinations together with PEG-IFN and RBV in a triple therapy regimen to reduce the frequencies of resistant mutants and viral breakthrough, and they can improve the SVR rates by 15% to 20% compared with PEG-IFN- $\alpha$  and RBV<sup>[42,43,80]</sup>.

Viral resistance may develop even in triple combinations with PEG-IFN and RBV, and due to this problem strict stopping rules are applied in triple therapy-based regimens.

Response to HCV therapy in genotype 1 can be predicted by identifying the single nucleotide polymorphisms located in the region of interleukin-28B (*IL-28B*) gene through genome-wide association studies.

High response rates have been reported in patients with CC genotype of *IL-28B* as compared to CT or TT *IL-28B*-genotype (70% vs 25%-30%). Testing for *IL-28B* genotype is thus a useful tool in the management

**Table 1 Classification of new antiviral drugs**

NS3/4A PIs	First-generation protease inhibitors
	Telaprevir
	Boceprevir
	Second-generation protease inhibitors
	Simeprevir
	Faldaprevir
	Paritaprevir
	Ritonavir
NS5B NPIs	Sofosbuvir
NS5B NNPIs	Dasabuvir
NS5A inhibitors	Daclatasvir
	Ledipasvir
	Ombitasvir

PIs: Protease inhibitors; NPIs: Nucleoside polymerase inhibitors; NNPIs: Non-nucleoside polymerase inhibitors.

of patients<sup>[81]</sup>.

First-generation PIs increase the number of patients with genotype 1 infection who respond to treatment, however, the side effect profiles of these triple combination therapies are not favourable, because it can cause clinically significant adverse events.

The most common side effects of telaprevir are anaemia, pruritis, nausea, diarrhoea, and anorectal discomfort. Around 4% of patients develop severe dermatitis, necessitating cessation of treatment.

Drug reactions like eosinophilia and systemic symptoms or Stevens-Johnson syndrome are rare, but have been reported. Boceprevir causes dysgeusia and anaemia<sup>[43]</sup>.

Several drug-drug interactions can occur, so the use of first-generation PIs has been significantly restricted<sup>[82]</sup>.

### Second-generation PIs

Second-generation PIs offer several benefits, for example, few drug-drug interactions and less frequent and less severe side effects.

In addition, second-generation PIs also appear to have increased efficacy against genotype 1 HCV<sup>[83]</sup>; as treatment options have progressed and improved, HCV- 1, HCV-2 and HCV-4 are considered to be easy to treat<sup>[84]</sup> but HCV genotype 3 infection has become the most difficult to treat.

**SMV:** SMV was the first available second-generation PI with antiviral activity against genotypes 1, 2, 4, 5 and 6<sup>[85]</sup>.

SMV is administered orally as a daily pill, and has limited drug-drug interactions.

No dose recommendation can be given for patients with Child-Pugh class B or C cirrhosis, because higher SMV exposure (particularly in Child-Pugh C patients) may be associated with increased frequency of adverse reactions. No dose adjustment is required in the setting of renal impairment, because SMV is eliminated by the liver<sup>[85]</sup>. SMV is well tolerated, and adverse reactions in patients receiving SMV in combination with PEG-IFN- $\alpha$

and RBV are rash, pruritus and nausea. Because SMV is an inhibitor of the transporters OATP1B1 and MRP2, mild, transient hyperbilirubinaemia not accompanied by changes in other liver parameters was observed in approximately 10% of cases. SMV is oxidatively metabolized by CYP3A subfamily, which consists mainly of hepatic and intestinal CYP3A4 metabolism<sup>[86]</sup>. Co-administration of SMV with inhibitors of cytochrome P450 3A (CYP3A) is not recommended.

In post-liver transplant patients with HCV infection, co-administration of SMV with cyclosporine resulted in significantly elevated SMV levels, so it is not recommended<sup>[87]</sup>. SMV can be safely administered with tacrolimus or sirolimus. SMV was approved by the FDA for genotype 1 treatment in November 2013 under the name of "OLYSIO", in Japan it was licensed in September 2013, finally in Europe in May 2014 (European Medical Agency approval).

In phase II of COSMOS trial, sofosbuvir (SOF; 400 mg daily) was administered in combination with SMV (SMV 150 mg daily) with or without RBV for 12 wk or 24 wk in genotype 1 patients. SVR12 rates were not different between 12 or 24 wk of treatment, with or without RBV, and comparing naive patients to experienced (95% vs 91%)<sup>[87,88]</sup>.

In this small study, the regimen SOF plus SMV with or without RBV was well tolerated; the most common side effects were headache, fatigue, and nausea, and only four (2%) patients discontinued treatment due to these events.

Although the results of this study are encouraging, due to the small number of patients and the future availability of other oral regimes with better antiviral efficacy and fewer side effects, this regimen should be considered as a second-line option.

Two phase III trials of SMV/SOF without RBV are ongoing (OPTIMIST-1 and -2)<sup>[89]</sup>. These studies provide us much bigger data about SOF/SIM regimen, and investigate the efficacy and safety of SMV 150 mg in combination with sofosbuvir 400 mg in HCV genotype 1 infected naïve or experienced patients, with and without cirrhosis.

SMV/SOF treatment led to high SVR12 rates in patients infected with HCV GT-1 subtype, regardless of treatment duration or the addition of RBV. SVR12 rates were high, regardless of baseline characteristics, including HCV GT-1 subtype, *IL-28B* allele, or Q80K polymorphism. On-treatment virologic response, including RVR, was not predictive of SVR. Two ongoing phase III trials are investigating SMV/SOF without RBV (OPTIMIST-1 and -2).

Baseline predictive factors significantly associated with virologic relapse were male sex, body weight  $\geq 75$  kg, *IL-28B* non-CC allele, cirrhosis, baseline HCV RNA  $\geq 800000$  IU/mL, and prior treatment failure. Current SOF regimens are highly efficacious, even in patients with multiple traditional negative predictors of diminished efficacy; SVR12 rates are comparatively lower in patients who have five or six negative predictors<sup>[90,91]</sup>.

The approval of the treatment scheme "SMV plus PEG-IFN/RBV" is based on a clinical trial program comprising three phase III studies, with more than 1000 patients with genotype 1.

The studies, QUEST-1, QUEST-2 and PROMISE, have evaluated the use of SMV in combination with PEG-IFN/RBV in naive patients (Quest-1 and 2)<sup>[92,93]</sup> and relapsed patients (PROMISE<sup>[94]</sup>) after an IFN-based treatment. All three studies have shown that SMV, in combination with PEG-IFN/RBV, gets significant SVR rates when compared to PEG-IFN/RBV.

A triple therapy with SMV, PEG-IFN and RBV has been recommended for genotype 1 also after the data of other four phase III trials: CONCERTO-1, -2, -3 and -4<sup>[95-98]</sup>.

**Faldaprevir:** Faldaprevir is one of the new-generation NS3/4A PIs in development. It is a pan-genotypic potent NS3/NS4 PI (antiviral activity against genotypes 1, 2, 4, 5 and 6 *in vitro*). It was used in genotype 1 infection in two combinations: (1) a triple regimen with faldaprevir, PEG-IFN and RBV for a total of 24 wk<sup>[98,99]</sup>; and (2) IFN-free regimens with faldaprevir and deleobuvir with or without RBV<sup>[100,101]</sup>.

In both combinations faldaprevir provides high SVR rates, but IFN-containing regimens registered most cases of breakthrough and relapse, while with the IFN-free combination of faldaprevir and deleobuvir with RBV, very encouraging results were obtained<sup>[102]</sup>.

Faldaprevir is administered orally, once a day. The most common adverse events are gastrointestinal dysfunction, rash and photosensitivity skin. Faldaprevir in combination with PEG-IFN and RBV appears to be associated with fewer adverse events than the first PIs telaprevir and boceprevir.

**Paritaprevir and ritonavir:** Paritaprevir is an HCV protease inhibitor that is given with low dose ritonavir for a pharmacologic boosting effect.

Ritonavir is a protease inhibitor that does not have anti-HCV activity but it is a pharmacoenhancer that is included to increase levels of paritaprevir through inhibition of CYP3A-mediated metabolism.

Paritaprevir and ritonavir are available as a fixed-dose combination with ombitasvir and given with the non-nucleoside NS5B inhibitor dasabuvir. This regimen is given with and without RBV for the treatment of HCV GT-1 subtype<sup>[103]</sup>.

## NS5A INHIBITORS

The NS5A is a multifunctional non-structural protein involved both in viral replication and in the assembly of HCV<sup>[104]</sup>. However, the precise molecular mechanisms of HCV NS5A inhibitors are unclear.

NS5A inhibitors have high antiviral activity against a lot of genotypes, but a low genetic barrier. They significantly reduce HCV-RNA levels and enhance SVR when given in conjunction with PEG-IFN and RBV. They

**Figure 3** ION-2 sub-analysis of cirrhosis vs without cirrhosis. Error bars represent 95% CIs. LDV: Ledipasvir; RBV: Ribavirin; SOF: Sofosbuvir; SVR12: Sustained virologic response at 12 wk post-treatment.

also result in very high SVR rates among patients with genotype 1 infection when given in combination with other direct-acting antivirals with or without RBV<sup>[105]</sup>.

### Daclatasvir

Daclatasvir is a pangenotypic NS5A inhibitor that is available for use in Europe. According to EASL guidelines daclatasvir should be administered orally (60 mg once daily) with low potential for drug-drug interactions. It is well tolerated. Dose adjustments are not needed in patients with Child B or C disease. Side effects with daclatasvir are fatigue, headache, and nausea. Little information has been released on daclatasvir drug-drug interactions.

In previously untreated patients infected with genotype 2 or 3, SVR was reported in 94%-100% of patients treated with the combination of daclatasvir plus sofosbuvir. In the ALLY-3 study<sup>[106]</sup>, 133 patients with genotype 3 infection were treated for 12 wk with 400 mg of sofosbuvir and 60 mg of daclatasvir for 12 wk. Ninety-one percent of previously untreated patients had an SVR compared with 86% of treatment-experienced patients.

In the COMMAND GT2/3 study, Dore *et al.*<sup>[107]</sup> compared the efficacy and safety of daclatasvir plus PEG-IFN- $\alpha$ -2a/RBV administered for either 12 or 16 wk with a standard 24-wk course of PEG-IFN- $\alpha$ -2a/RBV in HCV GT-2 or GT-3 subtype. Daclatasvir has been given with PEG-IFN- $\alpha$ -2a/RBV for 12 or 16 wk to previously untreated patients with genotype 2 or 3 infection. Around 83% of patients infected with genotype 2 and 70% of patients with genotype 3 infection have been reported to achieve SVR<sup>[107]</sup>. In another open-label study, the drug's effectiveness has been demonstrated<sup>[108]</sup>.

### Other NS5A inhibitors

Other NS5A inhibitors available in the United States are ledipasvir and ombitasvir, and they are each available in fixed-dose combinations with other direct-acting antivirals.

**Ledipasvir:** Ledipasvir is the first NS5A inhibitor

available in the United States. Ledipasvir and sofosbuvir are co-formulated in a single tablet in a fixed-dose combination (90 mg ledipasvir/400 mg sofosbuvir) that is administered once daily with or without food. This combination is well tolerated, and ledipasvir has the same drug interactions as sofosbuvir. This regimen is administered with or without RBV, depending on the patient population, in genotype 1 infection.

**Ombitasvir:** Ombitasvir (also known as ABT-267) is available as a fixed-dose combination with the PIs paritaprevir and ritonavir (12.5 mg ombitasvir/75 mg paritaprevir/50 mg ritonavir). This single tablet is administered orally with an additional drug: The non-nucleoside polymerase (NS5B) inhibitor dasabuvir<sup>[109,110]</sup>. This regimen is given with and without RBV in genotype 1 infection.

The combination ombitasvir-paritaprevir-ritonavir plus dasabuvir is generally well tolerated, and mild adverse effects are nausea, pruritus, insomnia, diarrhea, and asthenia<sup>[111,112]</sup>. Some of these symptoms may be attributable to RBV<sup>[113,114]</sup>.

The most important studies that evaluated treatment duration of ledipasvir/sofosbuvir treatment and its safety and efficacy (SVR12) in naive and treatment-experienced patients are ION-1, LONESTAR, and ION-2<sup>[115-117]</sup> (Figure 3).

## NS5B RNA-DEPENDENT RNA POLYMERASE INHIBITORS

NS5B is an RNA-dependent RNA polymerase involved in post-translational processing that is necessary for replication of HCV. The structure of NS5B is highly conserved across all HCV genotypes, so the drugs that inhibit NS5B have efficacy against all six genotypes.

There are two classes of polymerase inhibitors: NPIs and NNPIs. These two classes generally differ in specificity, according to their mode of action.

The NPIs mimic natural components and thus are incorporated into the nascent RNA chain, causing premature chain termination<sup>[118]</sup>. NNPIs act as allosteric inhibitors, and in fact they bind to one of four allosteric sites on the surface of NS5B.

### NPIs

NPIs have high antiviral efficacy across all genotypes, although they have a very high barrier to resistance.

**Sofosbuvir:** Sofosbuvir is the first NS5B NPI available in the United States.

Sofosbuvir is a pangenotypic NS5B polymerase inhibitor with a high barrier to resistance and favorable clinical pharmacology profile. It is administered orally as a 400 mg pill once a day, and has no food effect. Sofosbuvir is well tolerated, and the most commonly reported side effects of sofosbuvir and RBV, with or without PEG-IFN, are fatigue, headache, nausea,

insomnia, and anemia<sup>[74,119]</sup>.

Although renal clearance is the major form of elimination, in patients with mild or moderate renal impairment (glomerular filtration rate greater than 30 mL/min)<sup>[120]</sup>, any adjustment dose is not required.

No dose adjustment has been needed in patients with moderate (Child Pugh class B) or severe (Child Pugh class C) hepatic impairment.

Sofosbuvir has substantially less drug interactions than those observed with the HCV PIs. Sofosbuvir is a substrate of P-glycoprotein (P-gp), a drug transporter, so drugs that are potent intestinal P-gp inducers may decrease sofosbuvir levels. Thus, coadministration of sofosbuvir is not recommended with rifampin, rifabutin, rifapentine, St. John's wort, carbamazepine, phenytoin, phenobarbital, oxcarbazepine, or tipranavir/ritonavir.

Sofosbuvir was approved by FDA for genotype 1 in combination with PR, and in genotypes 2 and 3 in IFN free regimens in December 2013, in Canada during the same month and in Europe in January 2014 (European Medical Agency approval).

In the NEUTRINO study (an open-label, single-arm phase III registration trial) 327 treatment-naïve patients were treated with a regimen comprising sofosbuvir plus PR for 12 wk<sup>[119]</sup>. The overall patient population included mainly those infected with genotype 1 (89%) as well as a few patients infected with genotypes 4, 5 and 6; 17% of patients in this trial had cirrhosis. This sofosbuvir-based triple-therapy regimen resulted in a very high RVR, with the 4-wk RVR rate approaching 99%. The SVR rate for the entire trial population remained high at 90%, 12 wk after the end of treatment (with 99% of patients achieving virologic response at the end of treatment). Analyzing the groups based on viral genotype, patients with genotype 1 had an SVR rate of 89%, and the small number of patients with genotype 4, 5 and 6 had SVR rates between 96% and 100%. Overall, this sofosbuvir-based triple therapy regimen resulted in very high SVR rates across all genotypes that were evaluated. One important point from the NEUTRINO trial was the relative decrease in the overall response rate for patients with cirrhosis (SVR, 80%) compared with non-cirrhotics (SVR, 92%)<sup>[121]</sup>.

Other representative studies on genotype 1 are ELECTRON, QUANTUM, VALENCE and LONESTAR-2<sup>[122-125]</sup>.

Genotypes 2 and 3 have been studied together in three sofosbuvir phase III trials (FISSION, POSITRON, and FUSION)<sup>[119,122,126]</sup>.

Therapy with sofosbuvir-RBV for 12 wk in patients with HCV genotype 2 infection and for 24 wk in patients with HCV genotype 3 infection resulted in high rates of SVR<sup>[127]</sup>.

To date there are very few data on genotype 4 patients treated with sofosbuvir without PEG-IFN<sup>[128]</sup>. There are no data currently on treatment-experienced populations or any patients with genotypes 5 and 6<sup>[129]</sup>.

Sofosbuvir is used in various combinations with other antivirals for different indications: (1) with ledipasvir for HCV GT-1; (2) with SMV ( $\pm$  RBV) for HCV GT-1;

(3) with RBV for HCV GT-2, -3, -4, -5, and -6 infection (and among patients with any genotype awaiting liver transplant); and (4) with PEG-IFN and RBV for genotypes HCV GT-1 and -4.

### NNPIs

NNPIs bind to one of four allosteric sites on the surface of NS5B and cause a conformational change, making the enzyme ineffective. Despite the active site of NS5B is well conserved across all genotypes, and they should have a pan-genotype antiviral activity, NNIs have a more limited spectrum of activity specifically targeting against GT-1 (all NNPIs in clinical development have been optimized for GT-1). They have a low to moderate barrier to resistance variable toxicity profiles<sup>[130]</sup>. Consequently, this class of drug has been studied primarily as an adjunct to more potent compounds with higher barriers to resistance.

**Dasabuvir:** Dasabuvir is a non-nucleoside polymerase (NS5B) inhibitor administered with the fixed-dose combination ombitasvir-paritaprevir-ritonavir (12.5 mg ombitasvir/75 mg paritaprevir/50 mg ritonavir).

**ABT-450/ritonavir with ombitasvir (ABT-267) and dasabuvir (ABT-333):** TURQUOISE- II is a global, multi-center, randomized, open-label study evaluating the efficacy and safety of 12 or 24 wk of treatment with ABT-450/ritonavir (150/100 mg) co-formulated with ombitasvir (ABT-267) 25 mg, dosed once daily, and dasabuvir (ABT-333) 250 mg with RBV in adult patients with GT-1 HCV infection with compensated liver cirrhosis. Patients achieved SVR<sub>12</sub> rates of 91.8% and 95.9% in the 12 and 24-wk treatment arms, respectively<sup>[131]</sup>. In TURQUOISE- II, both cirrhotic non-responders and treatment-naïve cirrhotic subjects achieved higher SVR rates if they were genotype 1b-infected vs genotype 1a-infected. According to Asselah *et al.*<sup>[132]</sup> we support the efficacy and safety profile in GT-1 HCV cirrhotic patients, and in some cases the efficacy was demonstrated also in borderline compensated cirrhosis. However, current data in patients with cirrhosis and other HCV genotypes, such as genotype 3 and 4, are clearly an unfulfilled need. Another significant study is the PEARL- II<sup>[133]</sup>.

### New drugs: Cyclophilin A inhibitors

Cyclophilins (Cyp) are host proteins involved in the HCV lifecycle. CypA binds to the non-structural protein NS5A of HCV to promote replication of viral RNA, so molecules that are CypA antagonists, such as cyclosporines, are potent inhibitors of HCV replication. NS2, a non-structural protein of HCV involved in virus assembly, also plays an important role in the inhibitory effect of CypA inhibitors; NS2 modulates HCV sensitivity to cyclosporines and so NS2 may increase the inhibitory effect of cyclosporines on HCV replication<sup>[134,135]</sup>.

Alisporivir, is the first Cyp A inhibitor in clinical development. It is a cyclosporine analog without immunosuppressive properties, and due to its mechanism of

action, alisporivir is a pangenotypic antiviral, provides a high barrier for development of viral resistance, and does not permit cross-resistance to direct-acting antivirals.

This drug is also well tolerated. This drug has been used alone or in combination with PEG-IFN and RBV with very promising results<sup>[136,137]</sup>.

## GUIDELINES TREATMENTS HEPATITIS C

The treatment of CHC is performed following the American, European and Italian guidelines (AASLD, EASL, and AISF guidelines); this allows to optimize the therapy and customize it for various patient characteristics. Priority should be given to patients with advanced disease, patients with extrahepatic manifestations, HIV coinfection, post-liver transplantation recurrence and non-hepatic solid organ transplant recipients. Patients with mild disease can be treated with regimens containing PEG-IFN or deferred up to a worsening of the disease and the degree of liver fibrosis<sup>[138,139]</sup>.

## DISCUSSION AND CONCLUSION

Today, it can be anticipated that the future of HCV infection treatment seems very bright after the addition of first-generation HCV PIs as well as SMV and the first-in-kind HCV RNA polymerase inhibitor, "sofosbuvir", in the standard of care (*i.e.*, PEG-IFN/RBV). However, the real success of these drugs is very much dependent on careful monitoring of viral load and resistance, patterns of response to previous treatment, side effects and drug-drug interactions. Moreover, the logical meaning of novel emerging therapies must be to achieve high SVR and thorough clearance of the virus from treated patients. Nevertheless, the triple therapeutic regimens have several limitations. First, concomitant use of PEG-IFN plus RBV is essential to prevent the emergence of viral escape mutants and viral breakthrough during triple therapy. Second, triple therapy becomes less effective in prior null responders to PEG-IFN plus RBV and cannot be administered to patients who are contraindicated for PEG-IFN or RBV. To overcome these limitations, in the near future, many patients will be treated with two or more DAAs with or without IFN- $\alpha$  plus RBV based combination therapies. Currently, the approval of sofosbuvir- and SMV-based IFN-free regimens is an indication in this way. Triple and quadruple treatment regimens including multiple DAAs with or without PEG-IFN and RBV will likely be a suitable option for difficult-to-treat populations and for the prior null responders. All-oral IFN free regimens including drugs with a high genetic barrier to antiviral resistance (*e.g.*, NS5B inhibitors) and high antiviral efficacy (*e.g.*, NS3/4A PIs or NS5A inhibitors) may be a potent option for numerous patients contraindicated for PEG-IFN plus RBV. All oral regimens consisting of daclatasvir plus sofosbuvir once daily presented higher rates of SVR in untreated HCV GT-1, -2 and -3 infected patients and

in HCV GT-1 infected patients who had failed previous treatment with PIs. We hope that such combinational treatment strategies will become "the weapon" to treat the majority of HCV infected patients who represent the difficult population (*i.e.*, IL-28 polymorphism, HCV genotypes 1 and 4 subtypes, receipt of RBV, and the emergence of resistant variants) and will be more efficient to access the treatment in the near future. The testing of adenovirus vector based vaccines, which escalate the innate and acquired immune response against the most conserved regions of HCV genome in chimpanzees and humans, may be a promising therapeutic approach against HCV in the near future, although its fate still needs to be exploited fully in diverse HCV populations. One thing must be of special concern is whether the newly developed or being developed DAAs added in triple or quadruple therapies are safer or not than antiretroviral and traditional IFNs. Overall, the achievements in the field of HCV medicines may predict that we are near to complete elimination of HCV disease in the world<sup>[140]</sup>. The real challenges that our efforts must be directed are: (1) the effectiveness of IFN-free regimens in HCV-3, especially in cirrhotic non-responders; in this setting, combination with PEG-IFN is still possible; (2) the effectiveness of IFN-free regimens in decompensated cirrhosis are scarce in relation to the current correlation data between SVR and clinical outcome (literature confirms that the results of IFN-free regimens are good in compensated cirrhosis even if further clinical development is necessary in certain groups to improve SVR rates); (3) the development of new treatment strategies for patients who show resistance to new drugs; and (4) free-access to care<sup>[141]</sup>. In fact, many patients with CHC have mild disease and are currently excluded from the interferon-free treatment. In the near future we will inevitably prioritize this category in order to prevent progression to cirrhosis, decompensation and HCC.

### Abstract

Hepatitis C virus (HCV) is a global health problem affecting a large fraction of the world's population: This virus is able to determine both hepatic and extrahepatic diseases. Mixed cryoglobulinemia, a B-cell "benign" lymphoproliferative disorders, represents the most closely related as well as the most investigated HCV-related extrahepatic disorder. Since this virus is able to determine extrahepatic [non-Hodgkin's lymphoma (NHL)] as well as hepatic malignancies (hepatocellular carcinoma), HCV has been included among human cancer viruses. The most common histological types of HCV-associated NHL are the marginal zone, the lymphoplasmacytic and diffuse large cell lymphomas. The role of the HCV in the pathogenesis of the B-cell lymphoproliferative disorders is confirmed also by the responsiveness of the NHL to antiviral therapy. The purpose of this review is to provide an overview of the recent literature and a meta analysis of the epidemiology data, to explain the role of HCV in the development of NHL's lymphoma. Furthermore, the possibility to treat these HCV-related NHL with the antiviral therapy or with other therapeutic options, like chemotherapy, is also discussed.

**Key words:** Hepatitis C virus; Non-Hodgkin's lymphoma; Hepatitis C virus genotypes; Alpha-interferon

**Core tip:** The goal of this article is to review the epidemiological data from different countries to perform

an up-to-date meta-analysis of the risk to developing non-Hodgkin's lymphomas in hepatitis C virus (HCV)-infected patients. Finally, we highlighted the clinical and the biological data necessary to optimize the cure of the patients affected by HCV-positive non-Hodgkin's lymphomas.

## INTRODUCTION

Non-Hodgkin's lymphomas (NHL) are neoplastic diseases of the lymphoid tissue. Given the high heterogeneity in terms of histological and clinical characteristics, anatomical location, and putative aetiologies, several causative factors have been reported including inherited or acquired immunodeficiency, exposure to some toxic substances (pesticides) or radiation, smoking habits, and, in the last few years, infectious factors. In fact, the Epstein-Barr virus (EBV) has been shown to be involved in the development of the Burkitt's lymphoma<sup>[1-3]</sup> and of other haematological malignancies (immunoblastic lymphoma, Hodgkin's disease, nasopharyngeal carcinoma), the human retrovirus HTLV-I in the T-cell leukemia-lymphoma<sup>[4,5]</sup>, and the double stranded DNA human herpes virus 8 in the Kaposi sarcoma<sup>[6,7]</sup>, primary effusion lymphoma and multicentric Castlemann disease<sup>[8]</sup>. But not only viruses are involved in pathogenesis of NHL, even the Gram-negative microaerophilic bacterium *Helicobacter Pylori* is thought to be the cause of gastric mucosa associated lymphoid (MALT) lymphoma<sup>[9,10]</sup>. However, although these infectious agents are widespread (EBV infects near 100% of all populations and remains in B-cell throughout the life span), only a very small fraction of virus-carriers develops lymphomas. This indicates the key role of some, not yet understood, host factors: Maybe genetic factors like HLA antigens or cytokine signalling pathways or acquired factors like exposure to toxic substances (ethanol, drugs, etc.) or immunosuppression secondary to therapy for rheumatological disorders or to chemotherapy for malignancies.

Hepatitis C virus (HCV) is a RNA virus belonging to the flaviviruses discovered in 1990 and involved in acute and chronic liver disease. The genome consists of a single-positive-stranded RNA molecule enveloped by a lipid bilayer within which two different glycoproteins are anchored<sup>[11]</sup>. The viral genome contains three distinct regions<sup>[12]</sup>: (1) a short 5' non-coding region with two domains: A stem-loop structure involved in HCV replication and the internal ribosome entry site the structure responsible for attachment of the ribosome

and polyprotein translation<sup>[13]</sup>; (2) A large, unique open reading frame of more than 9000 nucleotides, which encodes a single polyprotein precursor, that is cleaved co- and post-translationally to give the structural and non-structural viral proteins; and (3) The 3' non-translated region endowed with high variability in the length and structure. The HCV shows a high genetic diversity since, similarly to all RNA positive-strand viruses, the RNA-dependent RNA polymerase lacks a 3'-5' exonuclease proofreading activity for removal of the misincorporated bases. Therefore, the viral replication is error-prone, and this determines a large number of variants (quasispecies virus population)<sup>[14]</sup>. The frequency of the nucleotide mutations ranges from  $1.4 \times 10^3$  to  $1.9 \times 10^3$  substitutions per nucleotide per year. The HCV is classified into six genotypes with a different distribution by geographical region and between patient groups; each genotype contains a variable number of genetically distinct "subtypes". At the nucleotide level, the genotypes differ from each other by 31% to 33%, while subtypes from 20% to 25%<sup>[15]</sup>. The peculiar characteristic of HCV is the ability to infect not only the liver cells but also the lymphocytes<sup>[16]</sup> and, likely, other cells and tissues<sup>[17,18]</sup>. This is due on the fact that liver cells and lymphocytes share the same HCV receptor, *i.e.*, the CD81. The lymphotropism might explain the several extra hepatic manifestations of the chronic HCV infection<sup>[19-26]</sup>, among which mixed cryoglobulinemia (MC) is the most common<sup>[27-32]</sup>. MC is a disease characterised by the presence in the serum of immuno-complexes able to precipitate with cold temperature and to re-dissolve with rewarming<sup>[33]</sup>. The main clinical manifestations of this disease are the skin lesions (purpura) secondary to vasculitis, which is caused by the deposition of the cryoglobulins in the small and medium sized blood vessels<sup>[34]</sup>. In addition to skin lesions, MC may involve several organs and tissues, determining peripheral neuropathy and/or glomerulonephritis. Since cryoglobulins are the production of monoclonal B-cells and lymphoid infiltrates are present frequently in the bone marrow<sup>[35]</sup> of these patients, MC should be considered as a smouldering lymphoma. Accordingly, even the first cases of MC described by Melzer, later, by other researchers<sup>[36-38]</sup> developed lymphomas months or years after the onset of the symptoms of MC<sup>[39]</sup>. These reports suggest that chronic HCV infection induces clonal B-cell proliferation, which can evolve from a "benign" lymphoproliferative disorder to an overt malignant lymphoma<sup>[40]</sup>. Since, according to some estimates, near 170 million of people are carriers of the virus<sup>[41]</sup>, the clinical impact of the extrahepatic disorders, leading to neoplastic diseases of the hemopoietic system in addition to the liver diseases, makes HCV a major public health problem.

## THE EPIDEMIOLOGY OF HCV-POSITIVE NHL: META-ANALYSIS UP-DATING

The first studies, which described the association of

HCV and lymphoproliferative disorders, were performed recording the prevalence of anti-HCV antibodies in small-unselected groups of patients affected by lymphomas<sup>[42-46]</sup>. These preliminary reports excluded the association between HCV infection and Hodgkin's disease, while showed a strong association between NHL and HCV, especially in low-grade lymphomas. However, this association was found mainly in Italy and other researchers from the North of Europe did not confirm these findings. Therefore, some authors considered this relationship as due to the high prevalence of HCV in the Italian general population. In the following years, several studies addressed the possible association between HCV and NHL<sup>[47]</sup> and many papers have been published from different areas of the world. At present, more than 10000 cases of NHL have been screened for the presence of HCV infection and several meta-analyses on the relationship between HCV and lymphoma have been published<sup>[48,49]</sup>.

In this review, the most recent meta-analysis have been updated to include only the studies (until the end of 2011) with a control groups. Unfortunately, these control groups were heterogeneous, in fact, some papers included patients with hematological diseases other than NHL, other studies included cases with solid cancers, or cases undergoing an invasive procedure (like surgery or endoscopy) or population-based samples, other studies enrolled volunteer blood donors. Only recently, some authors designed these studies as case-control or as cohort studies with well-defined inclusion criteria. Therefore, these authors are able to estimate the odds ratios or the relative risks (RRs) adjusted for age, sex, and other confounding factors. In the present review, we discarded the studies including the patients with other lymphoproliferative diseases as control group since also these diseases might be correlated with HCV. In addition, we considered eligible for meta-analysis only the studies with at least one of the following requirements: (1) Sex- and age-adjusted RRs; (2) Cases and controls matched by age and sex; and (3) A measure of age and of the male/female ratio in both cases and controls.

If the authors did not provide RRs, we calculated the crude RRs (with 95% CIs) according to the Wald method, assuming the items 2 and 3 were available. In the analysis on NHL and HCV infection, we discarded the papers including less than 100 cases of NHL, while we included all the prospective studies (case-control or cohort studies) regardless of the number of NHL enrolled. Several problems of comparability were found in the retrieved studies since not all authors shared the definition of lymphoma. For instance, some authors included chronic lymphocytic leukemia (CLL) among NHL cases, whereas others did not. Since CLL patients show a prevalence of HCV infection lower than that observed in the general population, the inclusion or the exclusion of this very common lymphoproliferative disorder has a great impact on the epidemiological studies. In addition, the CLL cells and the small lymphocytic lymphoma (SLL) have the same immuno-phenotype<sup>[50,51]</sup>, but SLL was

included among NHL by all authors<sup>[51]</sup>. Most authors excluded the cases with human immunodeficiency virus (HIV) infection; therefore, we did not review the studies including HIV patients. To avoid bias, we discarded also the studies including only selected populations, non-representative of general population<sup>[52,53]</sup>. Another problem was the method of checking and confirming the HCV infection: In the first papers, most authors used only the enzyme-linked immunosorbent assay (ELISA) whereas, more recently, most authors used recombinant immunoblot assay (RIBA). To increase the complexity of the analysis, some authors enrolled only the patients with active HCV replication, *i.e.*, with detectable levels of serum HCV-RNA. Since the first generation ELISAs showed low sensitivity and specificity, in this review we included only the studies employing second or third generation ELISAs. However, we did not consider the detection of HCV-RNA as a requirement for including a study.

**Statistical methods:** We calculated the summary RR and corresponding 95%CI with the models of DerSimonian and Laird, which incorporate both within and between-study variability, as a weighted average of the estimated RRs, by giving each study a weight proportional to its precision. The heterogeneity among studies was evaluated using the *Q* statistics. The Begg's and Egger's asymmetry tests were used to assess the publication bias.

Figure 1 indicates the results of studies on HCV and NHL. The highest prevalence of HCV infection in the general population (over 20%) was found in Egypt. A rather high prevalence (5%-10%) was found in Italy and in Japan, while most countries (South Korea, Northern Europe, United States, Australia, and Canada) showed a prevalence below 5%. The 19 case-controls studies included in this review enrolled altogether 9038 cases and 12224 controls. The pooled RR from this large group was 2.4 (95%CI: 2.0-3.0), and most of them (11/19) showed a RRs significantly elevated (Figure 1). The RRs of the cohort studies was 2.0 (95%CI: 1.4-3.0). The overall RR estimation was 2.3 (95%CI: 1.8-2.9) with no significant heterogeneity between study designs. The different prevalence of the HCV infection in the control groups determined the great heterogeneity in the results. In fact, the studies performed in areas with a high HCV prevalence (above 5%) showed a more elevated RR (> 3) than those performed in areas with a low HCV prevalence (RR < 2). A significant heterogeneity emerged also for the publication period: In fact, the studies published up to 2003 indicated higher RRs when compared with the studies carried out thereafter. In addition, there are regional variations: people infected by HCV from Japan and from the Mediterranean basin show a relative risk of NHL from 2 to 4 times higher than people of Northern Europe<sup>[54]</sup>.

The mechanisms by which lymphoma is induced by HCV are still limited. The HCV-induced transformation process of B-cell may occur in three ways: (1) Chronic stimulation of B-Cell Receptor or other receptors placed

Figure 1 Relative risk estimates and corresponding 95%CI of non-Hodgkin's lymphoma by hepatitis C virus seropositivity in case-control and cohort studies.

on the surface of B-cells by the viral antigens (in absence of cell infection) with secondary proliferation; (2) Infection and persistent replication of HCV inside B-cells with oncogenic effects by some viral proteins; and (3) Temporary intracellular virus replication with damage of B-cells<sup>[55]</sup>. However, since an active replication of HCV in human B or T lymphocytes *in vivo* (with evidence of the HCV-RNA negative strands) has never been demonstrated, a direct oncogenic effect by HCV inside B cells is unlikely. In addition, viral proteins, indicative of active replication, could never be demonstrated in the neoplastic lymphoid tissue of the HCV-NHL. Based on these considerations, it is likely that the neoplastic transformation is determined by the chronic antigen stimulation of B cells by viral surface proteins<sup>[56]</sup>. There are several experimental data supporting this theory: (1) the B lymphocytes from HCV patients show a higher level of activation markers<sup>[56]</sup> than normal lymphocyte; and (2) the long-term exposure to the epitopes of HCV lead to selection and expansion of a oligoclonal B-cells, which evolve in clonal B-cells and finally in an overt HCV-

NHL.

In conclusions, HCV infection seems to be associated with a 2.5-fold increase in the risk of developing NHL. The fraction of the NHL secondary to HCV infection may be 10%-15% in areas where HCV prevalence is high, but it is smaller in the countries of low prevalence. Based on epidemiological and experimental evidence, IARC recently concluded that there was sufficient evidence in humans to indicate the HCV infection as a cause of non-Hodgkin lymphomas, in addition to the previously recognized causal association with hepatocellular carcinoma<sup>[57]</sup>.

## THE THERAPY OF HCV-POSITIVE NHL

As previously indicated, the HCV-positive NHL are heterogeneous in terms of histological features and clinical aspects. The most common HCV-related NHL are indolent lymphomas (marginal-zone), but several aggressive and, rarely, very aggressive NHL are reported. Since the relationship between viral

replication and monoclonal lympho-proliferation is by now consolidated, the antiviral therapy could appear to be an attractive therapeutic option, in analogy to the antibiotic therapy employed to treat MALT lymphoma associated with *Helicobacter Pylori* infection<sup>[7]</sup>. However, before starting antiviral treatment of "bona fide" HCV-related NHL, several points should be taken in consideration, including: (1) Is the NHL really related with HCV infection? How the haematologist can be sure that a given NHL is HCV-associated? (2) Which is the best therapeutic approach? (3) Is the chemotherapy safe? In the case of the need to plan a chemotherapy, are the HCV-positive NHL exposed to higher risks than HCV-negative cases? and (4) The outcome of the HCV + NHL is the same as compared with the HCV-NHL with the same histotype?

The HCV-related NHL show some typical, histological, clinical, laboratory and molecular characteristics. The most common histological types of HCV+NHL are lymphoplasmacytic, primary nodal marginal zone, splenic marginal zone, MALT marginal zone, while other histotypes are less closely associated with HCV<sup>[58-61]</sup>. The clinical course of the disease is generally indolent. The most common feature of true HCV + NHL is the longstanding presence of MC<sup>[62]</sup>, and the late appearance of overt NHL, often after years from the onset of the clinical symptoms of MC. From a biological point of view, the HCV-related NHL often show a monoclonal IgMk component and the presence of several auto-antibodies (mainly anti-thyroid). From a molecular point of view, these patients use a restricted *IgHV* gene repertoire<sup>[63]</sup>, with a strong bias for the IGHV1-69 and V3-A27<sup>[64,65]</sup>. In addition, the same set of V region genes, VH1-69 and Vk3 -A27 encode for the monoclonal IgMk component (if present). Finally the bcl-2/IgH translocation has been described in some studies, although not confirmed by others, present in HCV + NHL, at least of the lymphoplasmacytic subtype<sup>[66-68]</sup>.

To choose the best therapeutic strategy several factors should be taken in consideration. Firstly the tumour burden: If there are large or huge nodal or extra nodal masses, chemotherapy becomes the first choice; on the contrary, if the tumour burden is low (confined to enlarged spleen and mild lymphoid infiltration of bone marrow) antiviral therapy is more indicated. A second factor to be considered is the course of the disease: If the course is indolent and lymphoma discovered occasionally during the follow-up of the patient, the antiviral therapy is more attractive, while if the patient show progressive and rapid node or spleen enlargement, chemotherapy is again the best choice. A third factor should be always taken in consideration, *i.e.*, the presence or the absence of a chronic liver disease (CLD), and, if present, the severity of such a CLD. This means that the patient should undergo a complete hepatological evaluation including ultrasonography and, if indicated, endoscopy and liver biopsy. If the patient is affected by chronic C hepatitis without evidence of cirrhosis, the antiviral therapy should be indicated, while an advanced chronic

liver disease with severe portal hypertension could be a contra-indication for antiviral and chemotherapy as well. A fourth factor to be considered is the presence and the quality of clinical symptoms. In fact the symptoms could be tumour-related (fever, weight loss, asthenia, *etc.*) or MC-related (vasculitis, neuropathy, arthralgias, *etc.*), in the former case chemotherapy is indicated while in the latter antiviral treatment could be the right choice. Finally, some specific contra-indications to antiviral therapy should be considered, often not familiar to haematologists<sup>[69]</sup>, like deep depression<sup>[70,71]</sup> or immunological disorders<sup>[72]</sup>.

The presence of HCV replication, *i.e.*, detectable levels of HCV-RNA, without liver disease, cannot be considered a contra-indication for chemotherapy. In fact, the experience in the treatment of HCV + cryoglobulinemia<sup>[73]</sup> shows that when these patients undergo either anti-CD20 therapy, or other intensive immunosuppressive treatment, though a mild elevation of HCV-RNA levels has been noticed, the liver function never worsens. On the contrary, some author reported a mild improvement in some cases. Despite few papers focused on this topic, the literature data confirm this point of view: Faggioli *et al.*<sup>[74]</sup>, in a small series of cases, did not detect any acute hepatitis due to the reactivation of HCV replication. These data were confirmed by other authors in larger cohorts of patients: Takai *et al.*<sup>[75]</sup> found that, after chemotherapy, the fraction of NHL patients who developed liver function test alterations was higher in non-hepatitis virus carriers (12%) than in HCV-bearing patients (10%), while a significant proportion of HBsAg carriers (36%) showed post-chemotherapy liver injuries. To further confirm these data, Visco *et al.*<sup>[76]</sup>, during the follow-up of 136 HCV-positive diffuse large cell lymphomas, found that only 5 cases (4%) discontinued the chemotherapy due to severe liver function impairment. It is noteworthy that 9 cases (7%) of the series had liver cirrhosis, and 26 cases had chronic hepatitis (19%). Altogether, this means that even in presence of HCV-related chronic liver disease, chemotherapy is feasible with a reasonable margin of safety.

Contradictory data on the outcome of HCV-positive NHL are present in the literature. A first Japanese paper of Tomita *et al.*<sup>[77]</sup> showed that the cases affected by HCV-positive aggressive NHL have the same prognosis as HCV-negative aggressive NHL, at least in the subjects without an advanced chronic liver disease. On the contrary, Besson *et al.*<sup>[78]</sup>, grouping together two large GELA studies (NHL93 and NHL98), found that the proportion of patients with high and high-intermediate IPI was higher among HCV-positive patients, and that, at 2 years, the OS and PFS of HCV-positive cases was 56% vs 80% and 53% vs 75%, respectively. These surprising results could be explained, at least in part, by taking into account a possible selection bias of cases. In fact, the prevalence of HCV in these two cohorts of cases affected by NHL is largely lower (0.46%) of that found in the general population of France, where the

prevalence is 2.8%. Since, as previously indicated, the prevalence of HCV-infection is always higher in NHL than in the general population<sup>[79]</sup>, the very low number of HCV-positivity in the two groups of patients indicates the possibility of a selective enrolment in the trial of high-risk HCV-positive cases only, while standard- or low-risk cases were discarded. Nearly at the same time, Visco *et al*<sup>[76]</sup> following his large cohort of HCV-positive NHL showed that the OS and PFS of HCV-positive cases were similar to HCV-negatives. The question is still open and further controlled clinical trials should be needed to have definitive answers.

As shown in Table 1, antiviral therapy of HCV-NHL yielded different outcomes, according to the various authors. Since the number of cases is usually rather limited, several histotypes were enrolled with obvious different response rates, which makes published data are often contradictory. Moreover, several authors included cases with liver disease while others excluded these cases, and, finally, the presence of cryoglobulinemia is scattered among the cases and not recorded by all the authors. From 1996 to 2011, only 112 cases of HCV-positive NHL underwent antiviral therapy, the first three groups have been treated with interferon alone, thereafter with interferon and ribavirin and the last three groups with PEG-interferon (PEG-IFN) and ribavirin. The different antiviral power of these three regimens increases the difficult to interpret the results. In the first studies, the complete remission of the lymphomas was obtained in large fractions of patients (75% range: 64% to 84%), but most cases relapsed within few months. Much better results were achieved in the patients affected by splenic lymphoma with villous lymphocytes<sup>[80]</sup>, in fact all HCV-positive cases entered complete remission upon treatment with interferon alone or with interferon and ribavirin, while

HCV-negative lymphomas with villous lymphocytes controls did not benefit from antiviral therapy. The results obtained by Hermine *et al*<sup>[80]</sup> were confirmed subsequently by other studies<sup>[81-83]</sup>. These results suggest to perform a systematic screening for HCV in the patients affected by the marginal-zone lymphomas, since in the HCV-RNA positive cases, the antiviral therapy should be considered the treatment of choice. Several studies have documented the regression of different histotypes of NHL after antiviral treatment, such as lymphoplasmacytic lymphoma<sup>[84-86]</sup>, mantle-cell lymphoma<sup>[87]</sup>, nodal marginal zone lymphomas<sup>[88]</sup> or extranodal marginal zone lymphoma of MALT tissue (MALT lymphomas)<sup>[89]</sup>. In the last three published studies all the patients were treated with the same antiviral regimen (PEG-IFN plus ribavirin), allowing better interpretation of the homogeneous results. In all three papers the haematological response significantly ( $P < 0.005$ ) correlates to the disappearance of HCV-RNA, and the sustained virological response was more frequently obtained in patients with genotype 2 or 3 more than genotype 1 or 4, which are usually found in HCV-chronic hepatitis without NHL. Given the high antiviral power of the treatment, the relapse rate is lower in these three studies (30%) than that previously recorded. At present, no data are available on the triple therapy in HCV-NHL.

## CONCLUSION

In addition of acute and chronic liver diseases, the HCV infection determines many extra hepatic manifestations. Among them, the ability of the virus to interact with B cells leads to antigen-driven B-cell transformation, which ultimately may determine MC and finally a frank NHL. Based on clinical and biological considerations, the antiviral therapy should be considered as the treatment

of choice in HCV-associated lymphomas, especially in the presence of MC. However, the traditional antiviral therapy, based on PEG-IFN plus RIBA, is fading given the low efficacy and the numerous and severe side effects. At present, a new era is born for the management of HCV infection: The new strong direct antiviral agents<sup>[90-93]</sup> opened the gate for a complete eradication of viral infection. These new drugs, described as lacking in side effects, can be used even in heavily pretreated patients or in cases with advanced liver disease with high possibility of success. It is likely that these new treatment options will be able to reduce drastically the number of the chronic carriers of HCV, as consequence, the number of HCV-related NHL.

and prevalence of HEV infection in this population remains unclear but is certainly greater than historical estimates. Identifying acute HEV infection in this population is imperative for choosing the right course of management as it is very difficult to distinguish histologically from acute rejection on liver biopsy. Current suggested approach to manage acute HEV involves modifying immunosuppression, especially discontinuing calcineurin inhibitors which are the preferred immunosuppressive agents post-orthotopic liver transplantation. The addition of ribavirin monotherapy has shown promising success rates in clearing HEV infection and is used commonly in reported cases.

**Key words:** Chronic hepatitis E infection; Solid organ transplant; Immunosuppression; Ribavirin; Hepatitis E virus; Orthotopic liver transplantation

**Core tip:** Hepatitis E virus (HEV) is an emerging pathogen in developed countries and an important cause of graft hepatitis in the post-orthotopic liver transplantation population that is often misdiagnosed either due to low index of suspicion or due to poor diagnostic assays. We recommend mandatory HEV testing in such cases, and careful treatment with modification of immunosuppression, especially switching from calcineurin inhibitors to a different class. Ribavirin has shown to be increasingly successful in treating HEV infection and preventing graft failure from acute HEV infection, if diagnosed early.

### Abstract

Hepatitis E virus (HEV) is an emerging pathogen and an increasingly recognized cause of graft hepatitis, especially in the post-orthotopic liver transplantation immunocompromised population. The exact incidence

## INTRODUCTION

Hepatitis E virus (HEV) is one of the major causes of acute viral hepatitis globally. HEV genotypes vary globally in terms of transmission and pathogenicity (Table 1). There have been large scale epidemics of HEV across the low and middle income countries of Asia and Africa as well as sporadic cases in the same geographical regions<sup>[1]</sup>. More recently, HEV has been identified as an emerging pathogen in developed countries as well, particularly among immunosuppressed solid organ transplant recipients.

The overall prevalence varies greatly among existing studies, which are primarily from Europe. In the United States, diagnoses of symptomatic autochthonous HEV infection are very rare compared to the number of cases reported in several European countries. The annual incidence of *de-novo* HEV infection in the United States is reported to be approximately 0.7%<sup>[2]</sup>. However, it is interesting that serological evidence of HEV exposure is more common than expected in a low endemic area like the United States (around 21%)<sup>[3,4]</sup>. In general, HEV seroprevalence was found to be higher in liver transplant recipients, particularly those with liver cirrhosis (7.4% and 32.1%, respectively)<sup>[5]</sup>. Whether cirrhosis is a predisposing factor for HEV or whether HEV infection may play a role in the pathogenesis of cirrhosis, remains controversial.

HEV has been identified as a cause of graft hepatitis in liver transplant recipients. The true frequency and clinical importance of HEV infections after liver transplantation is still unclear<sup>[6]</sup>. A study conducted in France estimated pre-transplant anti-HEV IgG prevalence as 29% increasing regularly with age from 7% in children < 15 years old to 49% for adults > 60 years old<sup>[7]</sup>. On follow-up, the annual incidence of HEV infection post-transplantation was 2.1% in previously seronegative patients, and it was much higher than that those found in other areas of the world. In previously seropositive patients, the annual incidence of post-transplantation re-infections detected by HEV RNA was 3.3%, an incidence similar to that of *de novo* infection<sup>[8]</sup>. Another group in the Netherlands retrospectively estimated HEV prevalence in a cohort of 285 adult liver transplant recipients and found 274 (96.1%) to be negative for all HEV parameters (HEV RNA, IgM/IgG). The prevalence of acquired *de novo* HEV hepatitis in this cohort was 1%-2% after transplantation. Therefore, despite low prevalence, chronic hepatitis E needs to be considered in the differential diagnosis of graft hepatitis<sup>[9,10]</sup>.

## PRESENTATION

HEV in most individuals is known as self-limiting, acute, icteric hepatitis which recovers without sequelae in most cases. Case fatality rates in the general population can vary from 0.1% to 3.0%<sup>[11]</sup>. However, pregnant women often have worse outcomes with more likeli-

hood of progression to fulminant liver failure and a case fatality rate of 10%-20% or higher, especially in developing countries<sup>[12]</sup>. Although the usual outcome of HEV is favorable, in a minority of cases, fulminant liver failure often leads to liver transplantation have been well described, many in non-endemic areas and autochthonous without any evidence of foreign exposure. HEV testing thus should be performed during the initial evaluation of every acute liver failure regardless of epidemiological context<sup>[13,14]</sup>.

## HEV IN SOLID ORGAN TRANSPLANT RECIPIENTS

In patients with chronic liver disease, acute viral hepatitis from HEV can worsen rapidly to a syndrome called acute on chronic liver failure leading to very high mortality (0%-67% with a median of 34%)<sup>[1]</sup>. In immunocompromised individuals, HEV can take up a more chronic course with prolonged viremia<sup>[15]</sup>. Those with solid organ transplant have been studied the most with overall chronic HEV infections reported in up to 50%-60% of organ transplant recipients<sup>[16]</sup>. The chronic HEV infection usually manifests as mild elevation in liver enzymes without clinical signs of overt hepatitis. However rapid fibrosis progression causing cirrhosis within 1-2 years of infection and graft failure is seen in some cases<sup>[9,16,17]</sup>. Prospective study by Kamar *et al.*<sup>[18]</sup> evaluated evolution of liver fibrosis in chronic HEV infected 16 organ transplant patients by sequential liver biopsies. Three out of 16 patients progressed to cirrhosis and two out of these died from decompensated cirrhosis<sup>[18]</sup>. The same group looked at virological and immunological factors associated with viral persistence leading to chronic infection in solid organ transplant (SOT) patients. The patients that had progressive liver fibrosis were found to have less quasispecies diversification during the first year than patients without liver fibrosis progression. This along with a weak inflammatory response [low serum concentrations of interleukin-1 (IL-1) receptor antagonist and soluble IL-2 receptor] and high serum concentrations of the chemokines involved in leukocyte recruitment to the liver in the acute phase were associated with persistent HEV infection<sup>[19]</sup>. HEV related extra-hepatic manifestations like neurological symptoms, kidney injuries and hematological disorders have also been reported<sup>[20]</sup>. Most of chronic HEV infection cases observed belonged to genotype 3, however there are recent reports of genotype 4 infections as well<sup>[21,22]</sup>.

## HIGH INDEX OF SUSPICION

A high index of suspicion is needed in patients with graft hepatitis of unclear etiology since graft failure can result from missed chronic HEV infection. Cases where re-transplantation was done as a last resort have been described<sup>[23]</sup>. Similarly, in allo-hematopoietic stem cell transplant recipients, liver enzyme abnormalities are

**Table 1** Hepatitis E virus genotypic characteristics

Characteristics	Genotype 1	Genotype 2	Genotype 3	Genotype 4
Geographic location	Africa and Asia	Mexico and West Africa	Developed countries	China, Taiwan, Japan
Transmission	Water-borne, fecal oral, person to person	Water-borne, fecal oral, person to person	Food-borne	Food-borne
Group at high risk for infection	Young adults	Young adults	Older adults (> 40 yr) and males. Immuno-compromised persons	Young adults
Zoonotic transmission	No	No	Yes	Yes
Chronic infection	No	No	Yes	Yes
Occurrence of outbreaks	Common	Smaller scale outbreaks	Uncommon	Uncommon

Adapted from centers of disease control and prevention (<http://www.cdc.gov/hepatitis/hev/hevfaq.htm>).

often attributed to hepatic graft vs host disease or drug induced liver injury and possibility of HEV infection is overlooked<sup>[24]</sup>. Presence of anti-HEV antibodies may not protect against re-infection, especially in low concentrations (< 7 World Health Organization units/mL)<sup>[8]</sup>.

A study in France compared SOT recipients who developed chronic HEV infection with those who cleared infection. In general acute aminotransferase levels were higher in those who cleared their infection. Also levels of IgM, IgG anti-HEV antibodies and HEV RNA during acute infection phase were not predictive of whether or not the infection will become chronic. In acute phase itself, only 24% had abnormal bilirubin levels<sup>[25]</sup>. This further emphasizes that an acute HEV infection can be easily missed unless clinician had a high index of suspicion. Now there is increasingly common recognition of HEV and this emerging pathogen is coming within the spectrum of differential diagnosis of US physicians.

## INADEQUACY OF AVAILABLE DIAGNOSTIC ASSAYS

Currently available antibody assays have shown low and variable sensitivity<sup>[26,27]</sup>. In severely immuno-compromised person, anti-HEV IgG detection could be false negative. Comparison of two commercially available assays (Adaltis and Wantai) showed a wide discrepancy in results. Anti-HEV IgG positivity among both assays was wide (10.9% vs 31.3%,  $P = 0.005$ ). On immunoblot, specificity of both assays remained 80%-86%. For anti-HEV IgM testing, both assays were concordant for 97% of the serum samples<sup>[28]</sup>.

Also there was a considerable variability in the accuracy of PCR tests assays used in various studies from Europe from where most of our data regarding HEV infection has been derived<sup>[29]</sup>.

The testing for HEV hence should be done during initial evaluation of graft dysfunction irrespectively since histological appearance on liver biopsy may not clearly distinguish rejection and acute viral hepatitis.

Early diagnosis of HEV should lead to prompt treatment particularly adjusting the immunosuppressive drug regimen as some drugs have been shown to exert opposing effects on HEV replication<sup>[30]</sup>.

## MANAGEMENT

### Modification of immunosuppressive regimen

Immunosuppressive therapy has been proposed to be a key factor for developing chronic hepatitis E in organ transplant recipients<sup>[31]</sup> and is often attributed to diminished antiviral immunity. However, the effect of various immunosuppressive agents on HEV replication is lesser known. Role of steroids is particularly important in the setting of liver transplantation as it is known that steroid boluses used to treat acute rejection in HCV patients can increase the severity of HCV recurrence and viral load. Wang *et al.*<sup>[30]</sup> studied the different immunosuppressants in two HEV replication models. They demonstrated that steroid (prednisone and dexamethasone) did not affect viral replication. It was also demonstrated that calcineurin inhibitors (CsA and FK506) promoted HEV infection. In fact the use of FK506 was found to be the main predictive factor for chronic hepatitis E in organ recipients in another study by Kamar *et al.*<sup>[16,18]</sup>. On the other hand mycophenolic acid/mycophenolate mofetil (MPA/MMF) suppressed viral infection in replica model. The clinical benefit was demonstrated in heart transplant recipients where MMF containing regimens were assumed to play a role in more frequent HEV clearance<sup>[17]</sup>. These were *in vitro* studies and will need further validation with randomized controlled clinical trials. Nevertheless the results provide valuable reference for the management of immunosuppression in these patients.

## ROLE OF PEGYLATED- INTERFERON ALPHA

Pegylated-interferon alpha (Peg-IFN $\alpha$ ) is a strong immune-stimulatory drug that is being already used for the treatment of chronic hepatitis B and C infections. However Peg-IFN $\alpha$  is suggested to induce allogenic immunity, leading to transplant rejection in patients after solid organ transplantation which possibly limits its use in the treatment of chronic hepatitis E.

Successful use of Peg-IFN $\alpha$  therapy for chronic HEV has been reported in a patient with hemodialysis dependent end stage renal disease after failed renal transplant after 3 mo of therapy and achievement of

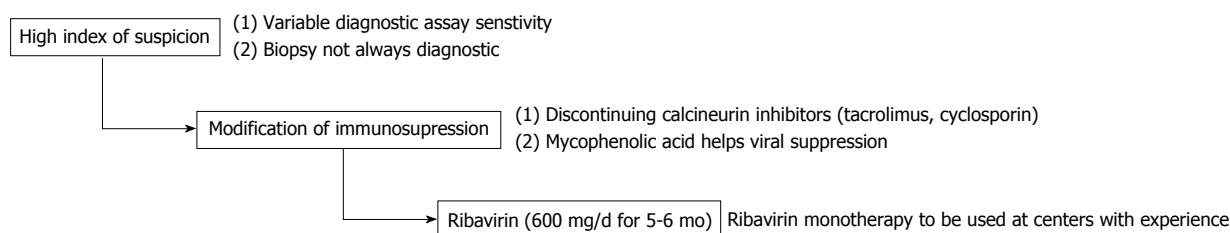

Figure 1 Key steps in the management of hepatitis E virus.

sustained viral response (SVR) at 6 mo<sup>[32]</sup>. The use of Peg-IFN $\alpha$  in post-orthotopic liver transplantation (OLT) patients was successful in achieving SVR, albeit with variable and longer course of therapy<sup>[33,34]</sup>. A recent systemic review found total 8 patients treated with Peg-IFN. SVR was achieved in 6 out of 8 patients (75%) after cessation of therapy, but only 2 out of 8 patients (25%) achieved SVR at or greater than 6 mo. Also 2 patients experienced acute rejection of their transplant organ during treatment<sup>[35]</sup>. This suggests the use of other antiviral agents like ribavirin preferable option, especially in post-OLT chronic HEV.

## ROLE OF RIBAVIRIN

Despite a clear benefit to manipulating immunosuppressive regimens, a substantial proportion of patients are still not able to clear the virus and rapidly progress toward chronic hepatitis<sup>[16]</sup>. Although no proven medication is available, the use of ribavirin monotherapy as an off label drug is gaining acceptance for treating hepatitis E. There is not enough data to recommend treatment with role of ribavirin (RBV) for adult liver transplant recipients, although this has been previously well studied in other SOT populations including lung<sup>[36]</sup>, heart<sup>[17]</sup>, kidney<sup>[37,38]</sup>, and kidney-pancreas<sup>[39]</sup> transplantation. A large retrospective multicenter case series to assess the effects of RBV as monotherapy for SOT was done by Kamar *et al*<sup>[40]</sup>. It included 59 SOT patients (37 kidney, 10 liver, 5 heart, 5 kidney pancreas, and 2 lung) with prolonged HEV viremia. Fifty-four out of 59 had genotyping performed and were HEV genotype 3. Ninety-five percent had HEV clearance with RBV median therapy duration of 3 mo (1-18 mo). SVR measured as undetectable serum HEV RNA at 6 mo after therapy cessation was observed in 46 out of 59 (78%) patients<sup>[40]</sup>. Recently, there have been several case reports of RBV monotherapy for post orthotopic liver transplant, the earliest case reporting SVR-8 following 16 wk therapy<sup>[41]</sup>. Pischke *et al*<sup>[42]</sup> demonstrated successful HEV clearance with RBV monotherapy at 600 mg daily for 5 mo in 11 liver transplant patients.

There have been small number of patients who were non responders to antiviral therapy. One of the identified mutations is G1634R mutation in viral polymerase that was detected in HEV RNA of non-responders. Although there was no resistance to RBV in mutated HEV *in vitro*, but this mutant form of a sub-genomic replicon

of genotype 3 HEV replicated more efficiently *in vitro* than the non-mutant strains. Similar results were seen for infectious virus in competition assays<sup>[43]</sup>. Also, interestingly a higher lymphocyte count at the time of RBV initiation was associated with a greater likelihood of achieving SVR<sup>[40]</sup>.

The exact mode of action of RBV against HEV is not known but successful clearance of both HEV genotype 1 and 3 indicate broad antiviral activity across genotypes<sup>[42]</sup>. However the standard dose and duration of RBV is yet to be determined. Successful outcomes with RBV monotherapy along with tailoring of immunosuppression regimen could provide an acceptable management approach to post OLT HEV. A beneficial effect of combining ribavirin with MPA was seen *in vitro* as well<sup>[30]</sup>.

## CONCLUSION

HEV is an emerging pathogen and an increasingly recognized cause of graft hepatitis especially in the post-OLT immunocompromised population. The exact incidence and prevalence of HEV infection in this population might be unclear but certainly more than historical estimates. Identifying acute HEV infection in this population is imperative for choosing the right course of management as it is very difficult to distinguish histologically from acute rejection on liver biopsy. The current suggested approach to manage acute HEV involves modifying immunosuppression, especially discontinuing calcineurin inhibitors which are the preferred immunosuppressive agents post-OLT. Along with immunosuppression modification, addition of RBV monotherapy has shown promising success rate in clearing HEV infection with current studies suggest using RBV 600 mg/d for a minimum of 5-6 mo successfully with a high SVR rate. We recommend maintaining high index of suspicion and mandatory confirmatory testing for HEV infection in post-OLT hepatitis with careful use of RBV in cases of established diagnosis (Figure 1).

### Abstract

Before the advent of direct acting antiviral agents (DAAs) ribavirin, associated to pegylated-interferon played a crucial role in the treatment of chronic hepatitis C, preventing relapses and breakthroughs. In the present era of new potent DAAs, a place is still devoted to the drug. Ribavirin associated with sofosbuvir alone is efficient in the treatment of most cases of G2 infected patients. All options currently available for the last difficult-to-treat cirrhotic G3 patients contain ribavirin. Reducing treatment duration to 12 wk in G1 or G4 cirrhotic compensated patients is feasible thanks to ribavirin. Retreating patients with acquired anti NS5A resistance-associated variants using ribavirin-based strategies could be useful. The addition of ribavirin with DAAs combinations however, leads to more frequent but mild adverse events especially in cirrhotic patients. Preliminary data with interferon-free second generation DAAs combinations without ribavirin suggest that future of the drug is jeopardized even in difficult-to-treat patients: The optimization of ribavirin dosage according to an early monitoring of blood levels has been suggested to be relevant in double therapy with peginterferon or sofosbuvir but not with very potent combinations of more than two DAAs.

**Key words:** Ribavirin; Hepatitis C; Peginterferon; Direct acting antiviral agents

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Ribavirin plays a crucial role when associated with peginterferon, preventing relapses and

breakthroughs and doubling the support vector regression rate. Its antiviral effect is weak and ribavirin could enhance the response of interferon-stimulated genes in the combination. Ribavirin is still useful in the era of approved new direct acting antiviral agents (DAAs), in order to shorter treatment duration in genotype 1 or 4 cirrhotic patients, in all options available for genotype 3 cirrhotic patients, and as the only drug associated with sofosbuvir in genotype 2. Preliminary data with interferon-free second generation DAAs combinations without ribavirin suggest that future of the drug is jeopardized.

## INTRODUCTION

Before the advent of direct acting antiviral agents (DAAs) ribavirin played a crucial role in the treatment of chronic hepatitis C associated to pegylated interferon<sup>[1]</sup>. This combination is still relevant in many parts of the world which do not have access to new therapies because of cost issues<sup>[2]</sup>. Although the role of ribavirin in the era of DAAs will probably decrease in the future with the arrival of second generation drugs, it remains essential in strategies decreasing treatment duration or in some difficult situations. The goal of this review is to briefly recall the recent past of ribavirin and consider its present and potential future.

## RIBAVIRIN: MECHANISMS OF ACTION

So far, multiple mechanisms of action of ribavirin have been described. The antiviral mechanism is probably the best documented, the erroneous incorporation of ribavirin triphosphate into replicating RNA strands inhibiting chain elongation<sup>[3]</sup>. *In vitro*, in the hepatitis C virus (HCV) RNA replication system, ribavirin reduces HCV replicon colony-forming efficiency in a dose-dependent manner, reinforcing this hypothesis<sup>[4]</sup>. The inhibition *via* inosine monophosphate dehydrogenase of the *de novo* synthesis of GTP, required for the synthesis of viral RNA, is another but probably weak potential mechanism of action<sup>[5]</sup>. However, the mutagenesis hypothesis remains controversial<sup>[6]</sup>. The last most attractive mechanism of action is that ribavirin could enhance the response of interferon-stimulated genes making cells more sensitive to exogenous interferon and increasing the production of endogenous interferon<sup>[7]</sup>.

Two phases of plasma HCV RNA decline in patients treated with peginterferon and ribavirin have been described: A rapid first phase in the first two days<sup>[8]</sup> reflecting the genesis and release of new virions and a slower second phase corresponding to the elimination

of infected cells. The impact of the first-phase decline is weak (0.5 log) and goes unnoticed during double therapy, but is enhanced in patients treated with ribavirin alone<sup>[9]</sup>. The second slope probably reflects the interferon-stimulated genes' response and the production of endogenous interferon.

Multiscale models recently considered the possible effects of DAAs on intracellular HCV RNA production, degradation, assembly and secretion as virus into the circulation<sup>[10]</sup>. The first-phase decline represents the viral clearance. The second represents the loss of intracellular viral RNA by export and degradation as well as the elimination of infected cells. The third represents a combination of the reduction in intracellular viral RNA production and the elimination of infected cells. Nowadays, there are no data available on the role of ribavirin in this setting, but we may imagine that ribavirin might impact the second- and the third-phase decline.

## PAST OF RIBAVIRIN: COMBINATION THERAPY PEGINTERFERON AND RIBAVIRIN

### Clinical history

Ribavirin, a guanosine analog is active against many DNA and RNA viruses and has clinical applications in respiratory syncytial infection in children, and Lassa Fever infection<sup>[11,12]</sup>. Di Bisceglie *et al*<sup>[13]</sup> first showed that ribavirin could double the efficiency of standard alfa interferon. A similar synergy was observed with the association of peginterferon and ribavirin<sup>[14,15]</sup>, ribavirin impacting favourably the number of relapses and breakthroughs<sup>[16]</sup>. A total daily dose of ribavirin during the first three months > 10.6 mg/kg of body weight was predictive of sustained virological response (SVR)<sup>[14,17]</sup> and ribavirin had to be administered for the total duration of treatment<sup>[16]</sup>. A pilot study also showed, that the use of high doses of ribavirin early during treatment led to high sustained virological rates<sup>[18]</sup>. The same team proposed to optimize the dose of ribavirin using a formula based on renal function and body weight<sup>[19]</sup>.

### Pharmacokinetics of ribavirin

Ribavirin is a drug typically adapted for therapeutic drug monitoring: Long half-life, large inter-individual variability of the dose-concentration relationship, and narrow therapeutic zone. After the first oral dose, a rapid absorption phase is observed with a maximum concentration at 1.5 h, followed by a rapid distribution phase (half-life of 3.7 h), and a long elimination phase of about 100 h post-dose<sup>[20]</sup>. The monitoring of ribavirin plasma concentrations during double therapy initially used trough concentrations at week 4 and week 8 of treatment<sup>[21,22]</sup>. However, trough concentrations had a lower influence than the genotype and the viral load on SVR<sup>[21]</sup>.

We secondly showed that ribavirin plasma exposure

after the first dose [*i.e.*, measured by the interdose area under the concentration curve, area under the curve (AUC<sub>0-12h</sub>) or abbreviated AUC<sub>0-4h</sub>] was strongly linked to SVR and was probably a more relevant tool<sup>[23]</sup>. Using receiver operating characteristic curve analysis, we defined an AUC<sub>0-4h</sub> threshold of 1755 µg/h per litre at day 0 as a target for ribavirin early dose adjustment, AUC<sub>0-4h</sub> being estimated using 3 blood samples (0.5, 1 and 2 h after the first dose) and Bayesian estimation. When comparing adapted and non-adapted patients with a suboptimal exposure to ribavirin at day 0 (*i.e.*, D0 AUC<sub>0-4h</sub> < 1755 µg/h per litre), the difference of SVR reached nearly 30%, enhancing the benefit of adapted dose in this population (unpublished results).

#### ***Ribavirin and anemia during peginterferon and ribavirin treatment***

Ribavirin-induced haemolytic anaemia is a frequent adverse event leading to drug discontinuation in 36% of the cases in real-life studies<sup>[24]</sup>, even if this anemia is reversible and dose-dependent. Medullar regeneration is partially prevented by various degrees of bone marrow suppression due to interferon impact. The prevalence of anaemia is high, with Hb level < 11 g/dL in 30% and < 10 g/dL in 9% to 13% of the patients<sup>[14,15]</sup> with 10% to 15% of the patients presenting with an Hb decline of more than 5 g/dL. Erythropoietin has been shown to improve the ribavirin treatment maintenance and tolerance<sup>[25,26]</sup> but did not prove its impact on SVR.

## **PRESENT OF RIBAVIRIN: TREATMENT WITH NEW DAAS**

Interferon-free regimens DAAs currently approved by FDA and EMEA are used in combinations: Pangenotypic polymerase inhibitor sofosbuvir (Sovaldi®) associated with NS5A inhibitors ledipasvir (associated with sofosbuvir: Harvoni®) or daclatasvir (Daklinza®) (genotype 1, 3, 4), or with a protease inhibitor simeprevir (Olysio®) (genotype 1, 4); triple combination paritaprevir boosted with ritonavir (protease inhibitor), ombitasvir (NS5a inhibitor) (Viekirax®) and quadruple combination of paritaprevir, ritonavir, ombitasvir and dasabuvir (Exviera®) a polymerase inhibitor are also available for genotype 1, 4 patients.

Most of the time, these regimens give more than 90% SVR rate without the addition of ribavirin. However, ribavirin is still relevant in some circumstances.

#### ***Ribavirin and sofosbuvir alone are efficient in the treatment of most cases of G2 infected patients***

Sofosbuvir and ribavirin combination is recommended in both European Association for the Study of the Liver (EASL) and French guidelines in G2 patients for 12 wk mainly<sup>[27]</sup> except for cirrhotic experienced-patients (24 wk)<sup>[28]</sup>. In this particular population, the only way to reduce treatment duration to 12 wk with similar SVR (95% to 100%) is to add peginterferon<sup>[29,30]</sup>.

#### ***Nowadays, ribavirin remains essential for the last difficult-to-treat cirrhotic G3 patients***

HCV G3 patients were first treated with sofosbuvir and ribavirin for 24 wk in phase III trials; response rates were 91% in patients without cirrhosis and only 68% in patients with cirrhosis, respectively<sup>[27]</sup>. Recently, the Boson study showed the potential superiority of a peginterferon sofosbuvir and ribavirin regimen for 12 wk with a 91% to 86% SVR in naive and pre-treated cirrhotic patients respectively<sup>[30]</sup>. Another strategy using sofosbuvir daclatasvir without ribavirin for 12 wk in G3 cirrhotic patients led to a weak 63% rate of SVR<sup>[31]</sup>. Results of the French initial authorization for new DAAs are in favour of a 24-wk treatment but the sofosbuvir daclatasvir and ribavirin strategy for 12 wk was not available<sup>[32]</sup>. This option could be a pertinent alternative to the 24-wk sofosbuvir daclatasvir association. Currently, EASL and French expert advices recommend treating patients with sofosbuvir daclatasvir for 24 wk, in the absence of the results of a new trial evaluating sofosbuvir daclatasvir ribavirin for 12 wk.

To sum up, all options currently available for cirrhotic G3 patients contain ribavirin and we have to wait for the results of new associations like sofosbuvir and the pangenotypic GS 5816 (astral 3 waiting results) or more sophisticated triple strategies like grazoprevir elbasvir and sofosbuvir<sup>[33]</sup>.

#### ***Ribavirin is still necessary for G1a patients treated with ritonavir-boosted paritaprevir, ombitasvir and dasabuvir***

The approval of the triple combination of ritonavir-boosted paritaprevir, ombitasvir and dasabuvir in patients infected with G1 was supported by six phase III clinical trials. In PEARL-IV, in patients infected with subtype 1a, the SVR rates were 97% and 90% with and without ribavirin respectively, suggesting that, unlike for G1b, ribavirin is needed in the 12-wk regimen for this subtype<sup>[34]</sup>. Moreover, considering treatment-experienced cirrhotic patients with subtype 1a infection a 24 wk-treatment duration with ribavirin was needed<sup>[35]</sup>.

#### ***Reducing treatment duration to 12 wk in G1 or G4 cirrhotic patients is feasible thanks to ribavirin***

##### **In compensated and decompensated cirrhosis:**

Recent data suggest that the addition of ribavirin allows the treatment duration to be limited to 12 wk in patients with advanced liver disease, including patients with compensated cirrhosis (especially if they are treatment-experienced), patients with decompensated cirrhosis and subjects in pre- and post-liver transplant setting.

#### ***Twelve weeks with ribavirin or 24 wk without ribavirin are equivalent in compensated cirrhosis:***

In the Sirius study<sup>[36]</sup>, ledipasvir-sofosbuvir plus ribavirin for 12 wk and ledipasvir-sofosbuvir for 24 wk provided similar high SVR12 rates in previous non-responders with HCV G1 and compensated cirrhosis. The shorter regimen, when given with ribavirin, might, therefore,

be useful to treat experienced patients with cirrhosis in case of no contra-indications to ribavirin.

Of note, in cirrhotic pre-treated patients with platelet count  $< 75000/\text{mm}^3$ , the SVR rate is suboptimal (84%)<sup>[37]</sup> and EASL guidelines recommend to extend the ribavirin-associated regimen to 24 wk in this subgroup.

In a post-hoc analysis of data from seven clinical trials which evaluated the efficacy and safety of the fixed-dose combination of ledipasvir and sofosbuvir, with and without ribavirin in 513 treatment-naïve and previously treated patients with G1 HCV compensated cirrhosis, Reddy *et al*<sup>[37]</sup> suggested the usefulness of ribavirin in the subpopulation of treatment-experienced patients receiving 12 wk of treatment (SVR12 rate of 90% vs 96% with ribavirin).

Finally in the hepather cohort<sup>[38]</sup>, difficult-to treat G1 (88% cirrhotics) patients receiving sofosbuvir daclatasvir and ribavirin achieved a SVR4 of 100% not different from sofosbuvir daclatasvir for 24 wk (SVR4 95%). In a multivariate analysis, factors associated with SVR in cirrhotics were the addition of ribavirin (OR = 6.3;  $P = 0.057$ ) and a treatment-duration of 24 wk (OR = 4.3;  $P = 0.008$ ).

Similarly, results from the same cohort study showed a benefit in the pre-treated cirrhotic population infected with G4 and receiving sofosbuvir daclatasvir or sofosbuvir simeprevir, with ribavirin<sup>[39]</sup>.

**Same results are observed in decompensated cirrhosis in the pre and post-transplant setting except for Child Pugh C patients:** The association of sofosbuvir ledipasvir and ribavirin for 12 wk in the pre and post transplant setting led to more than 85% to 95% SVR in cirrhotic patients<sup>[40,41]</sup>. However, in one study, the response rate was much lower (under 60%) in Child Pugh C patients suggesting a prolongation of treatment course to 24 wk<sup>[42]</sup>.

#### ***In non-cirrhotic G1 patients, ribavirin does not help to reduce treatment duration under 8 wk***

Among previously untreated patients with HCV G1 infection and without cirrhosis in the phase III ION 3 study, the 8-wk ledipasvir-sofosbuvir regimen showed no inferiority to the 12-wk regimen<sup>[43]</sup>. One interesting hypothesis could have been to further reduce the treatment duration by adding ribavirin to the combination.

However, in the electron study, among treatment-naïve patients receiving 6 wk of sofosbuvir, ledipasvir and ribavirin, only 17 of 25 (68%) achieved an SVR12. The addition of ribavirin in this setting does not seem to be an appropriate strategy<sup>[44]</sup>.

#### ***Retreating patients with acquired anti NS5A resistance-associated variants using ribavirin-based strategies could be useful***

In Reddy's study<sup>[37]</sup>, 91% of G1 cirrhotic patients with NS5A resistance-associated variants (RAVs) at baseline and treated with sofosbuvir-ledipasvir achieved SVR12 (95%CI: 84-96), as compared with 98% (407 of 417)

of those without baseline NS5A RAVs (95%CI: 96-99). This difference appeared to be mitigated by the addition of ribavirin to the regimen (88% of SVR without vs 94% with ribavirin).

#### ***The addition of ribavirin with DAAs combinations leads to more frequent but mild adverse events***

In the main studies comparing interferon-free DAAs combinations with or without ribavirin for 12 wk, adverse events (AEs) were significantly higher (about 10%) when ribavirin was included in the strategy: Particularly fatigue, insomnia, pruritus, cough and of course all grades of anemia but only 5% of grade 3 and 4. Treatment discontinuation due to AEs (4%) was slightly more frequent. However, these AEs were not significantly higher in compensated cirrhotic patients when a 12-wk regimen with ribavirin was compared to a 24-wk regimen without ribavirin<sup>[36]</sup>. Erythropoietin (EPO) was not used except in advanced cirrhotic disease and reduction of ribavirin dosage (9%) was most of the time sufficient with no impact on SVR<sup>[45]</sup>.

Of course, these AEs were more tolerable than in regimens including interferon, and even more than in triple therapy with first generation protease inhibitors.

#### ***There is probably no more place for ribavirin dose adjustment during treatment with DAAs***

In the NIAID SPARE trial, Rower *et al*<sup>[46]</sup>, showed that ribavirin-monophosphate concentrations in red blood cells at day 14 were related to anaemia and SVR. A therapeutic range was identified for ribavirin-monophosphate in persons with HCV G1 disease receiving 24 wk of sofosbuvir plus ribavirin, suggesting a potential pharmacological basis for individualized ribavirin dosing in this interferon-free regimen. However, Jacobson *et al*<sup>[45]</sup> showed in cirrhotic G1 patients, that ribavirin dose reduction due to anemia in the triple Abbvie combination (10% of the cohort) did not impact the SVR. One may hypothesize that the monitoring of ribavirin dose in G1 patients will not be useful when using at least two very potent new DAAs, unlike what was observed with the association of peginterferon and ribavirin or sofosbuvir and ribavirin.

## **FUTURE**

#### ***Preliminary data with second generation interferon-free DAAs combinations without ribavirin suggest that ribavirin future is jeopardized even in difficult-to-treat patients***

**New double combinations:** Grazoprevir elbasvir without ribavirin for 12 wk is efficient in difficult-to-treat G1 and G4 patients. In a phase II study (C-Worthy), high SVR12 rates were achieved irrespective of the use of ribavirin or of the extension of treatment duration from 12 to 18 wk in two cohorts of G1 patients, *i.e.*, cohort 1, naïve cirrhotic patients and cohort 2 previous null responders with or without cirrhosis. The SVR rate without ribavirin was 97% and 91% in the two

cohorts respectively<sup>[29]</sup>. In the Edge study, considering G1 and 4 patients (35% cirrhosis), the association of grazoprevir elbasvir gave similar results with and without ribavirin for a 12- or 16-wk duration (92% to 97%). Interestingly however, SVR rates were higher for the 16 wk + ribavirin arm regardless the status of the patient, the presence of cirrhosis and the presence of NS5A mutation (97%)<sup>[47]</sup> suggesting a small residual role of ribavirin. In a phase II preliminary study, the same combination without ribavirin was effective and well tolerated in G1 Child B-cirrhotic patients<sup>[48]</sup> leading to a 90% SVR. The combination of grazoprevir and elbasvir was useless or suboptimal for G3 and G2 patients respectively even with the addition of ribavirin and G5 patients, interestingly, still needed ribavirin<sup>[49,50]</sup>.

The sofosbuvir GS-5816 (pangenotypic NS5a inhibitor) combination without ribavirin was clearly efficient in G3 non cirrhotic patients (100% SVR) and more efficient than other previous combinations in experienced cirrhotic patients (88%). However in the latter case, the addition of ribavirin seemed to bring a mild benefit (96% of SVR)<sup>[51]</sup>.

#### Multiple DAAs combinations without ribavirin in difficult-to-treat patients:

In G1 naive or pre-treated cirrhotic patients, the association of daclatasvir NS5A pangenotypic inhibitor, asunaprevir NS3 protease inhibitor and beclabuvir NS5B non nucleosidic polymerase inhibitor without ribavirin, gave high response rates in naive patients (93%). However, ribavirin could still be useful in pre-treated patients (93% vs 87% SVR with and without ribavirin, respectively)<sup>[52]</sup>.

In G3 cirrhotic patients, preliminary results showed that the association of grazoprevir elbasvir sofosbuvir without ribavirin gave a 91% SVR suggesting that this combination could be an ideal strategy for these difficult to treat population<sup>[33]</sup>. Of course, these results have to be confirmed.

#### Renal insufficiency: It will be soon possible to avoid ribavirin

Ribavirin use is problematic in this setting due to the management of severe anemia and the delicate dose adjustment which is not standardized (200 mg × 3/wk to 200 mg/d) and requires ribavirin concentration measurement especially in hemodialysis.

Today, no DAA association is recommended in patients with estimated glomerular filtration rate < 30 mL/mn, especially because the key tool of the approved associations, sofosbuvir and its main metabolite are eliminated by the kidney and the appropriate dosing is not known. Preliminary studies however showed that the simeprevir sofosbuvir (200 mg/d) association without ribavirin gave a SVR rate of 88% to 100% with a quite good tolerance<sup>[53,54]</sup>.

The paritaprevir/ritonavir ombitasvir dasabuvir combination was also very efficient (100% response) but G1a subtype still needed ribavirin<sup>[55]</sup>.

Finally, in the largest study so far, out of 226 G1

patients with severe renal insufficiency, 191 with chronic kidney disease stage 5 and 179 hemodialysed showed a 99% SVR when treated with grazoprevir elbasvir for 12 wk without ribavirin with an excellent tolerance<sup>[56]</sup>.

These encouraging results will probably lead us to treat hemodialysed patients if no transplant perspective is envisaged, or before kidney transplantation, as HCV negatively impacts these patients' prognosis.

## CONCLUSION

Even if new DAAs are cost-effective, at their current prices, they are not cost-saving, and the addition of ribavirin with approved DAAs interferon-free regimens is probably the best option to decrease treatment duration without impacting SVR. The next step of course is one pill of DAAs a day without ribavirin to treat all patients whatever the stage of the disease or the genotype, with no side effects and for the shortest treatment duration possible. Even if second generation drugs do not yet fulfil all the criteria and probably will not for the next 5 years, they dangerously jeopardize ribavirin future.

### Abstract

Chronic hepatitis C virus (HCV) infection has been shown to be linked to a higher prevalence of type 2 diabetes compared with the general population or with patients with chronic hepatitis B infection and diabetes is the most common extra-hepatic manifestation of HCV. The HCV-diabetes association is due to insulin resistance (IR) that occurs early in the course of the

disease even in patients without or with minimal fibrosis. The mechanisms for HCV-induced IR are only partly understood and include a direct inhibitory effect of HCV on insulin signaling pathway. IR in chronic HCV results in an increased progression rate of hepatic fibrosis, cirrhosis and hepatocellular carcinoma. Some but not all studies found that IR reduces the response rate to interferon/ribavirin therapy. Whether IR affects the response to the new direct-acting antiviral treatments is still unknown.

**Key words:** Hepatitis C; Type 2 diabetes; Antiviral therapy; Insulin resistance; Insulin signaling

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Chronic hepatitis C virus (HCV) infection is associated with a higher prevalence of diabetes as compared to either the general population or patients with chronic hepatitis B infections. HCV hepatitis is linked to insulin resistance (IR) early in the disease course, mediated partly by direct inhibitory effect of the viral proteins on insulin signaling. The presence of IR is associated with an increased rate of disease progression to fibrosis, cirrhosis and hepatocellular carcinoma. Interferon and ribavirin treatment of HCV hepatitis may be less successful in the presence of IR. The effect of IR on the new direct-acting antiviral treatment is unclear.

### INTRODUCTION

Chronic hepatitis C virus (HCV) infection is a major healthcare problem worldwide with between 130-170 million people infected<sup>[1,2]</sup>. In addition, there are extra-

hepatic manifestations of HCV infection including mixed cryoglobulinemia, thyroid disorders and other autoimmune-mediated diseases<sup>[3]</sup>, but several studies published since 1994 provide evidence that diabetes mellitus (DM) maybe the most common extra-hepatic disease associated with chronic HCV.

## THE ASSOCIATION BETWEEN HCV AND DIABETES

The first studies that demonstrated an association between HCV and DM evaluated patients at advanced stage of liver disease necessitating liver transplantation and revealed that diabetes occurred in 50% and 62% of patients whose liver failure was HCV-related compared to 9% in patients whose liver failure was related to other causes<sup>[4,5]</sup>. These unexpected results were confirmed by studies from many parts of the world demonstrating that the increased prevalence of diabetes in HCV patients is unique and is significantly different compared to hepatitis B virus (HBV) infection<sup>[6-8]</sup>.

Many of these additional studies, however, also included patients with cirrhosis - a condition that by itself is known to lead to impaired glucose tolerance<sup>[9,10]</sup>.

### *Diabetes in non-cirrhotic HCV patients*

In order to avoid the confounding effect of cirrhosis on glucose metabolism, we designed a study conducted in patients without liver cirrhosis that included 45 patients with chronic HCV, 88 patients with chronic HBV infection and 90 healthy individuals<sup>[11]</sup>. Diabetes status was based on an oral glucose tolerance test (OGTT). We found that 33% of HCV patients had type 2 diabetes compared to 12% of patients with chronic HBV infection and 6% of a healthy control cohort. We have reported that HCV patients with diabetes had a higher incidence of a family history of diabetes as compared to HCV patients without diabetes ( $P < 0.001$ ). In addition on comparing liver biopsies from HCV patients with diabetes to those with HCV and no diabetes there was a significantly higher inflammatory activity, fibrosis grade and more steatosis.

### *Large cohort studies evaluating the relationship between HCV and diabetes*

The National Health and Nutrition Examination Survey (NHANES III) evaluated 9841 community-dwelling subjects and found that 8% of this population had type 2 diabetes and 2% were anti-HCV positive. The odds ratio (OR) for type 2 DM in those over 40 years of age after adjusting for sex, body mass index (BMI), ethnicity, poverty index, and previous drug or alcohol use was 3.77 (95%CI: 1.80-7.87)<sup>[12]</sup>. There was no increased risk for DM in those with chronic HBV infection. Although liver biopsies were not performed in these patients, there were no clinical signs of chronic liver disease. A large study of consecutive chronic HCV patients from Spain, found a 3-fold increase in the prevalence of glucose abnormalities in non-cirrhotic HCV+ compared

with HCV- subjects<sup>[13]</sup> but not in cirrhotic patients. Furthermore, multivariate analysis of chronic HCV patients without cirrhosis found that HCV infection was an independent determinant of glucose abnormalities, OR of 4.26 (95%CI: 2.03-8.93). In the Atherosclerosis Risk in Communities study, with a follow-up of 9-years pre-existing HCV infection was found to be a significant risk factor for developing diabetes in aged patients or those with a high BMI. This finding was strikingly robust with a relative hazard of 11.58 (95%CI: 1.39-96.6)<sup>[14]</sup>. Two meta-analyses including 47 cross-sectional and cohort studies found that HCV was associated with DM with an OR of 1.7<sup>[15,16]</sup> with an excess risk observed in comparison to HBV-infected controls.

However a recent additional report based on NHANES data 1999-2010 survey evaluated 15128 participants with known HCV and glucose status and did not find an association between HCV status and diabetes/pre-diabetes<sup>[17]</sup>. The reasons for this discrepancy are not entirely clear however the number of patients who were HCV positive was relatively small (1.7% were anti-HCV+ and 1.1% were HCV RNA+) and OGTT was not performed. Another factor that can reduce the strength of the association between HCV infection and diabetes in this recent United States survey is the increase within the rate of obesity and consequently obesity-induced diabetes that may dilute the effect of HCV.

Taken together, the vast majority of studies suggest that chronic hepatitis C is specifically associated with type 2 diabetes and the association is strongest in patients with additional risk factors such as older age and positive family history of diabetes implying that HCV leads to diabetes particularly in susceptible hosts.

### *Interferon-induced diabetes*

Interferon treatment that was until recently the cornerstone of HCV treatment was shown to induce a distinct form of diabetes. However this is a relatively rare complication that in contrast to the common form of HCV-related type 2 diabetes described above, has an abrupt onset, necessitates insulin treatment from onset and is mediated by an autoimmune process manifested by a very high titer of pancreatic autoantibodies<sup>[18]</sup>.

## PATHOGENESIS OF HEPATITIS C ASSOCIATED DIABETES

### *HCV and insulin resistance*

There is substantial evidence that insulin resistance (IR), that has a pivotal role in the pathogenesis of type 2 diabetes, develops early in the course of HCV infection<sup>[19-21]</sup>. A study of 260 subjects with HCV with assorted stages of fibrosis compared with 137 healthy volunteer in which IR was measured by the homeostasis model assessment-IR (HOMA-IR), found significant IR even in the sub-group of 121 patients with only stage 0 or 1 of hepatic fibrosis. However, although IR was detected even in subjects with minimal or no fibrosis,

more advanced fibrosis was associated with increased HOMA-IR<sup>[19]</sup>. Other studies confirmed these findings and showed a correlation between the degree of fibrosis and IR<sup>[20,22]</sup>. By using the gold standard measurement of IR, the hyperinsulinemic - euglycemic clamp it was shown that IR occurred mainly in the periphery, *i.e.*, in muscles and not in the liver and was related to viral load but not to liver fat content<sup>[23]</sup>. The notion that HCV has a direct effect on insulin sensitivity that is not mediated by virus-induced steatosis is also supported by a transgenic mice model which expresses the HCV core protein in the liver. IR was detected as early as 1 mo of age while hepatic steatosis developed after 3 mo<sup>[24]</sup>. In a landmark study, Aytug *et al*<sup>[25]</sup> evaluated liver specimens obtained from non-obese non-diabetic HCV patients compared to controls and their data not only confirmed the existence of HCV-induced IR but also revealed a specific impairment of insulin - stimulated IRS-1/PI3 kinase signaling pathway in HCV patients, a pathway that is responsible for insulin metabolic effects.

### IR and HCV genotypes

The relationship between IR and HCV genotype is still controversial. In a study of Hui *et al*<sup>[19]</sup> patients with genotype 3 had significantly lower HOMA-IR compared with other genotypes and this association remained significant even after adjusting for other variables. In another large study of 275 non-diabetic treatment-naïve HCV patients, HOMA-IR was significantly higher in non-3 genotype compared with genotype 3. However in non-obese patients with minimal fibrosis, using a cut-off level of HOMA > 3 as indicating IR, there was no significant effect of genotypes<sup>[26]</sup>. In another smaller study of 44 patients that used a cut-off level of HOMA  $\geq 2$  as indicating IR, the prevalence of IR was similarly high, 65% and 57% in genotype 1 and genotype 3, respectively<sup>[27]</sup>. However it is important to emphasize that the usage of these HOMA-IR criteria to define IR is problematic since there are no acceptable absolute cut-off levels.

### The underlying mechanisms for HCV-induced IR

**Tumor necrosis factor alpha:** The role of the cytokine tumor necrosis factor alpha (TNF- $\alpha$ ) in HCV-induced IR is supported by several studies (for review<sup>[28]</sup>). TNF- $\alpha$  producing cells, the majority of which are derived from macrophage/Kupfer cell lineage, are increased in HCV infection; and TNF- $\alpha$  activation was found to be significantly associated with the inflammatory process<sup>[29]</sup>. TNF- $\alpha$  also has an important inhibitory role on the insulin signaling pathway and the mechanism is mediated by activating serine/threonine (Ser/Thr) kinases that phosphorylate the insulin receptor substrate (IRS) protein, and uncoupling it from both upstream and downstream effectors<sup>[30]</sup>. TNF- $\alpha$  induces IR also by indirect mechanisms such as increasing lipolysis leading to increased serum free fatty acids and regulating expression of several adipocyte genes that modulate insulin sensitivity<sup>[31]</sup>. TNF- $\alpha$  binds to two distinct cell

surface receptors, TNFR-1 and TNFR-2 that undergo proteolytic cleavage producing soluble receptors sTNFR1 and sTNFR2. Serum levels of TNF- $\alpha$  and sTNFR were increased in HCV-infected patients compared with controls<sup>[32]</sup>. When serum sTNFR were measured in non-cirrhotic HCV patients with and without diabetes, non-HCV patients with type 2 diabetes and controls, a marked increase of sTNFR was found in the HCV-diabetes<sup>+</sup> group compared to HCV patients without diabetes, and non-HCV patients with type 2 DM<sup>[33]</sup>. A significant correlation was found between the degree of liver inflammation and sTNFR<sup>[29]</sup>. The role of TNF- $\alpha$  in HCV-induced IR is supported by the finding that anti TNF- $\alpha$  antibody administration restored insulin sensitivity in a transgenic mice model that specifically expressed the HCV core protein in the liver<sup>[24]</sup>.

However, increased levels of TNF- $\alpha$  are also present in other chronic liver diseases and thus cannot fully account for the unique association between HCV and IR. Therefore direct effects of HCV proteins on insulin signaling have been also considered.

### Direct effects of HCV proteins on insulin signaling

In human hepatoma cells, HCV core protein up-regulates suppressor cytokine signaling (SOCS)-3, which is known to inhibit insulin signaling by causing ubiquitination of IRS1 and IRS2 proteins<sup>[34]</sup>. These defects were not detected in SOCS3<sup>-/-</sup> mouse embryonic fibroblasts cells or in the presence of an inhibitor of proteasomal proteolysis<sup>[34]</sup>. We have reported several impairments of the insulin signaling cascade linked to the proteasomal degradation of IRS-1 protein<sup>[35]</sup>. Additionally we found that the core protein impaired insulin ability to inhibit the expression of the target gene insulin growth factor binding protein-1.

HCV can also inhibit insulin signaling by dephosphorylation of AKT involving the endoplasmic reticulum stress signal inducing over-expression of protein phosphatase 2A<sup>[36]</sup>. Taken together these data imply a direct effect of HCV core protein in inhibiting insulin signaling pathway.

## DOES ERADICATION OF HCV

### AMELIORATE IR?

A recent study of 8 normoglycemic men with chronic HCV infection that used the hyperinsulinemic-euglycemic clamp that provides a direct measurement of peripheral insulin sensitivity, showed that viral clearance led to improvement in glycemic control and to insulin sensitivity that become comparable to 15 matched HCV-negative controls<sup>[37]</sup>. A larger earlier study, using the surrogate marker HOMA-IR also showed that in HCV patients who were sustained responders HOMA-IR decreased while in it did not change in nonresponders and relapsers<sup>[38]</sup>. However, another study showed that HCV therapy improved IR regardless of virologic response but the response was greatly influenced by BMI

changes and interferon use making data interpretation difficult<sup>[39]</sup>.

## THE EFFECT OF IR AND DIABETES ON THE CLINICAL OUTCOME OF HCV

The link between HCV infection and IR and diabetes is complex. IR appears at an early stage of chronic HCV infection as discussed above and results in an increased rate of progression of hepatic fibrosis and the complications of cirrhosis including hepatocellular carcinoma (HCC)<sup>[40]</sup>.

IR is also related to obesity and type 2 diabetes and both of these conditions are known to be risk factors for HCC leading to about 2-fold increased prevalence<sup>[41,42]</sup>. The rise in HCV infection and HCV-induced IR together with increased obesity-induced IR may partly explain the marked increase in HCC in the last decades<sup>[43]</sup>.

The compensatory hyperinsulinemia that occurs in IR can lead to fibrogenesis. In human hepatic stellate cells (HSC), incubation with insulin and insulin growth factor (IGF)-1 led to increased HSC proliferation and type 1 collagen gene expression<sup>[44]</sup>. The increased IGF-1 levels that occur in the IR state is also one of the mechanisms for IR-associated malignancy and particularly HCC and changes in the expression pattern of IGF system components were found in human hepatoma cell lines and in animal models<sup>[45]</sup>.

In a recent systemic review of 14 studies including 3695 participants with HCV infection, the relative risk for fibrosis was 2.26 (95%CI: 1.52-3.06) for genotype 1, but the association was not significant for genotype 3<sup>[46]</sup>. HCV is also intimately related to hepatic steatosis<sup>[47,48]</sup> and steatosis is much more common in patients infected with HCV than in other liver diseases. This association is most marked for genotype 3<sup>[49]</sup>. Steatosis is also linked to HCC and in two lines of transgenic mice expressing the HCV core protein, HCC developed within fat-containing adenomas<sup>[50]</sup>.

## THE EFFECT OF IR AND DIABETES ON THE RESPONSE TO THERAPY

It has been shown that patients with high IR have a slower rate of decline in the viral load of HCV RNA compared to patients with low IR, even in the first 24 h of treatment<sup>[51]</sup>. In addition, there is an association between a high degree of IR and a low rate of rapid viral response in genotypes 1<sup>[52]</sup>, 3<sup>[53]</sup> and 4<sup>[54]</sup>. Several studies have shown that IR is associated with a higher likelihood of not achieving sustained virological response (SVR)<sup>[52-56]</sup>. A study from Spain of 159 patients with chronic HCV hepatitis found that those with a SVR had lower baseline HOMA scores compared to those patients who did not achieve a SVR<sup>[57]</sup>. The Virahep-C study which included both Caucasian and African-Americans found that IR and interferon dose were negatively associated with SVR<sup>[56]</sup>. The patients in this study had a high degree of obesity

and IR as compared to other published reports. These studies have used HOMA to assess insulin sensitivity, a surrogate measure of IR although this technique is less precise than more direct measurements such as the insulin suppression test<sup>[58]</sup>. Furthermore IR can change over time with in patients with chronic HCV infection<sup>[59]</sup>. When IR was directly assessed by means of an insulin suppression test in a cohort of 50 non-cirrhotic, non-diabetic patients with chronic HCV infection, SVR was not associated with insulin sensitivity<sup>[39]</sup>. The steady state plasma glucose level decreased during anti-viral therapy but was not statistically significant between those patients achieving SVR and those not achieving SVR during and after treatment<sup>[39]</sup>. IR often progresses to diabetes but in a study that evaluated SVR and the development of diabetes or impaired glucose tolerance, no such correlation was found during a median follow up of 8 years<sup>[60]</sup>. In 2011, two meta-analyses were published that examined the effect of IR on SVR including fourteen studies with more than 2700 patients<sup>[61,62]</sup>. The studies that did not find an association between IR and SVR had a baseline HOMA value of less than 3 and a low prevalence of advanced fibrosis. This suggests that the HOMA value may be predictive of response to antiviral treatment in those patients with advanced liver disease. These inconsistent data may be partly due the interplay between the baseline characteristics of the patients and the effect of the HCV virus on insulin sensitivity. Notably, about 25%-30% of the United States population have metabolic features of HCV-independent IR<sup>[63]</sup>.

## TARGETING IR AS PART OF HCV TREATMENT

In view of the link between IR and the progression of HCV hepatitis and the possible influence of IR on treatment, attention has been drawn to improving the metabolic factors related to IR before or during anti-viral treatment.

### *Lifestyle modification*

A 24 wk lifestyle and dietary intervention was shown to reduce BMI and HOMA in obese patients with chronic HCV hepatitis<sup>[64]</sup>. A 3-mo trial of a low calorie diet before starting anti-viral therapy has been shown to result in a higher end-of- treatment viral response in patients with type 1 chronic HCV hepatitis together with an improvement in IR.

### *Metformin*

Metformin is an insulin sensitizer that mainly decreases hepatic glucose production. An attempt to add metformin to treatment with peg-interferon-2a and ribavirin led to decreased HOMA-IR and viral load, together with an improvement in the SVR, but this effect was observed only in females<sup>[65]</sup>. In another study metformin administration led to an increase in SVR in both male and female HCV patients with genotype 1 treated by

pegylated interferon and ribavirin<sup>[66]</sup>.

### Thiazolidinediones

Thiazolidinediones produce an increase in insulin sensitivity *via* activation of the peroxisome proliferator-activated receptor- $\gamma$  in adipocytes and skeletal muscle<sup>[67]</sup>. Pioglitazone has been shown to produce an increase in SVR in patients with genotype 4 and IR but not in patients with genotype 1<sup>[68]</sup>. Another study of pioglitazone added to pegylated interferon-2a and ribavirin in non-diabetic HCV patients who previously did not respond to this treatment and who had HOMA > 2, was terminated after none of the first five patients achieved a 12 wk viral response, despite an improvement in IR in some of them<sup>[69]</sup>.

In a recent small study of patients with HCC, in a sub-group analysis of diabetic over-weight patients, the addition of pioglitazone to curative treatment resulted in reduced HCC recurrence<sup>[70]</sup>.

## THE EFFECT OF DIABETES ON THE RESPONSE TO THE DIRECT-ACTING ANTI-VIRAL TREATMENTS

The recently approved sofosbuvir, simeprevir, ledipasvir, and the combination of paritaprevir, ombitasvir and dasabuvir have ushered in the era of interferon-free therapy for HCV hepatitis. These direct-acting anti-viral treatments (DAA) achieve SVRs of more than 90% for most treatment groups<sup>[71]</sup>. With such an effective treatment available it is likely that the effect of IR will be less evident. However, a recent preliminary report suggests that metabolic factors such as diabetes and hyperlipidemia still compromise the effect of DAA treatment. This was based on the results of a recent study that examined SVR at 12-wk in 54 non-Caucasian populations in the United States, 65% of whom were Hispanic and 24% had diabetes. SVR in this study was 81% which is lower than the rate reported in previous studies. A pre-treatment glucose level of less than 126 mg/dL was shown to be linked to a higher rate of SVR<sup>[72]</sup>. Further studies are needed to evaluate the effect of IR and diabetes on the response to DAA treatment.

Although the future of treatment of HCV hepatitis will undoubtedly be oral, once-daily pangenotypic therapy with a nearly 100% SVR, in 2015 there is still a place for treatment of HCV hepatitis with interferon-containing regimens.

For patients with genotypes 2-6 peginterferon and ribavirin is still effective treatment. For patients with genotype 2, 24 wk of treatment is sufficient and an SVR of 85%-90% is achieved<sup>[73]</sup>. Interferon has an important role in the treatment of genotype 3, including a regimen with sofosbuvir<sup>[74]</sup>, and in the treatment of genotype 4 with an SVR of 43%-70% and 60%-85% SVR for genotype 6<sup>[75]</sup>.

In addition for many economically-constrained health services and patients who are self-funding, the

cost of the DAAs is prohibitive, and treatment with interferon will remain an option for the near future<sup>[76]</sup>.

## CONCLUSION

IR is intimately related to HCV infection based on numerous studies in animal models and humans resulting in increased prevalence of type 2 diabetes in HCV patients. The underlying mechanisms are only partly understood and recent data suggest a direct inhibitory effect of the virus on insulin signaling pathway. IR was shown by several, but not all studies, to have a deleterious effect on the clinical course of chronic HCV infection and the inconsistency maybe explained by differences in the baseline characteristics of the patients. Small studies suggest that life-style intervention and metformin may increase SVR rate but further studies are needed to confirm these findings. The effect of IR in the DAA drugs era is still unclear.

# World Journal of *Hepatology*

*World J Hepatol* 2016 January 28; 8(3): 139-206

## Editorial Board

2014-2017

The *World Journal of Hepatology* Editorial Board consists of 469 members, representing a team of worldwide experts in hepatology. They are from 53 countries, including Algeria (1), Argentina (6), Armenia (1), Australia (1), Austria (4), Bangladesh (2), Belgium (3), Botswana (2), Brazil (13), Bulgaria (2), Canada (3), Chile (1), China (98), Czech Republic (1), Denmark (2), Egypt (12), France (6), Germany (19), Greece (11), Hungary (5), India (15), Indonesia (2), Iran (4), Israel (1), Italy (52), Japan (35), Jordan (1), Malaysia (2), Mexico (3), Moldova (1), Netherlands (3), Nigeria (1), Pakistan (1), Philippines (2), Poland (1), Portugal (2), Qatar (1), Romania (6), Russia (2), Saudi Arabia (4), Singapore (1), South Korea (11), Spain (20), Sri Lanka (1), Sudan (1), Sweden (1), Switzerland (1), Thailand (4), Turkey (21), Ukraine (3), United Kingdom (17), and United States (56).

## Contents

Three issues per month Volume 8 Number 3 January 28, 2016

### TOPIC HIGHLIGHT

- 139 Advances in hepatitis C therapy: What is the current state - what come's next?  
*Zopf S, Kremer AE, Neurath MF, Siebler J*

### REVIEW

- 148 Management of immunosuppressant agents following liver transplantation: Less is more  
*Ascha MS, Ascha ML, Hanouneh IA*
- 162 Innate immunity and hepatocarcinoma: Can toll-like receptors open the door to oncogenesis?  
*Lopes JAG, Borges-Canha M, Pimentel-Nunes P*
- 183 Sofosbuvir treatment and hepatitis C virus infection  
*Nakamura M, Kanda T, Haga Y, Sasaki R, Wu S, Nakamoto S, Yasui S, Arai M, Imazeki F, Yokosuka O*

### MINIREVIEWS

- 191 Ablation techniques for primary and metastatic liver tumors  
*Ryan MJ, Willatt J, Majdalany BS, Kielar AZ, Chong S, Ruma JA, Pandya A*

### ORIGINAL ARTICLE

#### Observational Study

- 200 Cirrhotic cardiomyopathy: Isn't stress evaluation always required for the diagnosis?  
*Barbosa M, Guardado J, Marinho C, Rosa B, Quelhas I, Lourenço A, Cotter J*

## ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Mohammad K Parvez, PhD, Assistant Professor, Department of Pharmacognosy, College of Pharmacy, King Saud University, Riyadh 22451, Saudi Arabia

## AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/  
ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

## FLYLEAF

## Abstract

Chronic hepatitis C virus (HCV) infection affects 80-160 million people worldwide and is one of the leading causes of chronic liver disease. It is only a few years ago that standard treatment regimes were based on

pegylated interferon alpha and ribavirin. However, treatment of HCV has undergone a revolutionary change in recent years. The admission of the nucleotide polymerase inhibitor Sofosbuvir enabled an interferon-free regimen with direct antiviral agents (DAA). Meanwhile seven DAAs are available and can be applied in several combinations for 8 to 24 wk depending on HCV genotype and patient characteristics such as cirrhosis and chronic renal failure. High rates of sustained virological response (SVR) rates can be achieved with these novel drugs. Even in difficult to treat populations such as patients with liver cirrhosis, HCV-human immunodeficiency virus co-infections, after liver transplantation, or with chronic kidney disease comparable high rates of SVR can be achieved. The anticipated 2<sup>nd</sup> generation DAAs are strikingly effective in patients so far classified as difficult to treat including decompensated liver cirrhosis or post-transplant patients. These 2<sup>nd</sup> generations DAAs will have higher resistance barriers, higher antiviral effects and a pan-genotypic spectrum. This review highlights the current state of the art of antiviral treatment in hepatitis C and gives an outlook for upcoming therapies.

**Key words:** Hepatitis C virus; Direct antiviral agents; Sustained virological response; Liver transplantation; Renal impairment; Cirrhosis

**Core tip:** Treatment of chronic hepatitis C virus (HCV) infections has undergone a revolutionary change in recent years. This review highlights the current state of the art of antiviral treatment in chronic hepatitis C infections and gives an outlook for upcoming therapies. Difficult to treat populations such as patients with decompensated liver cirrhosis, HCV-human immunodeficiency virus co-infections, after liver transplantation and patients with renal impairment or on hemodialysis are highlighted.

## INTRODUCTION

Chronic hepatitis C virus (HCV) infection is one of the leading causes of chronic liver disease worldwide<sup>[1]</sup>. Worldwide 80-160 million people are estimated to be chronically infected with HCV<sup>[2]</sup>. The long-term follow of chronic HCV are highly variable, ranging from minimal histological changes to extensive fibrosis with or without cirrhosis<sup>[2]</sup>.

The primary goal of HCV therapy is to achieve eradication of the HCV which is currently determined by a sustained virological response (SVR) as surrogate marker. SVR is defined as undetectable HCV RNA 12 wk (SVR 12) or 24 wk (SVR 24) after end of treatment.

In recent years antiviral therapy has experienced a tremendous progress. It is only a few years ago that standard treatment regimes were based on pegylated interferon alpha and ribavirin (P/R). These therapies were associated with many adverse effects, long treatment durations of usually 48 wk and low SVR rates<sup>[3,4]</sup>. In 2011, the two protease inhibitors boceprevir and telaprevir were approved for treatment of genotype 1. Due to their comparatively lower antiviral effectiveness and rapid resistance development both drugs were used only as triple-therapy regimen in combination with pegylated interferon alpha and ribavirin<sup>[5-8]</sup>.

Since 2014 several direct acting antivirals (DAAs) have been approved enabling interferon-free antiviral treatments with high SVR rates.

The decoding of the HCV life cycle and the resolution of crystal structure of the relevant viral proteins enabled the development of many DAAs. The currently approved DAAs consist of three groups. The first group is directed against the viral protease NS3/4A (protease inhibitors; name ending on -previr), the second against the viral RNA-dependent RNA-polymerase NS5B (polymerase inhibitors, name ending on -buvir) and the third against the viral protein which is involved in the formation of the replicon complex NS5A (NS5A-inhibitors, name ending on -asvir)<sup>[9]</sup>.

## DAAs SUBSTANCES

### Sofosbuvir

Sofosbuvir (SOF) is an inhibitor of the NS5B-polymerase. As nucleotide analogue it causes chain termination during replication. SOF has a pan-genotypic effectiveness and a high resistance barrier. It is taken once daily with a good tolerability. No cross resistances with other substances have been reported. Drug interactions were described only for strong inducers of the gut transporters P-gp and

BCRP (e.g., rifampicin, St John's wort, carbamazepin, phenytoin)<sup>[10]</sup>.

### Simeprevir

Simeprevir (SMV) is a second-generation protease inhibitor. In addition to the activity against genotype 1 a simeprevir has clinically relevant antiviral effects against genotypes 4 and 6. Similar to boceprevir it needs to be taken only once a day. Adverse effects reported in clinical studies consisted mainly of skin lesions with or without itching, nausea and dyspnea. Of note, the variant (RAV) Q80K exhibits a preexisting resistance against simeprevir resulting in treatment failure of patients with genotype 1a<sup>[11]</sup>.

As SMV is metabolized by hepatic CYP3A4, inhibitors and inducers of CYP3A4 may affect plasma levels of SMV<sup>[12]</sup>.

### Daclatasvir

Daclatasvir (DCV) is a NS5A-inhibitor. DCV has a high antiviral activity against genotypes 1 to 4 *in vivo* and *in vitro* also against genotypes 5 and 6. On the other side the resistance barrier is relatively low. In case of treatment failure resistance-associated resistances (RAVs) may be selected, which remain detectable after end of treatment<sup>[13]</sup>. The influence of these RAVs on following therapies has not been systematically investigated so far. In studies using P/R the combination of DCV plus P/R showed no additional adverse effects<sup>[14]</sup>. Similar to SMV, DCV is also metabolized by CYP3A4.

### Ledipasvir

Ledipasvir (LDV) represents another NS5A-inhibitor with antiviral activity particularly against genotype 1 and partially against other genotypes such as 4-6. LDV is only available in a fix dose combination with SOF. The most commonly reported adverse effects were headache and fatigue. As with DCV, RAVs have been detected during therapy and were not clinically relevant due to the strong antiviral effect of SOF<sup>[15]</sup>.

*In vitro*, no detectable metabolism of ledipasvir was observed by human CYP1A2, CYP2C8, CYP2C9, CYP2C19, CYP2D6, and CYP3A4. Evidence of slow oxidative metabolism *via* an unknown mechanism has been observed. Biliary excretion of unchanged ledipasvir is a major route of elimination, with renal excretion being a minor pathway (approximately 1%).

### Paritaprevir/ritonavir + ombitasvir ± dasabuvir

The combination of paritaprevir/ritonavir (PTV/r) + ombitasvir (OBV) ± dasabuvir (DSV) is referred to as 3D. PTV is an NS3/4A-inhibitor, which is boosted by r to optimize its pharmacokinetics. OBV is an NS5A-inhibitor, while DSV is a non-nucleotide polymerase-inhibitor. PTV/r and OBV are available at fix dose combinations and have antiviral activity against genotypes 1 and 4, while DSV is only effective against genotype 1. Registered adverse effects were pruritus in clinical study cohorts

**Table 1** Current recommendations of antiviral regimens depending on the genotype

DAA-regime	HCV-genotype						
	1a	1b	2	3	4	5	6
SOF + R	(x)	(x)	x	x	(x)	(x)	(x)
SOF + SMV ± R	x	x			x		
SOF + DCV <sup>1</sup> ± R	x	x	(x)	x	x		
SOF + LDV ± R	x	x		(x)	x	x	x
OBV + PTV/r ± DSV ± R (3D)	x	x					
OBV + PTV/r ± R (2D)					x		

<sup>1</sup>DCV, no approval in the United States. DAA: Direct antiviral agents; LDV: Ledipasvir; SMV: Simeprevir; DCV: Daclatasvir; SOF: Sofosbuvir; OBV: Ombitasvir; PTV: Paritaprevir; HCV: Hepatitis C virus; DSV: Dasabuvir; R: Ribavirin; r: Ritonavir.

without ribavirin and in very few patient increased transaminases as well as elevations of bilirubin. As PTV/r is metabolized by CYP3A4 interactions with several other drugs may occur. There are existing cross-resistances to other protease-inhibitors and NS5A-inhibitors while DSV has a low resistance-barrier<sup>[16]</sup>.

## DAA COMBINATION REGIMENS

Of the approved DAAs the following combinations have been studied in clinical trials (Table 1).

SOF is the so-called backbone of most combinations, as it has a high resistance barrier and a pan-genotypic activity. In contrast, the high antiviral activity is achieved by the combination of the various groups of substances in the 3D-regime. In all regimes the addition of R is possible and may be useful for defined patient groups.

### SOF + R

This combination has high SVR-rates (86%-97%) in genotype 2 patients<sup>[10,17]</sup>. In genotype 1, however, SVR-rates were inconsistently in phase 2 studies. Especially in difficult to treat patients, *e.g.*, with cirrhosis, SVR-rates were unsatisfactory (SVR 10%-84%)<sup>[18]</sup>. Furthermore, genotype 3 treatment efficacy during a 12-wk regimen was low with SVR rates between 30% to 56%<sup>[10,17]</sup>. However, a significant increase in SVR-rates up to 85% could be achieved by extending the treatment duration to 24 wk in patients with genotype 3. Existence of cirrhosis was associated with poorer SVR-rates in genotype 3 patients (SVR 68% with cirrhosis and pre-treatment with P/R vs SVR 91% without cirrhosis)<sup>[19]</sup>. Smaller studies treating genotype 4 patients for 12 and 24 wk, respectively, have shown SVR-rates in therapy-naïve patients of 79% and 100%, respectively, and in pretreated patients 59% and 87%, respectively<sup>[20]</sup>.

### SOF + SMV ± R

The COSMOS-study, a phase II trial, analyzed the efficacy of SOF + SMV with and without R in patients with HCV genotype 1. This study consisted of two cohorts of which the first represented patients with null-response to P/R but without advanced fibrosis or

cirrhosis. The second cohort included patients with advanced fibrosis (F3) or cirrhosis. Patients were treated for 12 or 24 wk with and without R. In the first cohort a cumulative SVR of 90% was observed, while in the second cohort an even higher SVR of 94% could be achieved. Neither the extension to a 24-wk treatment nor the addition of R were of any advantage in this study<sup>[12]</sup>.

These results could be confirmed by two big observational-studies. The TRIO-trial was able to demonstrate a higher SVR in genotype 1b, compared to 1a (92% vs 80%)<sup>[21]</sup>. The TARGET-study with 883 genotype 1 patients (54% cirrhosis) treated with SOF + SMV ± R presented in an interim analysis a SVR4-rate of 93% in 98 patients without cirrhosis and in patients a SVR4 of 85% in 124 cirrhotics<sup>[22]</sup>.

Meanwhile results of two phase-III study entitled OPTIMIST 1 and 2 have been presented. In the OPTIMIST 1-study 310 naïve or pretreated genotype 1 patients without cirrhosis were treated with SOF + SMV for 8 or 12 wk. Patients treated for 12 wk achieved SVR-rates of 97% and those treated only for 8 wk 83%<sup>[23]</sup>. The OPTIMIST 2-study investigated 103 naïve or pretreated genotype 1 patients with cirrhosis being treated for 12 wk with SOF + SMV resulting in a SVR of 83%<sup>[24]</sup>.

### SOF + DCV ± R

The combination of SOF + DCV was investigated in treatment-naïve patients with genotypes 1, 2 and 3 without cirrhosis and in genotype 1-patients with treatment-failure of a protease-inhibitor based therapy. The treatment response in GT1 was investigated in different groups in a phase II -study. The results showed high SVR-rates between 93%-100% regardless of treatment duration and addition of R. In pretreated genotype 1 patients only 24 wk of therapy were evaluated with or without R. This regimen resulted in SVR-rates of 95%-100%. The ALLY-1 study investigated SOF + DCV + R for 12 wk in patients with cirrhosis (*n* = 60) or after orthotopic liver-transplantation (OLT) (*n* = 53). For genotype 1, patients with cirrhosis achieved a SVR rate of 82%, whereas the SVR rate after OLT was even higher with 95%<sup>[25]</sup>.

Initially only a 24-wk treatment was evaluated in genotype 2 and 3 patients. This lead to SVR rates of 92% in genotype 2 and 89% in genotype 3 patients<sup>[26]</sup>. In the ALLY-3 study genotype 3 patients were treated with SOF + DCV for 12 wk without R. Patients without cirrhosis achieved independent of pretreatment high SVR-rates of 97% in naïve and 94% in pretreated patients. In case of cirrhosis SVR rates were lower with only 58% to 69%<sup>[27]</sup>. The combination of SOF and DCV has an antiviral effectiveness in genotype 4 but results of studies are lacking.

### SOF + LDV ± R

For this fixe dose combination profound phase 3 study data exists. Studies were performed on 1.952 patients

**Table 2 Overview on clinical studies using the NSSB inhibitor sofosbuvir**

Study	Patient population	Therapy	Duration (wk)	SVR	Comments
ION-1	First-line therapy	SOF + LDV	12	99%	
		SOF + LDV + R	12	97%	
		SOF + LDV	24	98%	
		SOF + LDV + R	24	99%	
ION-2	Re-therapy	SOF + LDV	12	94%	86% cirrhotic
		SOF + LDV + R	12	96%	82% cirrhotic
		SOF + LDV	24	99%	100% cirrhotic
		SOF + LDV + R	24	99%	86% cirrhotic
ION-3	First-line therapy	SOF + LDV	8	94%	Only non-cirrhotic
		SOF + LDV + R	8	93%	Only non-cirrhotic
		SOF + LDV	12	95%	Only non-cirrhotic

SOF: Sofosbuvir; LDV: Ledipasvir; R: Ribavirin; SVR: Sustained virological response.

**Table 3 Overview on clinical studies using the combination of paritaprevir/ritonavir + ombitasvir ± dasabuvir**

Study	Patient population	Therapy	Duration (wk)	SVR	Comments
SAPPHIRE- I	First-line therapy	OBV + PTV/r + DSV + R	12	96%	No cirrhosis
SAPPHIRE- II	Re-therapy	OBV + PTV/r + DSV + R	12	96%	No cirrhosis
TURQUOISE- II	Cirrhosis	OBV + PTV/r + DSV + R	12	92%	GT1a 89%
					GT1b 99%
		OBV + PTV/r + DSV + R	24	96%	GT1a 95%
PEARL- II	Re-therapy, GT1b	OBV + PTV/r + DSV	12	100%	No cirrhosis
		OBV + PTV/r + DSV + R	12	97%	No cirrhosis
PEARL- III	First-line therapy, GT1b	OBV + PTV/r + DSV	12	99%	No cirrhosis
		OBV + PTV/r + DSV + R	12	99%	No cirrhosis
PEARL- IV	First-line therapy, GT1a	OBV + PTV/r + DSV	12	90%	No cirrhosis
		OBV + PTV/r + DSV + R	12	97%	No cirrhosis

OBV: Ombitasvir; PTV: Paritaprevir; DSV: Dasabuvir; R: Ribavirin; r: Ritonavir; SVR: Sustained virological response.

with genotype 1. The detailed results of the ION-studies are shown in Table 2. In all treatment-groups high rates of SVR were observed. In treatment-naïve patients there was neither advantage of treatment for more than 12 wk nor addition of R even in cirrhotic patients<sup>[28]</sup>. In contrast, pretreated patients with cirrhosis achieved higher SVR-rates after treatment for 24 wk. In these patients high SVR-rates could also be achieved by adding R to a 12 wk antiviral treatment<sup>[15]</sup>.

Treatment-naïve genotype 1-patients without cirrhosis achieved a SVR of 94% after only 8 wk of treatment. The higher number of relapses in this cohort were patients with a viral load above  $6 \times 10^6$  IU/mL<sup>[29]</sup>.

For genotypes 3 and 6 data from a small study showed also a high antiviral effectiveness for SOF/LDV + R. Genotype 3 treatment-naïve patients with cirrhosis achieved 100% SVR, pretreated patients with cirrhosis 89% SVR. Without addition of R only 64% of the treatment-naïve cirrhotic patients achieved SVR<sup>[30,31]</sup>. In genotype 6 SOF/LDV without R resulted in SVR-rates of 96%<sup>[31]</sup>.

### OBV + PTV/r ± DSV ± R (3D)

The 3D-regimen achieved high SVR-rates in several phase III-studies with a total of 1577 genotype 1

patients. The detailed results of these studies are shown in Table 3. The 3D-regimen achieved in genotype 1 patients without cirrhosis in the SAPPHIRE-study high SVR-rates of 96% regardless of a prior therapy<sup>[32,33]</sup>.

Due to a weaker antiviral activity of 3D in genotype 1a the PEARL-studies (which did not include cirrhotic patients) were performed separately for both subtypes. The treatment-regimes differed regarding the addition of R. In genotype 1b nearly all patients achieved SVR without R regardless of pretreatment indicating that R can be omitted for this patient population<sup>[16,34]</sup>. In contrast, genotype 1a patients exhibited higher SVR rates by addition of R compared to those being treated without R (97% vs 90%)<sup>[16]</sup>.

Genotype 1 patients with cirrhosis were investigated in the TURQUOISE- II -study. Here, 3D + R was admitted for 12 or 24 wk. For genotype 1a extension of treatment from 12 to 24 wk resulted in higher SVR-rates (89% vs 95%), whereas for genotype 1b nearly all patients were cured by a 12-wk treatment<sup>[35]</sup>.

In genotype 4 DSV was omitted due to lack of antiviral activity. Therefore, a combination of OBV + PTV/r with and without R was tested for 12 wk in the PEARL-I-study. Addition of R resulted in a SVR rate of 100%, whereas without R only 91% of patients

achieved SVR<sup>[36]</sup>.

Current treatment recommendations have been published in the AASLD and EASL guidelines. These take into account the specific conditions in different countries in terms of availability of DAAs<sup>[2,37]</sup>.

So far there are currently sufficient IFN-free DAA-regimes with excellent SVR-rates, in particular for genotype 1 patients. Unresolved issues represent patients with relapse after DAA-regimen as they exhibit RAVs and cirrhotic patients with genotype 3 as SVR rates remain unsatisfactory for this population. Current antiviral studies address these challenges and in the near future we expect efficient regimens for the remaining difficult to treat HCV patients.

## DIFFICULT TO TREAT POPULATIONS

### Cirrhotic patients

Liver cirrhosis is the most important negative predictor of SVR in DAA therapies. In nearly all regimens treatment efficacy is lower compared to non-cirrhotic patients. In pivotal studies on cirrhotic patients for the 3D-regime and SOF/LDV SVR could be increased by treatment extension to 24 wk and addition of ribavirin. It should be noted that only compensated patients with Child Pugh stage A were included in these studies. Recently, in a prospective study 108 patients with decompensated cirrhosis with Child Pugh stage B and C were treated with SOF/LDV + R for 12 or 24 wk. SVR was achieved in 87% of patients with Child Pugh B and 89% with Child Pugh C indicating that this therapy regimen is safe and effective even in decompensated liver cirrhosis. Of note, an improvement of liver function was observed during and after therapy<sup>[38]</sup>.

### Liver transplantation

After liver transplantation of patients with chronic HCV infections a reinfection is common. Due to immuno-suppression an accelerated progression of fibrosis in the transplant is often observed. Pre-treatment with SOF + R before transplantation in 61 patients with HCC within Milan criteria and compensated HCV-induced cirrhosis prevented a reinfection of the graft in 70%<sup>[39]</sup>. After liver transplantation a different study using the 3D-regime + R resulted in a SVR of 97% (33 out of 34 patients)<sup>[40]</sup>. Using SOF/LDV + R for 12 or 24 wk in 223 patients after liver transplantation similar high SVR rates could be achieved in patients without cirrhosis (96%-98%) or Child Pugh A cirrhosis (96%). However, in case of decompensated cirrhosis SVR rates were lower (Child Pugh B: 83%-85%, Child Pugh C: 60%-67%)<sup>[41]</sup>.

### Human immunodeficiency virus-HCV co-infection

Human immunodeficiency virus (HIV)-HCV co-infections result in a faster progression of fibrosis compared to mono-infections. In a variety of studies with similar designs comparable treatment responses were found. Thus, HIV-HCV co-infected patients can be treated equal to mono-infected patients. To give an example

the combination-therapy with SOF/LDV achieved SVR-rate of 98% in GT1 first line therapy<sup>[42]</sup>. It should be noted that possible drug-drug interactions between HCV regimes and antiretroviral substances may occur.

### Renal impairment

Due to its renal elimination SOF may only be given to patients with a glomerular filtration rate above 30 mL/min per 1.73 m<sup>2</sup>. Patients with severe renal impairment (glomerular filtration rate < 30 mL/min per 1.73 m<sup>2</sup>) or chronic renal failure undergoing dialysis therefore require other antiviral regimens.

Pharmacokinetic data showed the possibility of using OBV + PTV/r + DSV ± R (3D) in patients with severe renal impairment and chronic renal failure. Serum levels of the 3D substances were comparable to HCV-patients without renal impairment. SVR12 data are outstanding but all finished patients (10 out of 20) presented SVR4<sup>[43]</sup>.

Another placebo-controlled study with Grazoprevir (100 mg) plus Elbasvir (50 mg) for 12 wk in 122 HCV GT 1 patients with renal impairment (75% under dialysis) presented SVR12 rates of 94%, representing a potential future treatment regimen in this difficult to treat patient population<sup>[44]</sup>.

## FUTURE HCV TREATMENT OPTIONS

Future developments consist of second generation DAAs. The protease inhibitors of the second generation will exhibit a better resistance barrier and broader spectrum of activity against various genotypes of HCV, in particular subtype 1a (e.g., Grazoprevir, Sovaprevir) and pan-genotypic (e.g., ABT-493, GS-9857). Moreover, these substances do not have complete cross-resistances against associated RAVs against first-generation protease inhibitors (e.g., ABT-493)<sup>[45]</sup>.

The second generation NS5A-inhibitors will have higher resistance barriers, higher antiviral effects and a pan-genotypic spectrum (e.g., Elbasvir, Samatasvir, GS-5816, MK-8408, ABT-530). ABT-530 presented *in vitro* high antiviral effectiveness against frequent NS5A-RAVs<sup>[45]</sup>. Furthermore, novel drugs will be used as combination-regimes. Combinations of these protease inhibitors and NS5A-inhibitors could achieve similar SVR-rates than previous regimes based on nucleotide NS5B-polymerase inhibitors (NUC). It is likely that shorter treatment durations may be achieved using these regimens. A recently presented study using Grazoprevir/Elbasvir + SOF (C-SWIFT) in treatment-naïve genotype 1 and 3 patients with and without cirrhosis investigated the antiviral effectiveness in terms of treatment duration. In genotype 1 non-cirrhotic patients achieved SVR in only 33% after 4 wk of treatment. In contrast, an SVR-rate of 87% was achieved after 6 wk of treatment. Cirrhotic patients with HCV-genotype 1 achieved SVR in 80% after 6 wk and SVR in 94% after 8 wk of treatment. In genotype 3 non-cirrhotic patients were treated for 8 and 12 wk resulting in SVR-rates of 93% and 100%.

**Table 4 Overview on clinical studies using future antiviral drugs and combinations**

Substances (study)	RBV	Genotype	Population	Duration (wk)	Phase	Results (SVR)
SOF + GS-5816 (NS5A) <sup>[47]</sup>	±	1	TN, NCi	8	II	81% - R; 90% + R; (n = 60)
	±	2	TN, NCi	8	II	88% - R; 88% + R; (n = 52)
	±	3	TN, NCi	8	II	96% - R; 100% + R; (n = 53)
	±	1	TE, Ci, NCi	12	II	NCi: 100% (n = 38); Ci: 100% - R, 90% + R (n = 17)
	±	3	TE, Ci, NCi	12	II	NCi: 100% (n = 53); Ci: 88% - R, 96% + R (n = 52)

SOF + Grazoprevir + Elbasvir (C-SWIFT) <sup>[46]</sup>	-	1, 3	TN, NCi	4 or 6 (GT1)	II	SVR8: GT1: 39% after 4 wk (n = 31); 87% after 6 wk (n = 30)
				8 or 12 (GT3)		GT3: 100% after 8 and 12 wk (n = 15/14)
			TN, Ci	6 or 8 (GT1)	II	SVR8: GT1: 80% after 6 wk (n = 20); 89% after 8 wk (n = 21)
				12 (GT3)		GT3: 90% (n = 12)
Grazoprevir + Elbasvir (C-WORTHY) <sup>[50]</sup>	±	1	TN, NCi	8 or 12	II	8 wk GT1a: 80%
						12 wk: 98% - R; 93% + R
			TN, Ci	12 or 18	II	12 wk: 97% - R; 90% + R
						18 wk: 94% - R; 97% + R
			TE, Ci, NCi	12 or 18	II	12 wk: 91% - R; 94% + R
						18 wk: 97% - R; 100% + R
SMV + Samatasvir (HELIX-1) <sup>[51]</sup>	+	1b, 4	TN, NCi	12	II	SVR4: GT1b: 80% (n = 84)
						GT4: 100% (n = 9)
Asunaprevir + DCV + Beclabuvir (UNITY 1) <sup>[52]</sup>	-	1	TN, TE, NCi	12	III	TN: 91%; TE: 89%
Asunaprevir + DCV + Beclabuvir (UNITY 2) <sup>[53]</sup>	±	1	TN, TE, Ci	12	III	90% - R; 96% + R

TN: Therapy-naïve; TE: Therapy-experienced; Ci: Cirrhosis; NCi: No cirrhosis; GT: Hepatitis C virus-genotype; SOF: Sofosbuvir; LDV: Ledipasvir; R: Ribavirin; SVR: Sustained virological response; SMV: Simeprevir; DCV: Daclatasvir.

Cirrhotic genotype 3 patients being treated only for 12 wk achieved a SVR-rate of 91%<sup>[46]</sup>. These future substances will enable a shortened treatment time and increase the antiviral activity in individual populations. A selection of future therapies and their phase II - III trial results are presented in Table 4<sup>[46-53]</sup>.

As of mid 2016, the 2<sup>nd</sup> generations DAAs are expected to be available. These therapy regimes will have pan-genotypic and high antiviral effectiveness as well as a better resistance profile. It is likely that R will become dispensable and treatment duration may be reduced to 6-8 wk for the majority of patients. In addition, difficult to treat populations (e.g., genotype 3 with cirrhosis) may achieve higher rates of SVR.

However, in order to significantly lower HCV-induced morbidity and mortality, a higher proportion of infected patients would have to be treated. This will only be possible by an increased screening of risk populations and customized pricing.

### Abstract

Immunosuppression in organ transplantation was revolutionary for its time, but technological and population changes cast new light on its use. First, metabolic syndrome (MS) is increasing as a public health issue, concomitantly increasing as an issue for post-orthotopic liver transplantation patients; yet the medications regularly used for immunosuppression contribute to dysfunctional metabolism. Current mainstay immunosuppression involves the use of calcineurin inhibitors; these are potent, but nonspecifically disrupt intracellular signaling in such a way as to exacerbate the impact of MS on the liver. Second, the impacts of acute cellular rejection and malignancy are reviewed in terms of their severity and possible interactions with immunosuppressive medications. Finally, immunosuppressive agents must be considered in terms of new developments in hepatitis C virus treatment, which undercut what used to be inevitable viral recurrence. Overall, while traditional immunosuppressive agents remain the most used, the specific side-effect profiles of all immunosuppressants must be weighed in light of the individual patient.

**Key words:** Immunosuppression; Orthotopic liver transplantation; Metabolic syndrome; Acute cellular rejection; Hepatitis C virus

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The use of immunosuppressive agents is reviewed in the context of the modern post-orthotopic liver transplantation population. The side effects of mainstay immunosuppressive strategies exacerbate some patient pathologies, and combinations of different immunosuppressants could be more specifically tailored to patient needs. Acute cellular rejection and malignant complications are also discussed with respect to im-

munosuppressive strategies. Finally, hepatitis C virus and its impact on immunosuppression is re-evaluated in light of recent developments in viral clearance.

## INTRODUCTION

The use of immunosuppression in organ transplantation was revolutionary for its time, and its results were quickly embraced for their efficacy at suppressing host rejection of a graft.

However, given the increasing impact of metabolic syndrome (MS) as a public health issue<sup>[1]</sup>, immunosuppression and its side effects may pose a greater risk to patients than rejection of a newly-transplanted organ. In fact, metabolic complications of immunosuppressive therapy were at one point the leading cause of morbidity and mortality for patients following orthotopic liver transplantation (OLT)<sup>[2]</sup>. Reduction of immunosuppression is a widely-recognized strategy to addressing this issue<sup>[3]</sup>.

Cardiovascular disease (CVD) and renal disease account for 19.3% and 6.8% of nonhepatic causes of death in post-OLT patients, respectively<sup>[4]</sup>. In patients who survive at least 3 years, non-hepatic cause of death accounts for 58% of all-cause mortality post-OLT<sup>[5]</sup>. In their evaluation of liver transplantation as a cardiovascular risk factor, Madhwal *et al*<sup>[6]</sup> (2012) found that up to two-thirds of patients develop MS after OLT. Clearly, the trend towards post-transplant metabolic disturbances must be addressed; the first place to start is optimizing post-transplant immunosuppressive therapies<sup>[7]</sup>.

Further, with recent advances in the treatment of hepatitis C virus (HCV)<sup>[8,9]</sup>, long-term metabolic complications posed by immunosuppression must be weighed more heavily against the immediate issue of organ rejection. Just as the introduction of immunosuppression made longer-term complications a new focus in transplantation, eradication of this chronic liver infection leaves room to focus on metabolic issues.

## BRIEF OVERVIEW OF LIVER IMMUNOLOGY: THE LIVER IS IMMUNOPRIVILEGED

From a physiological standpoint, the liver is one of the first organs exposed to the absorbed contents of the external environment. Handling of newly-acquired blood content immediately after absorption from the external environment necessitates that the liver maintain its own unique balance of immunity vs tolerance. The

special status of the liver as immunoprivileged is well-recognized; for example, there is a paucity of hepatic B- and T-cell mediated autoimmune disease, and some autoimmune hepatitis liver markers are found in healthy and ill people alike<sup>[10]</sup>. Further, transplant tolerance is known to occur at greater frequency for liver transplant recipients, compared to other vascularized organ recipients<sup>[11]</sup>. At the same time, there remains much to be learned about liver immunology. For example, the role of humoral alloreactivity in ABO-compatible liver transplantation is still being elucidated<sup>[12-14]</sup>.

The liver is rich with parenchymal hepatocytes, but also contains non-parenchymal immune cells that serve as a first barrier to antigens arriving from portal circulation. Hepatic nonparenchymal cells include the largest population of fixed resident macrophages in the body, Kupffer cells, as well as other reticuloendothelial cells<sup>[15]</sup>. The parenchymal hepatocytes further contribute to immunity by secreting 80%-90% of complement components and pathogen-recognition receptors (PRR), as well as synthesizing membrane-bound PRRs to catch portal antigens<sup>[16]</sup>.

Along with antigens arriving from portal circulation, about 10<sup>8</sup> peripheral blood lymphocytes pass through the liver every 24 h<sup>[17]</sup>. These cells are squeezed through fenestrated capillaries that may open a window to T-cell priming<sup>[18]</sup>. The status of the liver as a major reservoir of immune cells has major implications, then, both as far as catching portal circulation antigens as well as immunomodulation.

For example, the privileged status of the liver might be used in the future to induce complete graft tolerance. As a promising example, animal models have shown a lifetime tolerance to liver grafts: In 20% of outbred pig liver recipients, lifetime tolerance can be achieved without the use of immunosuppressants<sup>[19]</sup>. The possibility of lifetime tolerance in humans, too, remains optimistic. Ramos *et al*<sup>[20]</sup> (1995) review their experience withdrawing immunosuppressive therapy after witnessing patient noncompliance with immunosuppression. They were able to accomplish immunosuppression-free tolerance in 16 patients for 3 to 19 mo, continuing efforts to completely wean 28 patients, but failed in 15 patients without any graft loss or demonstrable loss of function due to rejection.

Not only is the liver self-protective, but there is evidence of immunocompetence conferred to other organs: Simpson *et al*<sup>[21]</sup> (2006) showed that patients who receive combined same-donor liver and kidney transplants are immunoprotected compared to patients who receive kidney transplant after liver transplant. The authors speculate that the identical genotypes of the transplanted organs facilitates immunoprotective effects. There is, however, conflicting data: Katznelson *et al*<sup>[22]</sup> (1996), comparing incidence of acute rejection between 248 combined liver and kidney transplantations to a control group of 206 kidney-alone transplantations, found that 3-year survival rates are not significantly different.

Despite a key role in immunoregulation generally, human leukocyte antigen (HLA) histocompatibility has little clinical significance to liver allograft outcome<sup>[23,24]</sup>. On the other hand, HLA compatibility may play a more subtle role in OLT than we see clinically, where immuno-suppressive regimens may paint broad enough strokes to obfuscate nuances. Neumann *et al.*<sup>[25]</sup> (2003) report that HLA compatibility is associated with significantly less acute rejection, but no difference in graft survival. This peculiar behavior of the liver compared to other organs may further reflect the possibility that acute rejection is not as harmful to OLT as previously thought. A better understanding of the mechanisms of liver immunology is necessary to identify how to maximize the utility of histocompatibility<sup>[26]</sup>.

## IMMUNOSUPPRESSANT AGENT OVERVIEW

There are three signal pathways targeted by immuno-suppressive agents. The first is calcineurin-mediated nuclear factor of activated T-cells activation *via* the T-cell receptor (TCR) and CD3 meeting an antigen presented on an major histocompatibility complex (MHC) protein; the second is a B7/CD28 costimulatory signal required for TCR-MHC complex synapsing; and the third signal is mediated by interleukin 2 (IL-2) as a ligand to CD25, through adaptor proteins JAK3 and PI-3K to mechanistic target of rapamycin (mTOR) regulation of cyclin-dependent kinases and cyclins to control the cell cycle<sup>[27]</sup>.

Figure 1 depicts the process of an antigen-presenting cell (APC) travelling to a lymphoid organ, where it meets T cells in the paracortex. A native T-cell interacts with the APC, and if a set of several interactions and conditions are met, then the native T-cell replicates many times. This is called T-cell activation, and T-cell clonal expansion, and creates numerous effector T-cells that are specific to the antigen originally presented by the APC. These effector T-cells proceed to leave the lymph nodes and head back to the liver, where they can detect antigen and effect an immune response.

Many current immunosuppressive drugs target either those extracellular interactions or the intracellular signals that are highlighted in Figure 1. Calcineurin inhibitors (CNIs) prevent T-cell activation *via* an intracellular pathway, for example; on the other hand, the anti-IL-2 receptor antibodies basiliximab and daclizumab prevent IL-2 receptor activation<sup>[28]</sup>.

Immunosuppressant drugs can function as depleting agents, or as non-depleting agents. Depleting immuno-suppressive therapies cause destruction of T cells and/or B cells<sup>[27]</sup>, whereas non-depleting agents affect the immune system by preventing immune cell proliferation.

CNIs have been the mainstay of immunosuppression since they were discovered, and increased 1-year patient and graft survival to greater than 80%<sup>[29,30]</sup>. CNIs serve to prevent transcription of the autocrine factor IL-2, preventing cell proliferation. These drugs halt the phosphatase activity of calcineurin, which is an

intracellular signal transduction protein that mediates response to antigenic peptides. CNIs include cyclosporin A (CsA) and tacrolimus (TAC). There is no direct reduction in T or B cell count, so these agents are considered non-depleting.

Second, there is the non-depleting immunosuppressant, mycophenolate mofetil (MMF). MMF is a prodrug of mycophenolic acid (MPA), which inhibits inosine monophosphate dehydrogenase (IMPDH). Because IMPDH catalyzes the rate-limiting step of *de novo* guanosine synthesis, both genetic replication and transcription are inhibited. Further, MPA is five times more effective at inhibiting the type II isoform of IMPDH - the isoform expressed in activated lymphocytes<sup>[31]</sup>. Because it is specific to the lymphocyte isoform of IMPDH, MPA prevents lymphocyte proliferation and transcription of activation-associated genes. As far as small molecules go, MMF is one of the more specific immunosuppressant agents. Side effects of MMF include nonimmune issues such as diarrhea and anemia<sup>[27]</sup>, but, more importantly, exacerbation of cytomegalovirus infection<sup>[32]</sup>.

Finally, the third major class of immunosuppressive drugs are called mTOR inhibitors. Found in soil from an Easter Island bacteria called *Streptomyces Hygroscopicus*, this class blocks IL-2-mediated autocrine leukocyte proliferation *via* inhibition of an intracellular signal transduction mechanism - thus, mTOR inhibitors are considered non-depleting agents<sup>[33,34]</sup>. Everolimus (EVR) and sirolimus (SIR) are the two best-known mTOR inhibitors.

Besides their use as immunosuppressants, another interesting property of mTOR inhibitors is their effect on longevity and age-related diseases. It is well-established that one way to increase longevity is through dietary restriction, and this effect is partially mediated by the mTOR pathway. Inhibition of mTORC1 has been associated with protection against neurodegenerative disease, heart disease, metabolic diseases, and a host of other age-related diseases<sup>[35]</sup>. Rapamycin administration, specifically, has repeatedly been shown to increase both mean and median lifespan in genetically heterogenous mice<sup>[36]</sup>.

Immunosuppressive steroids such as methylprednisone are considered essential to graft tolerance induction, yet their use is highly associated with metabolic complications<sup>[37]</sup>. Several studies have examined outcomes of steroid-free or reduced-steroid immunosuppressive maintenance regimens<sup>[38,39]</sup>. In a prospective, randomized, placebo-controlled, double-blinded study, Lerut *et al.*<sup>[40]</sup> (2014) report that in a cohort of 156 patients, patients treated with minimal or steroid-free immunosuppression displayed excellent outcomes over a period of 5 years. They report 5-year biopsy results, finding that histology presents similarly across both groups. In support of steroid withdrawal, other prospective studies of prednisone withdrawal post-OLT have demonstrated no difference in 2-year and 1-year survival of patients treated with or without

**Figure 1 Signaling pathways targeted by modern immunosuppressive agents.** Starting from the top left, an antigen-presenting cell (APC) migrates from local tissue to lymphoid organs. In the paracortex of the lymphoid organ, the APC meets a naive T-cell. If the naive T-cell has a T-cell receptor (TCR) that binds the antigen as it is presented by a Major Histocompatibility Complex on the APC, a set of other T-cell-APC interactions are likely to follow. This includes T-cell CD4 binding to the MHC on an APC, as well as costimulatory signals via extracellular receptors CD28 or CD40. After this set of T-cell-APC interactions begins, a set of intracellular signals follow towards the nucleus of the T-cell. The naive T-cell is then activated, and begins to replicate. This replication is called clonal expansion, and produces a population of T-cells that eventually migrate back to the tissue that contains antigen. AP-1: Activator protein 1; CD: Cluster of differentiation; CDK: Cyclin-dependent kinase; IKK: Inhibitor of kappa-B kinase; IL: Interleukin; Jak3: Janus-associated kinase 3; PI3K: Phosphatidylinositol 3-kinase; MAPK: Mitogen-activated protein kinase; mTOR: Mechanistic target of rapamycin; NFAT: Nuclear factor of activated T-cells; NF- $\kappa$ B: Nuclear factor kappa-light-chain-enhancer of activated B cells; TCR: T-cell receptor; MHC: Major histocompatibility complex.

prednisone<sup>[41,42]</sup>. Today, the use of steroids is generally limited to tolerance induction and treatment of acute cellular rejection (ACR); many studies have further investigated the possibility of steroid-free transplantation<sup>[43-45]</sup>.

Depleting immunosuppressant agents are mostly antibody-based. The first monoclonal antibody to be approved for use in humans was OKT3, an anti-CD3 antibody that modulates T-cell activation<sup>[46,47]</sup>. There are currently a host of biologics directed against T-cell proliferation, these are specific enough that their metabolic impact is significantly less than that of CNIs<sup>[48,49]</sup>.

Issues associated with biological immunosuppression are unlike those of smaller molecules because they act extracellularly and are specific to their antigen<sup>[50]</sup>, in

contrast to small molecules such as tacrolimus that affect intracellular processes across a wider variety of cells. For example, one OKT3 side effect is called cytokine release syndrome, where widespread T-cell activation outweighs the antibody-mediated T-cell destruction that follows it<sup>[51]</sup>. This complication can become more severe if it leads to a positive-feedback loop, potentially causing a "cytokine storm"<sup>[52]</sup>.

Besides OKT3, biologic agents have shown varying degrees of success and outcomes. For example, basiliximab is an IL-2 receptor antagonist that reduces rates of ACR at the expense of increased disease progression in HCV liver transplant patients<sup>[53]</sup>. Basiliximab, though, has been found to successfully treat graft-vs-host disease<sup>[54]</sup>. For those patients with

metabolic dysfunction, avoidance of steroid immunosuppression may be enough of a concern to warrant use of basiliximab.

Another biologic used to treat multiple sclerosis and Crohn's disease, natalizumab, is associated with significant liver injury as a side effect<sup>[55]</sup>. While the medical field is ripe for biologic development, implementation of biologics requires close evaluation.

On the other hand, some biologics open doors that might otherwise stay shut. Rituximab is an anti-CD20 monoclonal antibody that has been successfully used as immunological prophylaxis for ABO-incompatible (ABOi) liver transplantation<sup>[56]</sup>. Further, Yoshizawa *et al.*<sup>[57]</sup> (2005) report that ABOi living-donor liver transplantation is possible without humoral rejection. Their protocol involves hepatic artery infusion and prophylactic use of rituximab, but, unlike previous attempts, does not involve splenectomy. Tanabe *et al.*<sup>[58]</sup> (2010) later explain that ABOi has progressed to the point that it is as effective as ABO compatible transplantation, in part due to rituximab prophylaxis. Perfection of ABOi OLT will hopefully lead to other organ allocation advancements, such as humanized livers grown in non-human primates<sup>[59]</sup>. Immunosuppression in this context may become a hot topic in coming years.

## ACR: DIAGNOSIS AND TREATMENT

ACR is most likely to occur within the first 6 wk of transplant, and is a very common event; in a study of 762 patients, the incidence of ACR post-transplantation is 64%. Several factors are associated with the occurrence of ACR, such as cold ischemic time of the organ, lower age of recipient, presence of edema, and HLA-DR mismatch<sup>[2]</sup>.

There are three distinguishing features of ACR, each visible on histological examination. The first feature is portal triad inflammation, indicated by mixed inflammatory infiltrate; the second feature is damage to the bile ducts, specifically nonsuppurative cholangitis involving interlobular ductal epithelia; third, venous endotheliitis<sup>[60]</sup>. Venous endotheliitis is the most reliable diagnostic sign of ACR, but it is worth noting that phasic increase and decrease in lymphocyte aggregation may affect biopsy results<sup>[2]</sup>.

In the clinic, ACR is suspected upon elevated liver function tests preceding jaundice and fever. Unfortunately, blood tests are neither sensitive nor specific for ACR diagnosis<sup>[61,62]</sup>. It follows, then, that liver biopsy is the gold standard of liver tissue evaluation<sup>[63]</sup>. To provide a level of standardization to biopsy evaluation, the Banff rejection activity index (RAI) assigns a score between zero and three to each characteristic of ACR<sup>[64]</sup>.

Treatment for ACR includes high-dose steroids, optionally tapering off steroids and/or using biological immunosuppression<sup>[65]</sup>. Response to steroids is favorable; however, incidence of steroid-resistant rejection has been found to reach up to 14%<sup>[66]</sup>.

## ACR MORBIDITY AND MORTALITY

Timing of rejection is of major clinical significance in evaluating the potential impact of ACR<sup>[67,68]</sup>. While different studies have used different definitions, one commonly accepted cutoff defines early and late ACR as occurring within and after 90 d of transplantation, respectively. Several studies have found that early ACR is common and of lesser significance than late ACR<sup>[69]</sup>. For example, in a retrospective review of 231 histologically-confirmed cases of early ACR, Höroldt *et al.*<sup>[64]</sup> (2006) report that neither total RAI score nor any of its components were correlated to steroid treatment response or graft survival. Indeed, Thurairajah *et al.*<sup>[70]</sup> (2013), in a retrospective review of 970 patients, confirms that early acute rejection cases yield the best 10-year graft survival rates, at 85%.

In contrast to the minimal impact of early ACR, it appears that late ACR is associated with decreased graft survival. Uemura *et al.*<sup>[69]</sup> (2008) found that of 1604 patients, 19.0% developed ACR later than 6 mo after the transplant; the only predictor of late ACR here was post-transplant lymphoproliferative disease. Thurairajah *et al.*<sup>[70]</sup> (2013) found that 11% of patients developed late ACR, and that the highest rates of late ACR were found in patients with seronegative hepatitis, primary biliary sclerosis, and primary sclerosing cholangitis. Other studies have found that post-transplant lymphoproliferative disorder, decreased age, and increased medication level variability index are associated with and can predict late ACR<sup>[71]</sup>.

Epidemiological evaluation of ACR is masked by its frequently subclinical character. Bartlett *et al.*<sup>[72]</sup> (2002) explain that in a retrospective review examining 15 studies with a total of 1566 patients, 32% of standard protocol post-OLT biopsy samples showed evidence of ACR without any biochemical dysfunction. Since ACR is defined according to biopsy but not serum biomarkers, incidence of ACR may be higher than previously accepted. Another study, Tisone *et al.*<sup>[42]</sup> (1999), explains that 80% of acute rejection episodes in their 45-patient cohort resolved spontaneously. The chances of clinically significant acute rejection, then, must be balanced against the risks of liver biopsy. In the future, metabolomic and other noninvasive studies could shed significant light on incidence of ACR<sup>[73-75]</sup>.

Reduction of immunosuppression in light of ACR is not a new subject: Volpin *et al.*<sup>[76]</sup> (2002), in a controlled study, evaluated two methylprednisolone regimens in the treatment of acute cellular rejection. They find that a 6-d taper regimen is safer than the higher-dose standard because ACR impact on graft rejection is minor, and the toxic effects of methylprednisolone outweigh the potential benefit of ACR suppression. Goddard *et al.*<sup>[77]</sup> (2002) reviewed the Volpin study, concluding that immunosuppression therapies should be tailored to the individual patient after careful consideration of the interaction between past medical history and

immunosuppression side effects.

More recently, Rodríguez-Perálvarez *et al.*<sup>[78]</sup> (2013) report that standard TAC trough concentrations are set too high (at 10–15 ng/mL), and that target TAC levels between 7 and 10 ng/mL are associated with longer graft survival while maintaining safety against rejection.

In contrast to the safety of simply reducing TAC, a randomized prospective trial of SIR monotherapy conversion regimen efficacy<sup>[79]</sup> found that liver transplant patients have no demonstrable benefit at 12 mo. Cumulative rates of graft loss or death were not significantly different, at 6.6% for the SIR group vs 5.6% for the CNI group. However, rates of acute rejection and discontinuation due to side effects were higher for patients treated with SRL. Then, one must consider the characteristics of the individual patient when designing an immunosuppressive regimen. For patients who are at great risk of end-stage renal disease (ESRD), the risk of acute rejection that is posed by conversion to SRL may be outweighed by the nephrotoxicity associated with the use of CNIs. For patients who are more concerned about acute rejection than nephrotoxicity, it makes sense to use CNI therapy.

## MALIGNANT COMPLICATIONS POST-OLT

Recurrent and *de novo* malignancies are the top nonhepatic causes of late death in liver transplant patients, often listed alongside CVD. Some of the increased incidence in *de novo* malignancies in liver transplant recipients compared to the general population can be attributed to the use of exogenous immunosuppression<sup>[80,81]</sup>.

The greatest incidence of post-transplant malignancies is associated with chronic viral infection. Specifically, Epstein-Barr virus-associated post-transplant lymphoproliferative disease, skin cancers, squamous cell carcinoma, and Kaposi's sarcoma are associated with status post-OLT<sup>[82]</sup>. Baccarani *et al.*<sup>[82]</sup> (2009) find that 42 (12.8%) of patients undergoing OLT, out of 330, developed *de novo* cancers. Further, these patients had a lower 10-year survival rate than those who did not develop *de novo* cancer.

In hopes of reducing malignancy, current immunosuppression strategies focus on minimizing TAC with optional use of mTOR inhibitors or MMF. mTOR inhibitors are known for their antineoplastic activity<sup>[83]</sup>, and CNI use can be associated with increased development of malignancy<sup>[84]</sup>, making CNI reduction and replacement with mTOR inhibitors particularly favorable for patients at risk for malignancy.

## MS

MS constitutes a number of symptoms that, when occurring simultaneously, indicate a primary clinical outcome of CVD. The criteria for MS is that a patient meet three of five components: Abdominal obesity

and visceral fat, increased triglyceride (TG), decreased serum high-density lipoprotein, high blood pressure (HTN), insulin resistance and/or glucose intolerance<sup>[85]</sup>. Despite the wide range of systemic effects, each of these symptoms converges towards provoking CVD<sup>[86]</sup>.

The Framingham study<sup>[87]</sup> found that 25% of all new-onset CVD could be predicted by presence of MS. More recently, Watt *et al.*<sup>[4]</sup> (2010) report that causes of death more than 1 year after OLT have the following etiologies: 28% hepatic, 22% malignancy, 11% cardiovascular, 9% infection, and 6% renal failure. They conclude that modifiable risk factors such as diabetes, hypertension, and renal insufficiency can be used to improve long-term outcomes. Table 1 describes some of the interplay between MS components and immunosuppression. Because immunosuppressive strategies can sometimes be altered, relative risks and benefits should be weighed on a case-by-case basis.

### Obesity: The boss of MS

Abdominal obesity is a prevalent characteristic of MS, and adipocyte dysfunction is hypothesized to underlie many metabolic disorders. Some explanations of adipocyte metabolism focus on the location of fat as a determinant of metabolic properties, such that visceral or abdominal fat might contribute more to MS than subcutaneous fat<sup>[88]</sup>; other explanations emphasize immunological modulation of adipocyte metabolism<sup>[89]</sup>. Whatever the underlying cause, obesity is a major public health issue<sup>[90]</sup>, one that may be an environmental hit to a genetic predisposition.

Stegall *et al.*<sup>[91]</sup> (1995) report that the incidence of obesity for adult liver transplant recipients 1 year after transplant was 41.9% for women, and 39.3% in men. In a more recent article, Richards *et al.*<sup>[92]</sup> (2005) found that by one and 3 years after liver transplant, 24% and 31% of patients met criteria for obesity as body mass index (BMI) > 30 kg/m<sup>2</sup>.

Despite clear evidence that obesity reduces graft and patient survival<sup>[93,94]</sup>, there are studies that dispute its independent predictive power. Leonard *et al.*<sup>[95]</sup> (2008) found that in a cohort of 1313 patients, obesity does not independently correlate to risk of graft or patient survival. Perhaps a measure of obesity is not enough, and there are more specific characteristics of excess adipose tissue that lead to it being a risk factor.

Després *et al.*<sup>[96]</sup> (2006) explain that the deposition of visceral fat, as opposed to normal subcutaneous fat, can lead to adipose tissue overflow and hormonal imbalance. The net effect of these factors is an increase in ectopic fat to muscle, liver, and epicardial tissue. Compounding this issue, visceral adipocytes are less responsive to insulin, and thus not subject to the antilipolytic effects of insulin<sup>[97]</sup>.

While the anatomical location of an adipocyte may be illuminating, physiologic factors also demonstrate the heterogeneity of metabolic dysfunction: Abnormal fat can accumulate as a result of defects in nuclear receptor genes involved in lipid sensing, synthesis, and

**Table 1 Summary of immunosuppressant effects on metabolic syndrome**

	Calcineurin inhibitors	Mycophenolate mofetil	mTOR inhibitors	Steroids
Body mass	Increase <sup>[92,103]</sup>	No change <sup>[105]</sup>	Less weight gain than CNIs <sup>[37]</sup>	Increase <sup>[144,145]</sup>
Dyslipidemia	Increase <sup>[104,121]</sup>	Less than CNIs <sup>[115]</sup>	Increase, but anti-atherosclerotic <sup>[144]</sup>	Increase <sup>[145]</sup>
Hypertension	Increase <sup>[107]</sup>	Less than CNIs <sup>[115,144]</sup>	No difference from CNI <sup>[146]</sup>	Increase <sup>[145]</sup>
Insulin resistance	Increase <sup>[128]</sup>	Potential benefit <sup>[145,146]</sup>	Potential benefit <sup>[149,150]</sup>	Increase <sup>[145]</sup>
Renal damage	Increase <sup>[112,113]</sup>	Less than both CNIs and mTOR inhibitors <sup>[147,151]</sup>	Decrease compared to CNIs <sup>[152]</sup>	Not significant
Note	Neoplastic <sup>[84]</sup>	Leukopenic <sup>[147,153,154]</sup>	Antineoplastic <sup>[155]</sup>	

CNIs: Calcineurin inhibitors; mTOR: Mechanistic target of rapamycin.

oxidation<sup>[98]</sup>. Supporting the ectopic fat hypothesis, Porter *et al.*<sup>[99]</sup> (2009) report that analysis of 3000 Framingham study participants indicated that abdominal subcutaneous fat had no corresponding linear increase of obesity-associated risk factors.

Further complicating the issue is what type of lipids are most abundant in a dysfunctional metabolic state. In the context of non-alcoholic steatohepatitis/nonalcoholic fatty liver diseases, it has been suggested that hepatocyte TG accumulation may be protective against free fatty acid (FFA)-induced oxidative lipotoxicity<sup>[100]</sup>. As far as dietary fats go, there is evidence that unsaturated fats contribute to this lipotoxicity, whereas saturated fats are actually hepatoprotective<sup>[101]</sup>.

Each of these issues - lipid distribution and lipid metabolism - is a qualitative issue that is outside the measure of BMI. Then, a more specific measure of adipose metabolism is necessary to further individualize treatment options for post-OLT patients. Given the heterogeneity of adipose metabolism, some authors suggest adipocyte transplantation as a treatment for metabolic issues such as diabetes, atherosclerosis, and nonalcoholic steatohepatitis<sup>[102]</sup>.

Not only is obesity incident to the population of liver transplant recipients, it is exacerbated by the effects of immunosuppression<sup>[92]</sup>. A mainstay of immunosuppression, steroids, are well-known for effects on weight gain<sup>[103]</sup>. CNIs are also associated with weight gain: Ersoy *et al.*<sup>[103]</sup> (2008) report that weight gain at 12 mo for renal transplant recipients prescribed TAC and CsA was 3.5 and 8.0 kg, respectively. As far as changing immunosuppressive regimens, it appears that using the mTOR inhibitor EVR in combination with a reduced dose of TAC can cause less weight gain than full-dose TAC immunosuppression<sup>[104]</sup>. If mTOR inhibitors are inappropriate for the specific patient, MMF is a different potential substitute that is not associated with post-transplant weight gain<sup>[105]</sup>.

### Hypertension and renal insufficiency

HTN and subsequent renal insufficiency are major concerns for post-OLT patients. Increased blood pressure and systemic vascular resistance is pathological, and can lead to hepatorenal syndrome. The use of immunosuppression, specifically CNIs, compounds the metabolic issues already present in liver transplant recipients<sup>[106,107]</sup>.

The incidence of severe renal dysfunction can

reach up to 18.1% at a mean of 13 years post-OLT<sup>[108]</sup>. Longenecker *et al.*<sup>[109]</sup> (2015) recently reviewed renal function before and after OLT, finding that the overall rate of progression to ESRD is strongly associated with estimated GFR (eGFR) less than 60 mL/min × 1.73 m<sup>2</sup> and diabetes, but find that eGFR at OLT is not associated with 12-mo mortality.

For patients presenting with proteinuria as a result of HTN due to renal-insufficiency, treatment includes standard approaches such as angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers<sup>[86,110]</sup>.

Aside from the standard of care for MS, the specific treatment of post-OLT patients with renal insufficiency should include reduction or withdrawal of CNI therapy as soon as possible because of the nephrotoxicity associated with CNIs<sup>[111,112]</sup>. Masetti *et al.*<sup>[113]</sup> (2010) evaluated whether early withdrawal of CsA followed by initiation of EVR monotherapy preserves kidney function compared to their standard CsA regimen. The study found that incidence of stage 3 chronic kidney disease (< 60 mL/min GFR) at 1 year was significantly higher in the standard CsA group (55%) than in the group treated with EVR monotherapy (15.4%). Further, there was no difference in patient survival between the two groups.

Saliba *et al.*<sup>[104]</sup> (2013) found that TAC reduction with addition of EVR were associated with increased estimated GFR, demonstrating a significant benefit to renal function. Tsai *et al.*<sup>[114]</sup> (2009) confirm that, for renal allograft recipients, CNI minimization with the introduction of SRL reduces acute rejection and improves renal function and survival.

CNI withdrawal and replacement with MMF is another promising approach to post-OLT immunosuppressive management in patients who have renal insufficiency. Orlando *et al.*<sup>[115]</sup> (2007) report success with MMF monotherapy as a means of reducing the toxic effects of CNIs. Of 42 post-OLT individuals who were weaned off of CNI therapy and placed on subsequent MMF monotherapy, renal function improved in 89% and arterial hypertension decreased in 80% of cases. In a separate study examining post-OLT patients with severe side effects from CNI therapy, Dharancy *et al.*<sup>[116]</sup> (2009) found that a switch to MMF monotherapy could lead to increased eGFR without significant increase in rejection. Several studies have concluded that MMF is

less nephrotoxic, indicating that MMF could be used preferentially in patients with renal dysfunction<sup>[117,118]</sup>.

### Dyslipidemia

Incidence of dyslipidemia exceeds 70% and 40% for patients with and without pre-transplant MS, respectively<sup>[119]</sup>. Because MS affects a such great proportion of OLT patients<sup>[7]</sup>, methods of preventing or reducing dyslipidemia could benefit a preponderance of patients.

In an evaluation of the metabolic impact of OLT, Luzi *et al.*<sup>[120]</sup> (1996) reported that liver transplant recipients had abnormal FFA levels at 5 mo post-OLT. A follow-up at 26 mo found reduction in abnormal lipid and protein metabolism - in fact, plasma free fatty acids were reduced for transplant recipients with respect to the control group.

CNI therapy is associated with dyslipidemia post-OLT; but the level of dyslipidemia might be reduced upon use of mTOR inhibitors in combination with TAC<sup>[121]</sup>. Saliba *et al.*<sup>[104]</sup> (2013) report that hyperlipidemia was more frequent in patients on EVR + reduced dose TAC compared to patients on only full dose TAC. In spite of an increase in dyslipidemia, mTOR inhibitors do seem to decrease arteriovascular plaque formation<sup>[122]</sup>.

Orlando *et al.*<sup>[115]</sup> (2007) found that CNI withdrawal and subsequent replacement with MMF improved dyslipidemia. Out of 41 patients, blood cholesterol decreased in 76% and blood TG decreased in 89%. Further supporting the use of MMF in patients who are at-risk for complications of atherosclerosis, Romero *et al.*<sup>[123]</sup> (2000) also reported that MMF specifically reduces atherosclerosis in rabbits.

For patients with hyperlipidemia who are resistant to lifestyle changes, hydroxymethylglutaryl-CoA reductase inhibitors (statins) should be considered. Even with the potential for hepatotoxicity, the use of statins to counter immunosuppressive side effects can benefit patients<sup>[124]</sup>. Martin *et al.*<sup>[125]</sup> (2007), in a retrospective review of 69 liver transplant patients, explain that there is a general tolerability and low incidence of adverse events in patients treated with lipid-lowering agents. Indeed, they report that there is no change in liver function tests.

### Diabetes

Post-transplant diabetes mellitus (PTDM) is a well-recognized issue, and minimization of immunosuppression is currently the best treatment option for PTDM patients. The diabetogenic properties of immunosuppressive therapies seem to be intimately related to the signaling processes that are shared between pancreatic islets and leukocytes. Moreover, in contrast to the physiological proliferative signaling mechanisms used by white blood cells, renal calcineurin mediates glomerular hypertrophy and extracellular matrix accumulation<sup>[126]</sup>.

Immunosuppressive regimens play a major role in new-onset diabetes, affecting patient and graft survival<sup>[127]</sup>. Rostambeigi *et al.*<sup>[128]</sup> (2011) explain that beta cells exposed to TAC and CsA decreased insulin

secretion and reduced mitochondrial density without affecting apoptosis rates, and posit that maybe there is a mitochondria-mediated dysfunction imposed by CNIs. Notably, the tacrolimus-exposed beta cells fared marginally better than their CsA counterparts. This is a reflection of the diabetogenic properties of TAC compared to CsA. On the other hand, some research finds no major metabolic differences between TAC and CsA post-OLT low-dose maintenance therapies<sup>[129,130]</sup>.

## HCV: FROM INVARIABLE TO INCONSEQUENTIAL

HCV recurrence after liver transplantation is nearly universal, immediate, and has an accelerated natural history<sup>[131]</sup>. However, the discovery of directly acting antiviral (DAA) protease inhibitors has dramatically reduced the impact of HCV. With SVR rates exceeding 90%<sup>[132]</sup>, high safety<sup>[133]</sup>, and a well-tolerated side-effects profile<sup>[134]</sup>, Hepatitis C treatment will hopefully become a non-issue.

Still, there are OLT patients who experience HCV recurrence, and these patients deserve special consideration. Notably, in contrast to patients who do not have HCV, an episode of early ACR in post-OLT HCV patients is associated with a higher risk for mortality<sup>[135]</sup>. Despite the emphatic importance of treating ACR in this population, there has been a lack of consensus on the impact of using steroids - the front line of ACR treatment - in post-OLT HCV patients<sup>[136,137]</sup>.

At the Cleveland Clinic Foundation, ACR treatment protocol first considers RAI of the HCV-positive post-OLT patient. For patients with RAI less than six, there is an increase in CNI dose and further monitoring for rejection before a bolus of steroids is administered. In contrast, patients who have HCV with a RAI greater than or equal to six are treated the same as patients who do not have HCV: 1 g of methylprednisone is administered daily for 3 d followed by steroid taper. Antibody therapy is used for steroid-resistant rejection.

Besides treatment of ACR, maintenance therapy for HCV-positive post-OLT patients can be nuanced. For example, use of the monoclonal antibody OKT3 is associated with early and severe post-OLT HCV recurrence, and must be approached with caution<sup>[138]</sup>. On the other hand, treatment with MMF and a 24-mo CNI taper appears to benefit liver function tests and presentation on histology for the hepatitis C patient<sup>[139]</sup>.

With the introduction of DAAs, however, focus has shifted from accommodating immunosuppression to early HCV treatment for potential liver transplant recipients. Achieving SVR before the time of transplantation is ideal, and helps reduce risk of HCV recurrence post-OLT<sup>[140-142]</sup>. Still, the efficacy of recently-developed protease inhibitors must be evaluated specifically for post-OLT patients<sup>[143]</sup>.

## CONCLUSION

While the landscape of immunosuppressive medications

remains steadfast, temperamental clinical weather demands that clinicians stay up to date on best practices. The good news is that HCV is nearly subdued as a post-transplant complication, increasing graft survival, perhaps even decreasing allocation of organs to retransplantation for HCV. The bad news is that MS is increasingly harming patients in ways that are exacerbated by immunosuppression - an issue in sore need of revolution like that in HCV treatment. Finally, given the confluence of MS and immunosuppressive side effects, treatment of early ACR could be excessive and must be reevaluated in light of today's average patient.

### Abstract

Hepatocarcinoma (HCC) is a highly prevalent cancer worldwide and its inflammatory background was established long ago. Recent studies have shown that innate immunity is closely related to the HCC carcinogenesis. An effective innate immunity response relies on the toll-like receptors (TLR) found in several different liver cells which, through different ligands and many signaling pathways can elicit, not only a pro-inflammatory but also an oncogenic or anti-oncogenic response. Our aim was to study the role of TLRs in the liver oncogenesis and as a consequence their value as potential therapeutic targets. We performed a systematic review of PubMed searching for original articles studying the relationship between HCC and TLRs until March 2015. TLR2 appears to be a fundamental stress-sensor as its absence reveals an augmented tendency to accumulate DNA-damages and to cell survival. However, pathways are still not fully understood as TLR2 up-regulation was also associated to enhanced tumorigenesis. TLR3 has a well-known protective role influencing crucial processes like angiogenesis, cell growth or proliferation. TLR4 works as an interesting epithelial-mesenchymal transition's inducer and a promoter of cell survival probably inducing HCC carcinogenesis even though an anti-cancer role has already been observed. TLR9's influence on carcinogenesis is also controversial and despite a potential anti-cancer capacity, a pro-tumorigenic role is more likely. Genetic polymorphisms in some TLRs have been found and its influence on the risk of HCC has been reported. As therapeutic targets, TLRs are already in use and have a great potential. In conclusion, TLRs have been shown to be an interesting influence on the HCC's micro-environment, with TLR3 clearly determining an anti-tumour influence. TLR4 and TLR9 are considered to have a positive relationship with tumour development even though, in each of them anti-tumorigenic signals have

been described. TLR2 presents a more ambiguous role, possibly depending on the stage of the inflammation-HCC axis.

**Key words:** Hepatocarcinoma; Carcinogenesis; Toll-like receptor; Innate immunity; Chronic inflammation

**Core tip:** The importance of hepatocarcinoma (HCC) is undeniable in the current medical perspective. However, a lot still remains to be understood in this context. Therefore, this review aims to present the significance of innate immunity in HCC through toll-like receptors as they have already shown interesting effects on tumour's microenvironment, influencing its progression or regression. As a result we also render some therapeutic usages of the established knowledge in this area.

## INTRODUCTION

Liver cancer is one of the most common cancers worldwide, with hepatocarcinoma (HCC) being, by far, the most frequent type<sup>[1,2]</sup>.

Due to its close contact with gut, *via* portal vein, liver faces a continuous exposure to gut-derived bacterial products, toxics and many other agents<sup>[3]</sup>. In the presence of such pathogens or irritants and associated molecules our body is able to respond in a manner that aims to prevent injury and combat infection. This protection system is called inflammation which, despite its tremendous defensive and antiviral/antibacterial importance in the short term, starts to become deleterious when prolonged or exaggerated - chronic inflammation - possibly leading to fibrosis, cirrhosis and, ultimately, HCC<sup>[4]</sup>.

Therefore, the idea that hepatic carcinogenesis arouses from an inflammatory basis is not new. Several studies already focused on the development of HCC and possibilities like the c-Myc elevation or the deregulated SRY and SGF29 pathways have been proposed<sup>[5]</sup>. However, just in the last few years we have become aware of the critical role of innate immunity in chronic liver diseases, including HCC<sup>[6,7]</sup>.

Toll-like receptors (TLRs) are a family of pattern-recognition receptors (PRRs) that can be activated by either pathogen-associated molecular patterns (PAMPs) or danger/damage-associated molecular patterns (DAMPs), with their own importance in eliciting innate immunity, regulation of inflammation and tissue

regeneration. To date, 11 human TLRs have been identified<sup>[8]</sup>. In recent years, activation of several TLRs have been associated with viral hepatitis, steatohepatitis (alcoholic or non-alcoholic) and to the progression of the inflammation-fibrosis-HCC axis<sup>[9-11]</sup>. However, data is somewhat contradictory and no clear conclusions have been made.

In this line of thoughts, this review aims to present an overview of the expression of TLRs in the liver, its influence on the development of liver carcinogenesis as chronic inflammatory inducers or potential oncogenes as well as possible therapeutic targets.

## RESEARCH

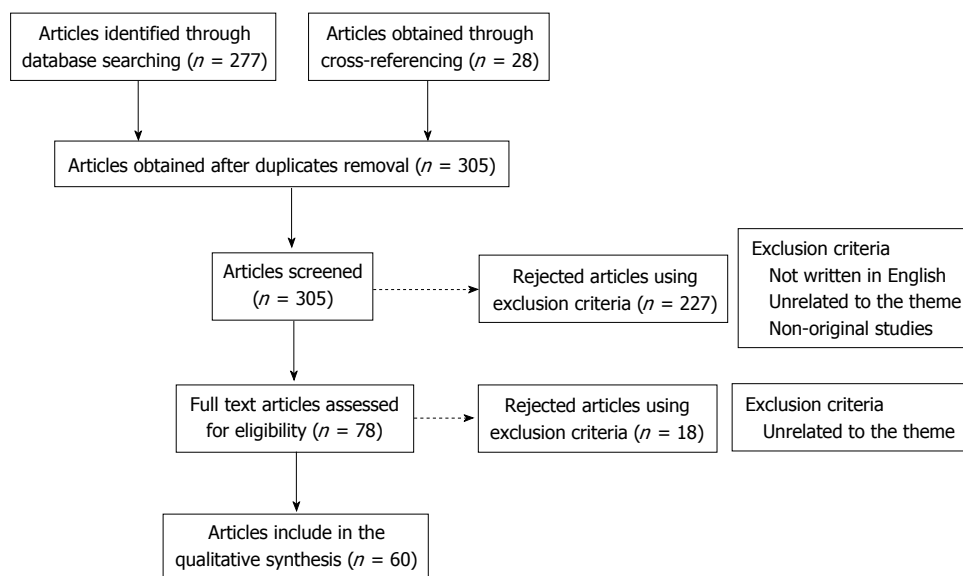

Specific criteria were defined in order to guide this systematic review. Firstly, a query to obtain the articles related to the theme on PubMed was built: [(Hepatocarcinoma) OR (Hepatocarcinogenesis) OR (hepatic cancer) OR (hepatocellular carcinoma) OR (liver cancer)] AND [(toll like receptors) OR (toll like receptor)]. With this query we intended to embrace a wide range of articles until March 2015, which then would be carefully selected.

A total amount of 277 articles were obtained through the referred search. After discarding the duplicates and adding 28 articles obtained through cross-referencing, 305 articles were available to be screened. The following inclusion criteria were used: (1) studies that were published until the end March 2015; (2) the article should be written in English; and (3) studies relevant to the theme (presenting original data). As exclusion criteria we defined: (1) studies considered by the authors as unrelated to the theme; and (2) non-original studies. These criteria were applied by reading the title and abstract resulting in 227 articles excluded. After this step, the remaining 78 studies were selected for full-text reading. On a second level of eligibility, 18 more studies were excluded and 60 studies were selected, analysed and included in this revision (Figure 1).

Data about the defined topics were obtained from each article (Table 1) and the information was then summed up and organized in the present systematic review according to: The TLRs' expression in each liver cell; separately role of TLR2, TLR3, TLR4 and TLR9 in inflammatory-driven hepatocarcinoma; known TLRs' polymorphisms/genetic variations that influence the risk of hepatocarcinoma and lastly, TLRs modulators possibly used in hepatocarcinoma's therapeutics.

## TLR EXPRESSION IN HEPATIC CELL POPULATION

The liver is a very special organ when it comes to dealing with pathogens. Due to its vascular links, contact with gut-derived bacteria is constant and, therefore, mechanisms not only to defend the organism from these pathogens but also to tolerate them, had to be

**Figure 1 Methods' flowchart.** A total amount of 277 articles were obtained, on PubMed, through the query [(hepatocarcinoma) OR (hepatocarcinogenesis) OR (hepatic cancer) OR (hepatocellular carcinoma) OR (liver cancer)] AND [(toll like receptors) OR (toll like receptor)]. After discarding the duplicates and adding 28 articles obtained through cross-referencing, 305 articles were available to be screened. The following inclusion criteria were used: (1) studies that were published until the end March 2015; (2) the article should be written in English; and (3) studies relevant to the theme (presenting original data). As exclusion criteria we defined: (1) studies considered by the authors as unrelated to the theme; and (2) non-original studies. These criteria were applied by reading the title and abstract resulting in 227 articles excluded. After this step, the remaining 78 studies were selected for full-text reading. On a second level of eligibility, 18 more studies were excluded and 60 studies were selected, analysed and included in this revision.

developed<sup>[8]</sup>. In this duality, TLRs play an interesting role as it is known that, in a healthy liver, mRNA levels of TLRs like TLR1, 2, 4, 6, 7, 8, 9 and 10 are decreased when compared to other organs<sup>[9]</sup>.

In the liver, hepatocytes represent 60%-80% of the total cell population. Here, it can be found mRNA from all TLRs; however, only a response from TLR2 and TLR4, to their ligands, can be obtained<sup>[12]</sup>. Interestingly, only the response of TLR2 is up-regulated under inflammatory conditions<sup>[13]</sup>.

Besides hepatocytes, it is possible to find, in the liver, non-parenchymal cells which consist of Kupffer cells (KCs), dendritic cells (DCs), Lymphocytes, hepatic stellate cells (HSCs) and liver sinusoidal endothelial cells (LSECs).

KCs not only express lipopolysaccharide (LPS)-responsive TLR4 but also TLR2, TLR3 and TLR9 that respond to their ligands<sup>[14]</sup>. These cells develop an inflammatory response to high levels of LPS but produce an anti-inflammatory cytokine (IL-10) in response to continuous low levels of LPS, known as LPS tolerance<sup>[15]</sup>. DCs represent a small population (< 1%). In humans, the plasmacytoid DCs subset expresses TLR1, TLR7 and TLR9 while other subsets carry all TLRs with the exception of TLR9<sup>[16]</sup>. When it comes to Lymphocytes population and TLRs relationship it is important to notice that differences can be found from one subpopulation to another. Natural killer (NK) cells contain TLR1, TLR2, TLR3, TLR4, TLR6, TLR7, TLR8 and TLR9<sup>[1,17]</sup> but T cells are only activated through TLR2 while B cells rely on TLR2, TLR4, TLR7 and TLR9<sup>[18]</sup>. HSCs, also in small proportion (< 1%), when activated are able to express TLR4 responsive to LPS which, in turn, enables

inflammatory cytokines' secretion<sup>[19]</sup>. LSECs express mRNA from TLR1 to TLR9 despite not being able to respond to TLR5 ligands<sup>[20]</sup>.

## IMPORTANCE OF TLRs IN INFLAMMATORY-INDUCED HCC

HCC has long been considered a chronic-inflammation driven cancer independently of the possible risk factors; virus induced hepatitis, smoke, alcohol or metabolic diseases. Despite that, the liver is an organ with several mechanisms readily available to defend against carcinogenesis. Among these, we found PRRs, with special attention to TLRs which were already shown to exhibit different roles in the regulation of tumorigenesis and tumour progression. To date several works have documented its influence not only in specific types of cancer - breast, ovarian, prostate and lung - but also in processes directly linked with cancer - resistance to apoptosis, increased invasiveness and metastasis. This is the reflection of their actions on metalloproteases and integrins, tumour cell immune escape, among others<sup>[21-23]</sup>. However, the cellular and molecular effectors mediating the interplay between TLRs and HCC are still largely unknown.

### TLR2

When the TLR2 signal is triggered, the downstream cascade initiates through a "Myd88 dependent pathway" with the activation of the apoptosis signal regulating kinase 1 (ASK1)/p38 mitogen-activated protein kinase (p38 MAPK)/nuclear factor kappa B (NF-κB), or through

Table 1 Table of original studies

Ref.	Year	Type of study	Methods	Limitations	Conclusions
Chew <i>et al</i> <sup>[1]</sup>	2012 December	Experimental	Natural killer cell activation and cytotoxicity were assessed <i>in vitro</i> after treatment with the TLR3 ligand poly (I:C). The effect of TLR in a spontaneous liver tumor mouse model and a transplanted tumor mouse model were determined by Immunohistochemistry and PCR	The effect of poly (I:C) on tumor growth was only analyzed in a transplanted, nonorthotopic model of HCC. The effect of poly (I:C) on human NK cells was assessed only with cells from healthy donors. Not all HCC cell lines undergo apoptosis after TLR3 triggering and the reason is not known	TLR3 is an important modulator of HCC progression and is a potential target for novel immunotherapy
Mohamed <i>et al</i> <sup>[2]</sup>	2015 March	Experimental	Tissue microarrays containing liver samples from patients with cirrhosis, viral hepatitis and HCC were examined for expression of TLR7 and TLR9. Proliferation of human HCC cell lines was studied following stimulation of TLR7 and TLR9 using agonists (imiquimod and CpG-ODN respectively) and inhibition with a specific antagonist (IRS-954) or chloroquine. The effect of these interventions was confirmed in a xenograft model and DEN/NMOR-induced model of HCC	Before translation to the clinical arena, it is important to further characterize the exact mechanisms through which TLR7 and TLR9 exert their actions and determine what effects their inhibition may have on the immune system	Inhibiting TLR7 and TLR9 with IRS-954 or chloroquine could potentially be used as a novel therapeutic approach for preventing HCC development and/or progression in susceptible patients
Dapito <i>et al</i> <sup>[3]</sup>	2012 April	Experimental	TLR2-deficient mice, TLR4-deficient mice, TNFR1-/IL-1R1-double deficient and C57Bl/6 mice were used. HCC was induced by intraperitoneal injection of DEN. Gut-sterilization was done using a combination of ampicillin (1 g/L), neomycin (1 g/L), metronidazole (1 g/L) and vancomycin (500 mg/L) in drinking water. Samples from patients with features of alcoholic hepatitis were used. Liver biopsies were obtained from mice and from cadaveric donors or resection of liver metastases	Clinically feasible methods of targeting the intestinal microbiota or TLR4 need to be established. The quadruple combination of antibiotics employed is not suitable for long-term treatment due to known side effects in patients with advanced liver disease	Gut sterilization restricted to late stages of hepatocarcinogenesis reduced HCC, suggesting that the intestinal microbiota and TLR4 represent therapeutic targets for HCC prevention in advanced liver disease
Eiró <i>et al</i> <sup>[8]</sup>	2014 July	Experimental	The expression levels of TLR3, TLR4 and TLR9 were analyzed from 30 patients with HCC and correlated with various clinicopathological findings and with overall survival	In the scoring system, after immunostaining analysis, when setting of the threshold for positive staining and the determination of the intensity different observers can set different thresholds and intensity levels	An association between TLR3, TLR4 and TLR9 expression and tumor aggressiveness and poor prognosis in HCC has been observed
Liu <i>et al</i> <sup>[12]</sup>	2002 July	Experimental	Cultures of primary mouse hepatocytes were incubated with LPS to assess its effects on the global gene expression, hepatic transcription factors, and MAP kinase activation	Using hepatocytes' cell lines loses the capacity to observe the importance of a direct response to LPS by hepatocytes	NF-κB activation was reduced in TLR4-mutant or -null hepatocytes compared to control hepatocytes
Matsumura <i>et al</i> <sup>[13]</sup>	2000 October	Experimental	PCR analysis of mice's hepatocytes and an murine hepatoma cell line Hepa 1-6	Murine hepatoma cell line Hepa 1-6 may have reached an overquantitative level after stimulation	LPS and proinflammatory cytokines differentially regulate gene expression of TLR2 and TLR4 in murine hepatocytes, which may lead to pathologic and host defense reactions in the liver
Thobe <i>et al</i> <sup>[14]</sup>	2007 March	Experimental	Western blotting and cytokine analysis in a cell culture. Evaluation of Kupfer cells response after a trauma-hemorrhage procedure	Does not explain if the increase in MAPK-activity is due to TLRs' overexpression	Kupffer cell TLR signaling employs different MAPK pathways in eliciting cytokine and chemokine responses following trauma-hemorrhage

Knolle <i>et al</i> <sup>[15]</sup>	1995 February	Experimental	Human Kupffer cells were isolated by collagenase perfusion followed by centrifugal elutriation and analyzed for cytokine secretion after 3 d in culture	Only IL-10 and IL-6 were analysed	The important role for IL-10 in the regulation of the local immune response in the liver sinusoid after Kupffer cells exposure to lipopolysaccharide
Edwards <i>et al</i> <sup>[16]</sup>	2003 April	Experimental	Splenocyte repopulations were enriched for D11c <sup>+</sup> and for Ly6C <sup>+</sup> cells using magnetic selection. Four populations were routinely isolated and TLR's mRNA was amplified by PCR	To analyze the functional significance of TLR mRNA expression in DCs subsets it was only used ligands for TLR7 and TLR9	mRNA for most TLRs is expressed at similar levels by murine splenic DC subtypes. TLR expression between plasmacytoid and non-plasmacytoid DC is not conserved between species
Sawaki <i>et al</i> <sup>[17]</sup>	2007 March	Experimental	Total RNA was extracted, and mRNA for TLR1, 2, 3, 4, 5, 6, 7, 9 and b-actin was determined by reverse transcription-PCR. Nuclear localization of NF- $\kappa$ B was determined and cytokines and chemokines were measured by a commercially available kit	It was not evaluated precise roles of NK cell responses <i>in vivo</i>	Upon microbial infection, macrophages produce IL-12 that renders NK cells highly responsive to TLR agonists to produce IFN- $\gamma$ and chemokines, which might in turn recruit and fully activate macrophages
Meyer-Bahlburg <i>et al</i> <sup>[18]</sup>	2007 December	Experimental	It was compared the TLR response profile of germinal center after immunization <i>vs</i> naive mature B cell subsets, using real time PCR, ELISA and Western Blotting to evaluate MyD88 pathway	TLRs' role in B-cells immune response was only accessed in splenic B cells from MyD88 WT, Het, or KO, being studied only the MyD88-dependent pathway	B cell-intrinsic TLR signals are not required for antibody production or maintenance
Paik <i>et al</i> <sup>[19]</sup>	2003 May	Experimental	LPS-associated signalling molecules in culture-activated HSCs and HSCs isolated from patients with hepatitis C virus-induced cirrhosis was evaluated by NF- $\kappa$ B-dependent luciferase reporter gene assays, electrophoretic mobility shift assays and <i>in vitro</i> kinase assays	It does not fully explain why only full activated HSCs respond to LPS. It was not evaluated the activation of TLR4 downstream molecules like MyD88	Human activated HSCs utilize components of TLR4 signal transduction cascade to stimulate NF- $\kappa$ B and JNK and up-regulate chemokines and adhesion molecules
Wu <i>et al</i> <sup>[20]</sup>	2010 March	Experimental	Isolated Kupffer cell and liver sinusoidal endothelial cells from wild-type C57BL/6 mice and examined their responses to TLR1 to TLR9 agonists. Characterization of cell surface protein expression was done by flow cytometry and quantification of mRNA was done by reverse transcription-polymerase chain reaction	The <i>in vitro</i> assay does not explore the organ-specific regulation of immune responses. For the identification of TLR-induced antiviral cytokine(s) only TLR3 and TLR4 were used	Non-parenchymal cells display a restricted TLR-mediated activation profile when compared with "classical" antigen-presenting cells which may, at least in part, explain their tolerogenic function in the liver
Huang <i>et al</i> <sup>[21]</sup>	2012 July	Experimental	TLR expression in BLE-7402 cells was assayed by RT-PCR, real-time PCR and FCM. To investigate the function of TLR2 in hepatocarcinoma growth, BLE-7402 cells were transfected with recombinant plasmids expressing one TLR2 siRNA	Only the effect on tumour volume is evaluated after tumour implantation in nude mice	TLR2 knockdown inhibit proliferation of cultured hepatocarcinoma cells and decrease the secretion of cytokines
Kim <i>et al</i> <sup>[22]</sup>	2009 January	Experimental	LLC cells were implanted in mice. Metastasis enhancing factors were identified on a QSTAR XL qTOF mass spectrometer. Gene and protein expression were monitored by Q-PCR and immunoblot analysis. Tumors were analyzed by immunohistochemistry and indirect immunofluorescence	It does not explain if the interaction between versican and TLR2 is direct or depends on a versican's ligand	By activating TLR2:TLR6 complexes and inducing TNF- $\alpha$ secretion by myeloid cells, versican strongly enhances lewis lung carcinoma metastatic growth
Lin <i>et al</i> <sup>[24]</sup>	2013 January	Experimental	A DEN injection was done in TLR2 <sup>-/-</sup> and WT mice. Then they were sham-treated or treated with interferon-gamma. TUNEL, heterochromatin and SA b-gal staining were performed	The mechanism by which TLR2 signaling participates in the regulation of cellular senescence to maintain growth arrest and promote programmed cell death remains inconclusive	Loss of immune networks may play a role in the failure of initiating and maintaining cellular senescence and autophagy flux in the TLR2-mutant liver tissue

Lin <i>et al</i> <sup>[25]</sup>	2013 October	Experimental	WT mice were pre-treated with anti-TLR2 antibody and a subset of TLR2 <sup>-/-</sup> mice were pre-treatment with NAC (antioxidant) or physiological saline. Both were submitted to DEN. Histology was submitted to western blotting, ROS assay, immunohistochemistry and immunofluorescence	It does not report any results about the effects on non-parenchymal cells like Kupffer cells. It does not reveal interactions that regulate the signal from TLR2 activation to suppression of oxidant and ER stressors in HCC	A TLR2 activity defends against hepatocarcinogenesis through diminishing the accumulation of ROS and alleviating ER stress and unfold protein response
Li <i>et al</i> <sup>[26]</sup>	2015 March	Experimental	WT and Tlr2 <sup>-/-</sup> mice were used. Flow cytometry, Histopathological analysis and Immunofluorescence, Western blot and ELISA were performed. MDSC induction <i>in vitro</i> and functional T cell suppression assay and knockdown of IL-18 and caspase-8 in hepatocytes with quantitative PCR were also done	The exact role of IL-18 in MDSC generation is still unknown. It does not reveal the levels of TLR2 that determine the possible use of IL-18 as a therapeutic target	TLR2 deficiency accelerates IL-18-mediated immunosuppression during liver carcinogenesis, providing new insights into immune control that may assist the design of effective immunotherapies to treat HCC
Soares <i>et al</i> <sup>[27]</sup>	2012 October	Analytic - cross sectional	It was used samples from patients with hepatitis, cirrhosis and hepatocarcinoma. mRNA isolation and quantification of TLR2, TLR4, NF-κB, TNF-α and COX-2 were performed. Immunohistochemical evaluation of TLR2 and TLR4 was also done	Most patients included in the reference group have evidence of NAFLD and it was demonstrated that NAFLD is associated with increased hepatic TLR2 and TLR4-mRNA expression. the hepatitis, cirrhosis and hepatocarcinoma groups included both patients with HBV infection or HCV infection. Included only patients with virus-induced chronic hepatitis. The method used for quantification of protein expression was semi-quantitative	Increased expression of TLR2 and TLR4 in hepatitis and cirrhosis and maintained expression in hepatocarcinoma. Up-regulation of TLR2, TLR4 and their pro-inflammatory mediators is associated with virus-induced hepatic IFC sequence
Dolado <i>et al</i> <sup>[31]</sup>	2007 February	Experimental	WT and p38a <sup>-/-</sup> were used. Growth in soft agar was evaluated. Intracellular ROS levels were determined, immunoblot Analysis was performed. To induce p38 MAPK activation, cells were treated with H <sub>2</sub> O <sub>2</sub> , sorbitol and cisplatin	The tumorigenesis enhanced by ROS is not evaluated on hepatocarcinoma	Oxidative stress sensing plays a key role in the inhibition of tumor initiation by p38alpha
Kang <i>et al</i> <sup>[32]</sup>	2011 November	Experimental	For transposon-mediated intra-hepatic gene transfer mice received a transposon- to transposase encoding vector (30 mg total DNA). DNA was administered by hydrodynamic tail vein injection. Immunohistochemical analyses were performed	It was not investigated if factors secreted from pre-malignant senescent hepatocytes also contribute to the oncogenic transformation of neighbouring cells	Indicates that senescence surveillance represents an important extrinsic component of the senescence anti-tumour barrier, and illustrates how the cellular senescence program is involved in tumour immune surveillance
Ogata <i>et al</i> <sup>[34]</sup>	2006 December	Experimental	Electron microscopic analysis was performed using neuroblastoma SK-N-SH cells exposed to ER stressors. GFP-LC3 fluorescence was used to monitor autophagy in cells transiently transfected with an expression vector for GFP-LC3. Then was performed an Amino acid uptake assay and autophagosome formation was evaluated	A signalling pathway other than the IRE1-JNK pathway may also play important roles in the activation of autophagy signalling after ER stress. The detailed signalling pathway for activation of the autophagy induced by ER stress is still unknown	Disturbance of autophagy rendered cells vulnerable to ER stress, suggesting that autophagy plays important roles in cell survival after ER stress
Pikarsky <i>et al</i> <sup>[36]</sup>	2004 September	Experimental	The possibility that NF-κB activation is involved in Mdr2-knockout hepatocarcinogenesis was investigated by RelA (p65) immunostaining. Hystological analysis was performed. To study the relationship between the	It does not explain how the inflammatory process in Mdr2-knockout mice is maintained in the double mutants as it is independent of hepatocyte NF-κB activity	NF-κB is essential for promoting inflammation-associated cancer, and is therefore a potential target for cancer prevention in chronic inflammatory diseases

Gong <i>et al</i> <sup>[37]</sup>	2013 September	Experimental	TNF- $\alpha$ -producing cells and NF- $\kappa$ B activation in the hepatocytes, liver sections were stained for both TNF- $\alpha$ and p65	It does not explain the mechanisms responsible by the NF- $\kappa$ B's phosphorylation in the first 30 min. It was observed only one of the pathways responsible for the involvement of HMGB1/RAGE in the NF- $\kappa$ B signaling	Activation of NF- $\kappa$ B was indispensable for the effect of HSP70. HSP70 induced a positive feedback loop involving Beclin-1/HMGB1 production, causing re-phosphorylation of NF- $\kappa$ B
			BALB/c mice were used and inoculated with H22 hepatocarcinoma cells into the hind thigh muscle. They were treated with TLR2/4 ligands, HSP70 and HMGB1. The main tumor nodules were measured and satellite tumor nodes counted. To downregulate HMGB1, RAGE or Beclin-1 in tumor cells, cells were transduced with short interfering RNA		
			Human hepatocellular carcinoma cell lines were used. Into the cell lines were transfected small-interfering-RNAs and at 48 h after transfection, the TLR2-siRNA-transfected group, scramble control group, and blank group were treated with recombinant-HMGB1. Evaluation included real time PCR, Western blot, MTT assay, Transwell assay and Flow cytometry assay		
			It was used mice and HCC cell lines. Eukaryotic expression vectors psTLR2 and psTLR4 were created. An adhesion assay, a tumor cell proliferation assay, a flow cytometric analysis, an apoptosis analysis, an analysis of gene expression by RT-PCR and a western blot analysis were performed		
			HCC cell lines and 74 HCC samples were used. Poly (I:C), cycloheximide and actinomycin were included in the study. Profiling analysis of TLRs recognized by viral components, flow cytometric analysis, immunohistochemical staining, Detection of TLR3 by immunofluorescence, Detection of cell viability and apoptosis assays, Detection of apoptosis-related proteins by immunoblotting, NF- $\kappa$ B activity assays and measurement of IFN- $\beta$ were also performed		
Shi <i>et al</i> <sup>[38]</sup>	2014 October	Experimental	Human hepatocellular carcinoma cell lines were used. Into the cell lines were transfected small-interfering-RNAs and at 48 h after transfection, the TLR2-siRNA-transfected group, scramble control group, and blank group were treated with recombinant-HMGB1. Evaluation included real time PCR, Western blot, MTT assay, Transwell assay and Flow cytometry assay	It does not explore the signaling pathway that regulates NF- $\kappa$ B through TLR2 inhibition or stimulation with recombinant-HMGB1	TLR2-siRNA could effectively inhibit the growth, migration, invasion, and expression of NF- $\kappa$ B/P65, and HMGB1 promoted HCC progression <i>via</i> TLR2
Wu <i>et al</i> <sup>[39]</sup>	2012 April	Experimental	It was used mice and HCC cell lines. Eukaryotic expression vectors psTLR2 and psTLR4 were created. An adhesion assay, a tumor cell proliferation assay, a flow cytometric analysis, an apoptosis analysis, an analysis of gene expression by RT-PCR and a western blot analysis were performed	More than one signaling pathways activated by HSPA1A might be required for the survival of tumor cells. The effect of eHSPA1A was only evaluated in one cell line. Injection of HSPA1A suppressed tumor growth in early stage of tumor development, but promoted tumor growth in later stage	Extracellular HSPA1A functions as endogenous ligand for TLR2 and TLR4 to facilitate tumor growth
Yoneda <i>et al</i> <sup>[41]</sup>	2008 November	Experimental	HCC cell lines and 74 HCC samples were used. Poly (I:C), cycloheximide and actinomycin were included in the study. Profiling analysis of TLRs recognized by viral components, flow cytometric analysis, immunohistochemical staining, Detection of TLR3 by immunofluorescence, Detection of cell viability and apoptosis assays, Detection of apoptosis-related proteins by immunoblotting, NF- $\kappa$ B activity assays and measurement of IFN- $\beta$ were also performed	Further evaluation of the possible roles and the type of regulation associated with TLR3 needs to be undertaken	Intracellular TLR3 signalling is involved in cell death, while in contrast, the cell surface TLR3 signalling is responsible for activation of NF- $\kappa$ B
Zorde-Khvalevsky <i>et al</i> <sup>[42]</sup>	2009 July	Experimental	It was used TLR3-WT mice and TLR3 <sup>-/-</sup> mice. Partial hepatectomy was done followed by immunohistochemistry stainings, plasma aminotransferase activity assay, measurements of serum cytokine levels, semi-quantitative reverse-transcription polymerase chain reaction, Western blotting, caspase-8 immunopurification and injection with poly (I:C) or saline solution	It is not explained what happens to the levels of ALT in mice's serum before the 10-h time point following 70% PHx. Cytokine evaluation only includes IL-6 and IL-22	TLR3 plays an inhibitory role in the priming of liver regeneration, thus reinforcing the role of the innate immune system in balancing tissue regeneration
Khvalevsky <i>et al</i> <sup>[44]</sup>	2007 April	Experimental	Various cell lines and plasmids pTLR7, pTLR8, and pTLR9, carrying the respective human <i>TLR</i> gene, were used. Transfection	The role of TLR3 signaling in normal hepatocytes requires further investigation <i>in vivo</i> . It is not specified the degree of	Preferential induction of the apoptotic pathway over the cytokine induction pathway by TLR3 signaling in

Chen <i>et al</i> <sup>[45]</sup>	2012 July	Experimental	assays, RNA quantification, immuno-staining and flow cytometry, were performed  The human HCC cell line HepG2.2.15 was used. After treating HepG2.2.15 with BM-06 or poly (I:C), NF-κB activity was checked by dual luciferase reporter gene kit. Then it was performed a nuclear and cytoplasmic extraction, Western blot analysis, a cell proliferation assay, cell invasion assays and flow-cytometry was used to determine the apoptotic rate	NF-κB activation obtained from the overexpression of TLR3 nor the degree of this overexpression that is needed  The role of TLR3 in the antiviral defense against HBV was not analyzed according to differences in the type of viruses, the type of cells that are infected, the viral load, its model of infection (endoplasmic <i>vs</i> cytoplasmic), and stage of infection	hepatocellular carcinoma cells with potential implications for therapeutic strategies  BM-06 inhibited the proliferation, invasion and secretion of HBV, and induced apoptosis in HepG2.2.15 cells. In addition, the antitumor effects of BM-06 were superior to poly (I:C)
Guo <i>et al</i> <sup>[46]</sup>	2012 February	Experimental	Cell cultures were used and submitted to BM-06 and poly (I:C) treatment. RNA isolation and one-step quantitative real-time PCR were performed. Analysis included detection of TLR3 by immunocytochemistry, luciferase reporter assays, Endothelial cell tube formation assay, rat aortic ring assay, annexin V/PI for cell apoptotic analysis and Cell migration assays	It does not evaluate the molecular mechanisms after TLR3 stimulation that lead to modulation of endothelial tube-forming activity of HUVECs and vascular sprouting or enhanced apoptosis	TLR3 agonists not only affect tumor microenvironment by suppressing angiogenesis but also directly induce tumor cell apoptosis and inhibit tumor cell migration
Bergé <i>et al</i> <sup>[47]</sup>	2010 December	Experimental	It was injected transgenic mice developing HCC with either control siRNAs or siRNA targeting neuropilin-1. The study used antibodies (goat anti-TLR3 and rabbit anti-tubulin antibody), Western Blotting, and Immunofluorescence Analysis. Real-time RT-PCR, ELISA, MTT assay and three-dimensional collagen assay were also performed	It is not known why INF-γ does not inhibit cells' functions in the <i>in vitro</i> study despite the high levels in HCC. <i>In vivo</i> evaluation was not performed	Synthetic siRNAs inhibit target-independently HCC growth and angiogenesis through the activation of the innate interferon response and by directly inhibiting endothelial cell function
Xu <i>et al</i> <sup>[48]</sup>	2013 October	Experimental	Thirty rats were used, all 30 were fed with 2-acetylaminofluorene to establish the HCC model. Two animal groups were treated, respectively, with the drug candidate (BM-06) and poly (I:C). It was performed a H and E staining, an Immunohistochemical staining, a Western blot analysis	It does not explore the pathway through which BM-06 and poly (I:C) are capable of inducing cell death. It is not evaluated TLR3's downstream molecules to explain the signalling pathway responsible for these results	Treatment with BM-06, showed a decrease in tumor growth and cell proliferation, and an increase in apoptosis compared with that in a phosphate-buffered saline control group
Wang <i>et al</i> <sup>[49]</sup>	2013 August	Experimental	Fifty-three HCC and ten normal liver specimens were analyzed by immunohistochemistry, and three cell lines were used for <i>in vitro</i> studies. Lipopolysaccharide was used to activate TLR4 signaling. Cell survival, proliferation and invasion were examined	Only a specific amount of LPS has shown to have an effect on the mRNA expression of IL-6, EGFR and HB-EGF. Opposing to HL-7702 cell line, PLC/PRF/5, with a moderate level of TLR4 expression, was not affected by inhibiting p38	Indicate that TLR4 signaling in cancer cells promotes cell survival and proliferation in HCC
Liu <i>et al</i> <sup>[50]</sup>	2015 March	Experimental	Two HCC cell lines and a splenic vein metastasis of the nude mouse model were used. A total of 88 clinical samples from HCC patients were used. A fluorescence activated cell sorting system and flow cytometry analysis were performed. Nude mouse splenic vein metastasis assay, immunohistochemistry analysis, real-time quantitative PCR, Western blot analysis, immunofluorescence and cell apoptosis assay were also done	More pathological specimens should be enrolled to verify the tendencies of association between TLR4 expression and malignant characteristics of HCC found in this study. A particular signaling pathway involved in the relationship between TLR4 expression and stem cell features remains elusive	There is a relationship between TLR4 expression and CSC's features, TLR4 may act as a CSC marker, prompting tumor invasion and migration, which contributes to the poor prognosis of HCC

Li <i>et al.</i> <sup>[52]</sup>	2014 October	Experimental	A HCC cell line was used where a Scratch assay was performed. Invasion assay, Western blot analysis, quantitative real-time reverse transcription PCR and siRNA knockdown of <i>TLR4</i> gene expression were also done	It does not reveal the time needed for induction of epithelial-mesenchymal transition after LPS stimulus. Does not explore influence of LPS on TLR2	TLR4/JNK/MAPK signaling is required for LPS-induced EMT, tumor cell invasion and metastasis, which provide molecular insights for LPS-related pathogenesis and a basis for developing new strategies against metastasis in HCC
Jing <i>et al.</i> <sup>[53]</sup>	2012 August	Experimental	Four HCC cell lines and a splenic vein metastasis of the nude mouse model were used and stable TLR4-expressed and knocked-down cell lines were generated. 106 clinical samples from HCC patients were also used. Quantitative real-time PCR, Western-blot analysis, Immunofluorescence, FACS Analysis and IHC analysis were performed	HCC development is a multifactorial and complicated process, which has a close association with various risk factors. Many gene alterations and cytokines also could induce EMT. HCC cells with low expression or even a lack of TLR4 are not susceptible to LPS, they might perform EMT induced by other TLR4-independent mechanisms	TLR4 signaling is required for LPS-induced EMT, tumor cell invasion and metastasis, which provide molecular insights for LPS-related pathogenesis and a basis for developing new strategies against metastasis in HCC
Xu <i>et al.</i> <sup>[54]</sup>	2014 October	Experimental	HCC and adjacent tissues were obtained from 84 patients. HCC cell lines were used and a PLV-PTPRO-GFP plasmid was constructed. Real-time PCR, immunofluorescence, Western blot analysis and cell proliferation assay were performed	It does not specify the doses of NF- $\kappa$ B specific inhibitor needed to result in a decreasing of PTPRO's levels in Huh7 cells stimulated with LPS	The effect of PTPRO on TLR4 signaling is dependent on NF- $\kappa$ B pathway, suggesting an interesting PTPRO/TLR4/NF- $\kappa$ B signaling feedback loop in HCC carcinogenesis and progression
Wang <i>et al.</i> <sup>[55]</sup>	2015 January	Experimental	It was used LPS-induced human hepatocellular carcinoma cell lines. Cell viability was assessed using the MTT assay. Double staining for annexin V-FITC and propidium iodide was performed. Inflammatory mediators were evaluated through a specific ELISA kit. Immunoprecipitation and Western blot analysis were also used	Only one type of cell line is used to observe the effect of CXC-195. It does not reveal the level (high or low) of TLR4 expression. It does not explore the influence of LPS in TLR2	Treatment with CXC195 could attenuate the TLR4-mediated proliferation and inflammatory response in LPS-induced HepG2 cells
Yu <i>et al.</i> <sup>[56]</sup>	2010 October	Experimental	Rats and mice were used, including TLR4-deficient mice. Immunohistochemical analysis and bone marrow transplantation were performed	It does not explore the effect of modulating gut flora. It does not evaluate the effect of different LPS' levels	Sustained LPS accumulation represents a pathological mediator of inflammation-associated HCC and manipulation of the gut flora to prevent pathogenic bacterial translocation
Lin <i>et al.</i> <sup>[58]</sup>	2012 September	Experimental	It was used wild-type and TLR4-deficient mice. A flow cytometry analysis and Isolation and Culture of CD4 <sup>+</sup> cells were performed	TLR4 knockout showed decreased liver injury induced by Con A, contrarily to what was expected. It is needed to determine whether the regimen with antiendotoxin effects will prove beneficial in preventing or delaying T cell-mediated hepatitis and hepatitis-induced HCC	Gut-derived LPS and TLR4 play important positive roles in Con A-induced hepatitis and modulation of the gut microbiota may represent a new avenue for therapeutic intervention
Chen <i>et al.</i> <sup>[60]</sup>	2013 July	Experimental	It used HCV Tg mouse models and patients with HCC functional cDNA. Then, functional cDNA screening for oncogenes was performed. <i>In vitro</i> and <i>in vivo</i> oncogenic activities were evaluated. It was also done a liver TIC engraftment <i>via</i> splenic injection	The degree of attenuation of TLR4 expression in TICs by Nanog, implying a feedback loop is not shown. Besides this, the underlying mechanisms are not known	TLR4/NANOG oncogenic pathway is linked to suppression of cytostatic TGF- $\beta$ signaling and could potentially serve as a therapeutic target for HCV-related HCC
French <i>et al.</i> <sup>[63]</sup>	2013 August	Experimental	Liver biopsies from patients diagnosed with alcoholic hepatitis, with or without cirrhosis were selected. Double Immunohistochemistry was performed	The antibody stain was only against TLR4	The Mallory-Denk-bodies forming cells expressed two additional progenitor cell markers. These markers were CD49f and TLR4

Machida <i>et al</i> <sup>[64]</sup>	2014 November	Experimental	An immunostaining of liver tumor sections from alcohol-fed Ns5a mice was performed along with TLR4 silencing with lentiviral short-hairpin RNA	LPS-independent mechanisms of TLR4 activation in TICs remain to be elucidated. The oncogenic role of TLR4 is explored only around the synergism alcohol-HCV	TLR4-dependent mechanisms of TIC generation actually contribute to or at least promote the initiation of HCC
Yan <i>et al</i> <sup>[65]</sup>	2012 June	Experimental	Human HCC liver samples and mice were used. Stable HMGB1-expressing cells and HMGB1 knockdown cells were established. immunoblotting analysis, RNA Interference by short interfering RNA, enzyme-linked immunosorbent assay, confocal microscopy exam, caspase-1 colorimetric assay, cell migration and invasion assays and metastatic potential exam were all performed	Mechanisms by which caspase-1 affects tumor cancer progression remain incompletely understood	In hypoxic HCC cells, HMGB1 activates TLR4- and RAGE-signalling pathways to induce caspase-1 activation which, in turn, promote cancer invasion and metastasis
Xu <i>et al</i> <sup>[67]</sup>	2008 February	Analytic - cross sectional	52 patients were studied. The protein and mRNA levels of TLR7 and TLR9 were evaluated using real-time PCR, Western blot analysis, and flow cytometry. We also detected the serum viral load of HBV in the patients and analyzed the correlation between HBV-DNA copies and the TLR expression	The statistical analysis indicated no difference in the TLR9 levels among the HCC and LC groups. If the sample size was enlarged, the results may be different. The expression of TLR7 was not different among the groups of patients, suggesting that TLR7 has no correlation with HCC	There are downregulations of TLR7 expression and TLR9 mRNA in PBMC of HBV-infected patients, but an increased TLR9 expression at the protein level
Tanaka <i>et al</i> <sup>[68]</sup>	2010 October	Experimental	HCC cell lines and 42 HCC tissues were used. The type C CpG oligonucleotide was used as TLR9 ligand. Flow cytometric analysis, Immunohistochemical staining, Cell proliferation assay, Immunoblotting, NF-κB activity assays and expression analysis of IRF-7, RNA extraction and oligonucleotide microarray and Microarray data analysis were all performed	Despite being present both intracellular or extracellular TLR9's intracellular function is not observed with TLR9 ligands and its function is not known	Functional cell surface expression of TLR9 in human HCC may play an important role in tumorigenesis and cancer progression
Liu <i>et al</i> <sup>[69]</sup>	2015 February	Experimental	C57BL/6 mice were injected with Hepa1-6 cancer cells. TLR9 and HMGB1 were inhibited using shRNA or direct antagonists. HuH7 and Hepa1-6 cancer cells were investigated <i>in vitro</i> to determine how the interaction of HMGB1 and mtDNA activates TLR9 signaling pathways	The contribution of TLR9 to cancer pathophysiology remains incompletely understood. The regulation of TLR9 signaling and the physiological ligands which may induce TLR9 mediated tumor growth remain poorly characterized	Reveals a novel mechanism by which the interactions of HMGB1 and mtDNA activate TLR9 signaling during hypoxia to induce tumor growth
Zhang <i>et al</i> <sup>[70]</sup>	2014 December	Experimental	It was used HCC cell lines to where was transfected CpG oligodeoxynucleotide and poly (I:C). Proliferation analyses, Detection of apoptosis with an Apoptosis Detection Kit, quantitative real-time PCR analysis, Western blot analysis and Fluorescence microscopy were also performed	The precise molecular interactions that likely occur between CpG ODNs and poly (I:C) to block poly (I:C) entry, remain to be established. Poly (I:C) may be influenced by many molecules in the microenvironment	When combining poly (I:C) and CpG ODN for cancer therapy, these agents should be used in an alternating rather than simultaneous manner to avoid the blocking effect of phosphorothioate-modified TLR9 ligands
Zhang <i>et al</i> <sup>[71]</sup>	2014 April	Experimental	Human hepatoma cell lines were used. Cells were transfected with CpG ODNs or small interfering RNAs targeting TLR9. Reverse transcriptase polymerase chain reaction assay, Proliferation measurements, cell cycle analysis, detection of apoptosis, quantitative real-time PCR analysis, Western blot analysis were all performed. An <i>in vivo</i> study was also done	Apoptosis induced by ODN M362 Ctrl and ODN M362 occurred independently of TLR9 stimulation. TLR9- and MyD88-independent mechanisms in ODN-stimulated immune cells, including B lymphocytes and neutrophils may exist	Phosphorothioate-modified TLR9 agonist ODN M362, and its control, elicit antitumor activity in HCC cells and may serve as a novel therapeutic target for HCC therapy

Bubici <i>et al</i> <sup>[74]</sup>	2004 December	Perspective			Induction of FHC and Mn-SOD represents an additional, indirect means by which NF- $\kappa$ B controls proapoptotic JNK signaling
Liu <i>et al</i> <sup>[75]</sup>	2009 April	Experimental	Cell cultures were used. Immunocytochemistry stain for TLR9, a Cell proliferation assay, reverse transcriptase PCR for TLR9 and real-time reverse transcriptase PCR for DNMT-1 and Bcl-2, NF- $\kappa$ B activation measurement and Cellular apoptosis analysis were all performed	L-02 cells were used to allow <i>in vitro</i> studies but cells may behave differently <i>in vivo</i> . Future <i>in vivo</i> models are needed	Identified a possible novel mechanism that indicates how CpG DNA of HBV DNA may contribute to the malignant transformation of benign liver cells
Nischalke <i>et al</i> <sup>[76]</sup>	2012 March	Analytic - cross sectional	A total of 197 patients with HCV-associated HCC, 192 HCV-infected patients without HCC and 347 healthy controls were included. HCV antibodies were detected for diagnosis. Determination of TLR2-196 to -174 del/ins polymorphism was performed by LightCycler real-time PCR. <i>In vitro</i> induction of TLR2 expression and IL-8 was performed	Analysis of the functional role of TLR2-196 to -174 del/ins alleles with respect to TLR2 expression was based on <i>in vitro</i> stimulation studies but it is not known if an <i>in vivo</i> analysis would have the same results	TLR2-196 to -174 del allele to affect HCV viral loads and to increase the risk for HCC in HCV genotype 1-infected patients
Junjie <i>et al</i> <sup>[77]</sup>	2012 February	Single center-based case-control	SNaPshot method was used to genotype sequence variants of TLR2 and TLR9 in 211 patients with HCC and 232 subjects as controls	Despite the SNP rs3804099 and rs3804100 were out of HWE ( $P = 0.01-0.02$ ), they were retained in the analyses	TLR2 rs3804099 C/T and rs3804100 C/T polymorphisms were closely associated with HCC. In addition, the haplotypes composed of these two TLR2 synonymous SNPs have stronger effects on the susceptibility of HCC
Jiang <i>et al</i> <sup>[79]</sup>	2014 December	Single center-based case-control study	426 HCC subjects and 438 cancer-free control subjects were used. SNP genotyping was performed. A Vector was constructed and luciferase reporter assays were done. TLR4 mRNA levels were evaluated and Western blotting was done	The hypothesis that the overexpression of TLR4 induced by the rs1057317 polymorphism miRNA-disrupting function may influence the development of hepatocellular carcinoma is possible but still not proved. More studies in this area are needed	The risk of hepatocellular carcinoma was associated with a functional variant at miR-34a binding site in <i>TLR4</i> gene. miR-34a/TLR4 axis may play an important role in the development of HCC
Minmin <i>et al</i> <sup>[80]</sup>	2011 April	Analytic-case-control	A systematic genetic analysis of sequence variants of TLR4 by evaluating ten single-nucleotide polymorphisms was performed from 216 hepatocellular carcinoma cases and 228 controls	The contribution of the SNPs in TLR4 to HCC is modest. More studies are needed to validate this finding in independent populations and to understand the mechanism by which TLR4 sequence variants affect the pathological role of TLR4 in the signaling pathways that control carcinogenesis	The risk of hepatocellular carcinoma was associated with TLR4 sequence variation. TLR4 single nucleotide polymorphisms may play an important protective role in the development of hepatocellular carcinoma
Kawamoto <i>et al</i> <sup>[82]</sup>	2008 April	Experimental	Mouse cells were used together with plasmids containing TLRs. Cells were submitted to LPS and TAK-242. Nitrite and TNF- $\alpha$ were measured. Reporter gene assay for ligand-dependent signaling by TLRs, Reporter gene assay for ligand-independent signaling by TLR4, CD4-TLR or adaptors and Western blot analysis were performed	Human studies are needed as the interacting affinity of TAK-242 with TLR4 may be affected by a subtle difference in the amino acid sequences of TIR between humans and mice	TAK-242 selectively suppresses TLR4-signaling mediated by the intracellular domain
Matsunaga <i>et al</i> <sup>[83]</sup>	2011 January	Experimental	293 cells of human embryonic kidney and murine resident peritoneal macrophages were used. They were subited to TAK-242 and LPS. Vectors for FLAG-TLR4 and FLAG-TLR2 were cloned. Measurement of nitrite and	To fully understand the physical basis whereby TAK-242 disturbs signaling complex formation and intracellular signal transduction, a crystal structure analysis of the TLR4-TAK-242 complex is needed	TAK-242 binds selectively to TLR4 and subsequently disrupts the interaction of TLR4 with adaptor molecules, thereby inhibiting TLR4 signal transduction and its downstream

			cytokine concentrations in culture supernatants, radiolabeling of the cells, immunoprecipitation, Western blot analysis and autoradiography, reporter gene assay and <i>in vitro</i> IL-1 receptor-associated kinase-1 kinase assay were all performed		signaling events
Xu <i>et al.</i> <sup>[84]</sup>	2013 November	Experimental	Four dsRNAs were designed and synthesized. The expression of proteins was compared. The migration, proliferation and apoptosis of HepG2.2.15 cells were evaluated in presence of BM-06, sorafenib alone or in combination of both. The similar treatments were also applied in an SD rat primary HCC model	Since synthetic siRNAs must be transfected into the target cells through a vector, such as Lipofectamine™ 2000 reagent, they always exhibit cytotoxicity, which may limit their use in clinic	dsRNA alone was capable of inhibiting the proliferation of HepG2.2.15 cells and tumor growth of orthotopic HCC SD rats, but the effect of combination of dsRNA with sorafenib was more prominent
Behm <i>et al.</i> <sup>[85]</sup>	2014 December	Experimental	Rabbits were randomised to receive RFA, CpG B, their combination or no therapy, further tested by rechallenging a separate group with intravenously injected VX2 tumour cells after 120 d. Animals were assessed for survival, tumour size and spread, and tumour and immune related histological markers after 120 d. Peripheral blood mononuclear cells were tested for tumour-specific T cell activation and cytotoxicity. Immune modulatory cytokines were measured in serum	Lack of antibody reagents for the VX2-tumour model in rabbits. It was not possible to elucidate in depth histopathological changes	The combination of TLR9 stimulation with RFA resulted in a potentiated antitumour T cell response and cytotoxicity in the VX2 tumour model. Only this combination prevented subsequent tumour spread and resulted in a significantly improved survival

a "Myd88 independent manner/toll/interleukin-1 receptor domain-containing adaptor protein inducing interferon beta (TRIF) dependent" with the extracellular signal-regulated kinase (ERK)/Junamino-terminal kinase (JNK) and PI3K/Akt pathways<sup>[24]</sup>. Besides this, TLR2 signal is also involved in processes like autophagy and senescence in response to oxidative stress and DAMPS release<sup>[25]</sup>.

Diethylnitrosamine (DEN) is a chemical carcinogen capable of inducing HCC through accumulation of reactive oxygen species (ROS) and endoplasmic reticulum (ER) stress. It was found that when a TLR2-deficient (TLR2<sup>-/-</sup>) mouse was submitted to DEN treatment the ROS and ER stress were abundantly accumulated, even though less apoptosis was observed<sup>[25]</sup>.

In fact, Lin *et al.*<sup>[24]</sup> demonstrated, in two separated works, that both TLR2<sup>-/-</sup> and wild-type (WT) mice developed HCC after being submitted to a DEN-treatment. However, the TLR2<sup>-/-</sup> mice revealed earlier tumours (every TLR2<sup>-/-</sup> mouse developed HCC at 6 mo after DEN treatment vs only 68% WTs)<sup>[24]</sup> that were, not only

significantly increased in number and in volume, but also less differentiated<sup>[24,25]</sup>. This increase reached the 3 fold (20.1%  $\pm$  4.5% vs 6.4%  $\pm$  1.0%,  $P < 0.01$ ) in the tumour area and 5 fold in visible tumour nodules (29.1%  $\pm$  2.8% vs 5.5%  $\pm$  0.9%,  $P < 0.001$ )<sup>[24]</sup>. Meanwhile, in the WT mice, is possible to attenuate HCC development if a TLR2 agonist is used<sup>[26]</sup>. Ultimately, TLR2<sup>-/-</sup> mice had shorter mean survival times with HCC than WTs<sup>[24]</sup>. Moreover, similar scenery was observed when a WT was pre-treated with an anti-TLR2 antibody<sup>[25]</sup>. Indeed, when observing liver samples from patients in different stages of liver diseases it is notorious that, in patients with HCC, not only the mRNA levels of TLR2 are lower but also TLR2 immunohistochemical expression grade and intensity are reduced, when compared to patients with hepatitis or cirrhosis<sup>[27]</sup>.

A ROS-generation reaction in cytochrome p450 2E1 is responsible for DEN metabolism. In spite of not finding any significant difference in cytochrome activity, TLR2<sup>-/-</sup> mice still revealed enhanced accumulation of ROS in their liver tissue<sup>[24]</sup>.

**Figure 2** Toll-like receptor 2's signalling pathways contributing to hepatocarcinoma. In the absence of TLR2, cells are incapable of responding to an increasing ROS when submitted to DEN. This is the result of an absence of MAPK/NF- $\kappa$ B pathway and an up-regulation of the UPR-JNK pathway. Consequently, cells containing higher ROS and DNA damages have more chances to survive and, HCC develops. In a second stage, where HCC is already established, HMGB1 and HSPA1A released by tumour's dying cells, through TLR2 stimulation, lead to an NF- $\kappa$ B up-regulation which, in this contest, seems to contribute to tumour's growth. HCC: Hepatocarcinoma; TLR2: Toll-like receptor 2; ROS: Reactive oxygen species; DEN: Diethylnitrosamine; MAPK: Mitogen-activated protein kinase; NF- $\kappa$ B: Nuclear transcription factor kappa B; UPR: Unfold protein response; JNK: Junamino-terminal kinase; HMGB1: High mobility group box 1; HSPA1A: Heat shock protein A1A.

Generation of ROS results in oxidative stress, which is often the source of DNA mutation or a direct link with chronic inflammation<sup>[28-30]</sup>. The ASK1/p38 MAPK/NF- $\kappa$ B pathway is one of the major sensors for ROS accumulation contributing to induced senescence cell death when risk of mutation is present<sup>[31]</sup>. However, in TLR2<sup>-/-</sup> mice submitted to DEN treatment, it is possible to assist to an attenuation of this major pathway<sup>[25]</sup> together with a suppression of biomarkers of autophagy-associated cell death and cellular senescence, like  $\beta$ -galactosidase<sup>[24]</sup>. Moreover, unlike the WT, TLR2<sup>-/-</sup> mice fail not only, to induce other important channels to premature cellular senescence like the p16-pRb/p21 pathway<sup>[24]</sup>, but also to activate DNA damage repair mechanisms<sup>[32]</sup>.

Furthermore, ER-stress is augmented after DEN-treatment in TLR2<sup>-/-</sup> mice as a result of ROS accumulation<sup>[25]</sup>. This leads to an enhanced unfold protein response (UPR) and activation of UPR-JNK pathway<sup>[33]</sup>, necessary for autophagy activation under ER-stress which, paradoxically, plays a dominant pro-survival role<sup>[34]</sup>. Lin *et al.*<sup>[25]</sup> noticed that, in livers from TLR2<sup>-/-</sup> mice there was an increased JNK activity.

Overall this data indicates that in the absence of TLR2, a down-regulation of common ROS neutralizing mechanisms, due to suppressed activation of ASK1/p38

MAPK/NF- $\kappa$ B, results in HCC cells containing higher ROS and DNA damages that, because of an up-regulated UPR-JNK pathway, have more chances to survive.

However, other pathways relating to TLR2 and hepatocarcinogenesis exist. Li *et al.*<sup>[26]</sup> focus their work on IL-18, which was found to be fundamental to carcinogenesis in TLR2<sup>-/-</sup> mice. In these mice, HCC developing after DEN treatment was capable of inducing IL-18 up-regulation in a caspase-8-dependent manner, therefore contributing to promotion of angiogenesis and suppression of NK cell arm of tumour immunosurveillance<sup>[26]</sup>.

Another perspective is related to the High mobility group box 1 (HMGB1), a nuclear protein released from dead/dying cells or even from cancer cells. It has the ability to bind to TLR2 and, with that, successfully activate NF- $\kappa$ B<sup>[35]</sup> which, in turn, can have an important role as a tumour promoter in inflammation-associated cancer<sup>[36]</sup>. Up-regulation of HMGB1 in an HCC cell line can result in increased matrix metalloprotease 9 and satellite tumour nodules in the liver, while blocking it suppresses tumour growth<sup>[37]</sup>. A recombinant HMGB1 (rHMGB1) was used by Shi *et al.*<sup>[38]</sup> in order to simulate TLR2 activation in an HCC cell line. Interestingly, rHMGB1 not only reduced cell apoptosis but also accelerated the tumour's growth and enhanced the ability of migration and invasion. Additionally, rHMGB1 activity significantly declined when HCC cells were pre-treated with a TLR2 inhibitor<sup>[38]</sup>.

Similarly to HMGB1, HSPA1A - a member of the HSP70 family - is also a TLR2's ligand released by the tumour's necrotic cells. With a resembling pathway based on up-regulation of NF- $\kappa$ B, HSPA1A is capable of promoting the proliferation and survival of tumour cells<sup>[39]</sup>.

TLR2 clearly represents an important modulator of cells' response to stress situations. It has influence in mechanisms like autophagy, apoptosis or even DNA damage repair, possibly contributing to a protective role against HCC. However, it is, also, important to notice that these pathways may not be, already, clearly understood as studies reveal that TLR2's ligands like HMGB1 and HSPA1A, can result in tumour enhancement (Figure 2).

Taken altogether this data suggests that TLR2 activation may slow down initiation and development of HCC (anti-oncogenic potential) in the earlier phases of HCC carcinogenesis. However, at later stages its activation may influence the progression of inflammation and fibrosis (pro-oncogenic potential). Therefore, new studies are required in order to understand the exactly pathways through which this receptor is able to work and to conclude if its role in HCC carcinogenesis is different or not depending on the stage of the Inflammation-fibrosis-carcinoma axis.

### TLR3

Several studies have already shown that TLR3 is expressed in many cancer cells such as colonic adenocarcinoma, lung cancer, breast cancer and melanoma.

**Figure 3** How toll-like receptor 3 stimulus works against hepatocarcinoma. Stimulation of intracellular TLR3 is able to elicit cell apoptosis in a TRAIL-dependent manner that synergistically accompanies a down-regulation of anti-apoptotic proteins. Additionally, TLR3 stimulus can promote either an inflammatory or an apoptotic response. The first one pending on NF-κB, the second in caspase-8 activation and INF-γ release. As a result, TLR3 works as a protector against cancer which stimulation results in diminished tumour growth. TLR3: Toll-like receptor 3; TRAIL: Tumour necrosis factor-related apoptosis-inducing ligand; INF-γ: Interferon gamma; NF-κB: Nuclear transcription factor kappa B.

In HCC it was found that 17-fold longer median survival accompanied patients with higher intratumoral TLR3 expression<sup>[40]</sup>. However, Yoneda *et al.*<sup>[41]</sup> observed that 52.7% of the HCC tissues and 34.8% of the HCC metastasis studied expressed TLR3. Furthermore, the receptor was not only present in the cytoplasm, but also in the membrane, particularly in the exterior, suggesting a cell surface recognition mechanism for TLR3 agonists<sup>[41]</sup>.

Other works have already implied that the TRIF-dependent pathway of TLR3 signalling could have a special contribution to a tumours response. In fact, this adaptor molecule can promote either an inflammatory or an apoptotic response. The first one pending on NF-κB, the second in caspase-8 activation and interferon-γ (INF-γ) release<sup>[42]</sup>. Experiments showed that using synthetic TLR3 agonists resulted in a rise in NF-κB. In fact, as it was seen with TLR2 signalling, NF-κB is normally associated with augmented tumour necrosis factor α (TNF-α) responsible for cells' growth and proliferation<sup>[43]</sup>. However, here, an NF-κB rise is responsible for affecting the tumour microenvironment and driving HCC and endothelial cells to apoptosis<sup>[44]</sup>, accompanied by a significantly decreased tumour invasiveness and angiogenesis/vascular endothelial growth factor (VEGF) levels<sup>[45-47]</sup>. Thus, it seems that, whether NF-κB promotes or inhibits hepatocarcinogenesis depends on the presence of inflammation and the degree of NF-κB inhibition/promotion<sup>[3]</sup>.

Moreover, INF-γ - a potent inhibitor of endothelial cell proliferation/angiogenesis - and caspase-8/caspase-3 - inhibitors of hepatocytes proliferation - were found to be significantly increased in HCC cell lines pre-treated with TLR3 agonists<sup>[48]</sup>.

However, it is important to notice that, when stimulated through polyinosinicpolycytidylic acid, the surface TLR3 is only able to induce apoptosis if a protein synthesis inhibitor or a RNA synthesis inhibitor are

present<sup>[41]</sup>. This might indicate that, in an HCC cell line, endogenous suppressors of TLR3-mediated apoptosis are present. Curiously, stimulation of intracellular TLR3, even without protein or RNA synthesis' inhibitors, was able to elicit cell apoptosis in a tumour necrosis factor-related apoptosis-inducing ligand-dependent manner that synergistically accompanies a down-regulation of anti-apoptotic proteins<sup>[41]</sup>.

Notably, despite overall tumour growth could be reduced through TLR3 activation (from a 3-fold increase, when no TLR3's stimulus is present, to an only 1.9-fold increase after TLR3's agonists being used), the number of tumour nodules increases even after eliciting TLR3 signalling, leading to the conclusion that it does not affects the incidence but limits their growth<sup>[47]</sup>.

Interestingly, it appears that in HCC carcinogenesis TLR3 is a TLR that works as a protector against cancer. This is possible through molecules, downstream to TLR3, such as caspases, INF-γ or NF-κB, influencing crucial processes like angiogenesis, cell growth or proliferation (Figure 3).

#### TLR4

It is known that, despite being present in multiple liver cells, TLR4 expression is relatively low in this organ<sup>[49]</sup>. However, following liver damage and inflammation it is possible to assist to an up-regulation of this receptor<sup>[50]</sup>. Emerging evidence associates TLR4 to several types of tumours, enlightening its role in carcinogenesis, metastasis and cancer progression<sup>[51]</sup>. Observation of human's livers detected a high expression of TLR4 in cancer cells of HCC patients<sup>[49]</sup>.

Bacterial LPS is capable of initiating TLR4 signalling and subsequently activating NF-κB and MAPK signalling pathways - p38, ERK, JNK. In fact, in a HCC cell line incubated with bacterial LPS both TLR4 expression<sup>[52-54]</sup> and MAPK signalling pathways are significantly augmented<sup>[52]</sup>. However, it was found that, in contrast with a normal hepatocytes cell line, in a HCC cell line, the cellular growth was augmented and the cytotoxicity induced by LPS was decreased and dependent on TLR4 expression (higher expression is equal to less cytotoxicity)<sup>[49]</sup>. Additionally, these effects are reduced after inhibiting TLR4 signalling<sup>[55]</sup>.

The explanation of these results is based on two perspectives. One based on the fact that, in TLR4-overexpressing cells, ERK and JNK's activity is promoted<sup>[49]</sup> contributing to cell survival and proliferation. Nonetheless, loss of TLR4 results in a substantial decrease in proliferating hepatocytes as well as in a reduced duration of JNK and ERK mitogenic signals<sup>[56]</sup>. This pro-survival effect, when facing LPS, can also be blocked by down-regulating this TLR4-downstream molecules - ERK and JNK<sup>[49]</sup>.

A second and slightly opposing situation relies on p38 - capable of inducing cell cycle arrest and apoptosis - and NF-κB - capable of stimulating pro-inflammatory cytokines (IL-1, -6, -10, TNF-α)<sup>[57]</sup> - that were inhibited by LPS, in a TLR4-overexpressing HCC cell line, allowing

cell proliferation<sup>[49]</sup>. In fact, after stimulating TLR4, either blocking<sup>[49]</sup> or augmenting<sup>[39,55]</sup> NF- $\kappa$ B have been reported to promote tumour's survival. Once more we face an ambiguity in interpreting NF- $\kappa$ B values. However, in this situation, the explanation can rely on the degree of the stimuli/block and the underlying inflammation<sup>[3]</sup>.

Consequently, we are able to conclude that increased expression of TLR4 may protect HCC cells from LPS-induced cytotoxicity and promote cell HCC survival and proliferation.

This pro-tumorigenic effect of TLR4 is confirmed by the fact that, in TLR4<sup>-/-</sup> mice subjected to DEN, tumour incidence is 25% lower and diameters are smaller accompanied by less inflammation, proliferation as well as enhanced apoptosis<sup>[56]</sup>. Moreover, using antibiotics to reduce the LPS levels results in diminished activation of T helper 1 cells<sup>[58]</sup> and consequently less liver damage, and lower cell proliferation in tumour mass<sup>[56]</sup>.

However, Xu *et al.*<sup>[54]</sup> presented a different vision when reported increased expression of protein tyrosine phosphatase receptor type O (PTPRO) in TLR4-over-expressing HCC cell lines after LPS treatment. Here, cell proliferation was inhibited and apoptosis was augmented as a result of the tumour suppressor capability of PTPRO<sup>[54]</sup>. To that end, it was found that, contrarily to the effects on LPS-induced cytotoxicity, TLR4-overexpression might also have a protective role through PTPRO and thus, worth being subjected to new studies.

Li *et al.*<sup>[52]</sup> also observed that, with TLR4 over-expression, came a gradual disappearance of epithelial cell markers and increased mesenchymal ones, suggesting an epithelial-mesenchymal transition (EMT). This EMT is considered to be the molecular basis of tumour cell infiltration and metastasis<sup>[59]</sup> and can, actually, be induced by two possible pathways related to TLR4 and LPS stimulus. On one hand, the TLR4 - MAPK/JNK pathway, confirmed by the fact that, blocking directly MAPK/JNK or indirectly through TLR4, lead to inhibition of LPS-induced EMT<sup>[52]</sup>. On the other hand, Snail, a transcription factor handled by NF- $\kappa$ B and a major inducer of EMT<sup>[53]</sup>.

For this reason, LPS, *via* activation of TLR4 signalling pathway and consequently MAPK/JNK pathway activation or NF- $\kappa$ B up-regulation, can significantly induce EMT.

This EMT phenotype is conveyed by cancer stem cells<sup>[60]</sup> which, in turn, are thought to be involved in processes like formation and progression of cancer, being, inclusively, responsible for chemotherapy resistance, metastasis and postoperative recurrence<sup>[61,62]</sup>. Recent studies revealed that TLR4 positive cells exhibit a series of stem cells characteristics<sup>[50,60]</sup>. These cells not only display a higher invasive ability, when compared to TLR4 negatives, but also express many stem cell markers (CD133 increase 85% when TLR4 is overexpressed<sup>[60]</sup>) as well as a stronger colony forming ability and increased chemotherapy/apoptosis resistance<sup>[50]</sup>.

In agreement with these results, Chen *et al.*<sup>[60]</sup> proposed that TLR4 could work as a proto-oncogene which aberrant expression/activation leads to induction

of pluripotency genes and genesis of tumour-initiating stem-like cells (TICs). This process is possible through activation of a TLR4/NANOG pathway<sup>[60,62-64]</sup> and consequent inhibition of the transforming growth factor  $\beta$  (TGF- $\beta$ )<sup>[60,62,64]</sup>.

NANOG is *per se* a core transcription factor found in pluripotent stem cells<sup>[62]</sup>. TGF- $\beta$  is an effective proliferation inhibitor and an apoptosis promoter that, when down-regulated, is able to initiate tumorigenesis *via* stemness gene induction in an epithelial tissue such as liver<sup>[60]</sup>. In fact, knockdown of TLR4 attenuated the induction of stem cell genes as well as DNA synthesis of TICs in 50% to 80% and blocking NANOG, results in a tumour growth reduction of 60% to 75%<sup>[60]</sup>.

However, some cancer cells grow efficiently *in vitro* without addition of LPS but this growth is still reduced by TLR4 knockdown, suggesting LPS-independent mechanisms of TLR4 activation in these cells<sup>[64]</sup>. One possibility includes non-LPS ligands influencing tumorigenesis through TLR4 signalling.

Yan *et al.*<sup>[65]</sup> observed that hypoxia was also responsible for TLR4 up-regulation in an HCC cell line. Hypoxia is a hallmark of several solid tumours, including HCC, and an important factor in tumour progression<sup>[66]</sup>. A possible explanation of this relationship may involve hypoxia-induced HMGB1 release, capable of activating TLR4 signalling and consequently augment caspase-1. This one is, in turn, related with maturation of pro-inflammatory cytokines and consequent tumorigenesis and tumour progression. After TLR4 blockage, caspase-1 expression diminished significantly<sup>[65]</sup>. Additionally, caspase-1 blocking was capable of decreasing HCC cell invasiveness<sup>[65]</sup>. This suggests that hypoxia-induced caspase-1 activation, as well as caspase-1-mediated tumour progression, can depend on TLR4 signalling.

In spite of several evidences attributing a pro-tumorigenic role to TLR4, the pathways to that end are many and still not fully understood. Diminished apoptotic-response to LPS, EMT-induction or caspase-1 up-regulation through TLR4 were already proposed but, opposing effects mediated by tumour suppressors like PTPRO were also found (Figure 4). According to these results new studies are suggested to clarify not only how each work, but also how they are related. However, contrarily to TLR2 most data suggests that TLR4 activation not only has an important role in inflammation and fibrosis but also in HCC initiation and progression.

## TLR9

A possible relationship between TLR9 and carcinogenesis came to light when its high expression levels of TLR9 were found in samples of lung and breast cancer cell lines<sup>[67]</sup>. HCC cells exhibit a broad repertoire of TLRs, also including TLR9. This receptor plays a crucial role in cell survival as it recognises several bacterial and viral components, including unmethylated CpG-DNA. Different works revealed that there is an augmented TLR9 positivity in human HCC cells<sup>[8,68,69]</sup> with Eiró *et al.*<sup>[8]</sup>

**Figure 4** Toll-like receptor 4's signalling pathways influencing hepatocarcinogenesis. Bacterial LPS is capable of initiate TLR4 signalling and subsequently activate NF- $\kappa$ B and MAPK signalling pathways. In one hand, in a HCC cell line incubated with bacterial LPS both TLR4 expression and MAPK signalling pathways are significantly augmented, contributing to cell survival and proliferation. On the other hand, TLR4 over-expression contributes to an EMT through MAPKs pathway and Snail. Additionally, NANOG induces TICs' formation. Both are considered to be the molecular basis of tumour cell infiltration and metastasis. HMGB1's stimulation of TLR4 with caspase-1 activation is related with maturation of pro-inflammatory cytokines and consequent tumorigenesis and tumour progression. TLR4: Toll-like receptor 4; LPS: Lipopolysaccharides; HCC: Hepatocarcinoma; MAPK: Mitogen-activated protein kinase; EMT: Epithelial-mesenchymal transition; TICs: Tumour-initiating stem-like cells; NF- $\kappa$ B: Nuclear transcription factor kappa B; HMGB1: High mobility group box 1.

showing a TLR9's prevalence of 60% (in a population of 30 cases) and Tanaka *et al.*<sup>[68]</sup> reaching the 85.7% (in a population of 42 cases) in their works with human samples of HCC. Moreover, in the later, 7 of 8 cases of HCC metastasis presented TLR9 positivity<sup>[68]</sup>. Additionally, it was found that, in both HCC cell line or HCC human samples, TLR9 was present not only in the cytoplasm but also on cells' membrane<sup>[68]</sup>. However, is important to notice that, possibly, only the stimulation of membrane receptors could result in increased cell viability as transfecting a TLR9 agonist, CpG-oligodesoxynucleotide (CpG-ODN), which stimulates intracellular TLR9 receptors, may not affect proliferation and survival<sup>[68]</sup>. The explanation for this tumour-promoter role of TLR9 comes from the fact that, after TLR9 stimulation, a HCC cell line is able to, not only up-regulate apoptosis inhibitors such as survivin, Bcl-xL, XIAP and cFLIP, but also, to closely modulate oncogenic genes with a major contribution in tumorigenesis and cancer progression<sup>[68]</sup> (Figure 5).

Although, this data is not that linear, and, somehow, different from what Zhang *et al.*<sup>[70,71]</sup> stated in their studies. Here, transfecting a TLR9 agonist into a HCC cell line lead to a marked increase in IFN- $\alpha$ , IFN- $\beta$ , TNF- $\alpha$ , IL-6 and IL-8 without activating NF- $\alpha$ B. As a result a cell-proliferation's inhibition rate was increased approximately 50% and apoptosis was augmented<sup>[70,71]</sup>.

The contradictory findings about the influence on tumour's environment of intracellular TLR9 agonists could be explained by the fact that the phosphorothioate-modified backbone of CpG-ODN are able to form a complex with or cause conformational changes in other compounds, like Poly (I:C) that, normally would result in enhanced apoptosis but, when together with CpG-ODN, are unable to act<sup>[70]</sup>. Moreover is important to look at the

**Figure 5** Toll-like receptor 9's signalling pathways influencing hepatocarcinoma. TLR9 is present not only in the cytoplasm but also on cells' membrane. However, it is still controversial whether cytoplasmatic stimulation results in increased cell viability. Independently, membrane receptors' stimulation results, not only, in up-regulation of apoptosis inhibitors such as survivin, Bcl-xL, XIAP and c-FLIP, but also, in a modulation of oncogenic genes with a major contribution in tumorigenesis and cancer progression. Additionally, a cytoplasmatic HMGB1-mtDNA interaction was proved to be capable of activating TLR9 and MAPK pathway as well as NF- $\kappa$ B leading to augmented survival, growth, proliferation, differentiation and migration of cancer cells. TLR9: Toll-like receptor 9; XIAP: X-linked inhibitor of apoptosis protein; c-FLIP: Cellular FLICE-Like inhibitory protein; MAPK: Mitogen-activated protein kinase; NF- $\kappa$ B: Nuclear transcription factor kappa B; HMGB1: High mobility group box 1.

protocols used, as CpG-ODN induces HCC cell apoptosis in a dose-dependent manner, at concentrations below 0.5  $\mu$ g/mL. In contrast, high concentrations of this agonist (e.g., 5  $\mu$ g/mL) had no effect on HCC cells<sup>[71]</sup>.

Additionally, this pathway from TLR9 signalling to carcinogenesis is supported by HMGB1. We have already seen that HMGB1 and hypoxia could influence tumorigenesis through different TLRs. Interestingly, they are, also, both involved with TLR9. It was seen that along with TLR9 overexpression, hypoxic cancer cells accumulate structurally and functionally abnormal mitochondria, which release mitochondrial DNA (mtDNA) to the cytosol, and induce translocation of HMGB1 from nucleus to cytoplasm<sup>[69]</sup>. The role of HMGB1 as a promoter of invasion, metastasis and angiogenesis when its location is extracellular is not new<sup>[72]</sup>. However, Liu *et al.*<sup>[69]</sup> revealed that, on top of this, an cytoplasmatic HMGB1-mtDNA interaction is required for complete activation of TLR9 signalling cascade and therefore essential for HCC cells to proliferate under hypoxic conditions. The underlying mechanism in this pro-tumorigenic pathway lies in MAPKs activation - fundamental in growth, proliferation, differentiation and migration<sup>[73]</sup> - and also in NF- $\kappa$ B signalling - capable of suppressing apoptosis in response to stress<sup>[74]</sup> - after the interaction between HMGB1/mtDNA and TLR9<sup>[69,75]</sup> (Figure 5).

## TLRS GENETIC POLYMORPHISMS AND VARIANTS AND HCC SUSCEPTIBILITY

Several authors have already focused their studies on the relationship between TLRs' genetics and carcinogenesis, approaching different cancers such as non-Hodgkin lymphoma, endometrial cancer, cervical cancer, non-cardiac gastric cancer, among others.

Genetic studies on the *TLR2* gene have shown a number of polymorphisms capable of interfering with host defenses and disease progression<sup>[76]</sup>. In fact, it was already seen that inherited variation in *TLR2* influence the risk of HCC. Genetic *TLR2* analysis revealed that two single nucleotide polymorphisms (SNP), rs3804099 and rs3804100, had a significantly different distribution between HCC patients and the healthy controls<sup>[77]</sup>. Interestingly, in what is concerned to these SNPs, Junjie *et al.*<sup>[77]</sup> suggested that, *TLR2* gene variation could play an important protective role in HCC as the heterozygous genotype comprise lesser HCC risk (OR from 0.331 to 0.759,  $P < 0.001$ ) when compared to wild-type homozygous genotype. In fact, individuals carrying the TT haplotype had a significantly decreased risk of HCC [odds ratio (OR) = 0.524, 95%CI: 0.394-0.697,  $P < 0.001$ ]. Contrarily, the CC haplotype had greater risk (OR = 2.743, 95%CI: 1.915-3.930,  $P < 0.001$ ). Unfortunately, the authors do not reveal the real influence of the referred SNPs on the *TLR2*'s activity and more studies are suggested to clarify this information.

Moreover, the frequency of a -196 to -174 deletion allele was, also, significantly higher in HCC patients than in healthy controls (22.5% vs 15.3%) and HCV-infected patients without HCC (22.5% vs 15.6%)<sup>[76]</sup>. Nischalke *et al.*<sup>[76]</sup> observations indicate that the -196 to -174 deletion allele possibly augment the risk of HCV-induced HCC, probably as a result of diminished *TLR2* signalling and thus increased viral loads. This -196 to -174 deletion not only had greater viral loads than -196 to -174 ins/ins but also, contribute to a 3-fold increase in HCC risk relatively to this -196 to -174 ins/ins when both are compared to healthy controls or a 1.5 fold increase when both are compared to hepatitis C patients without HCC<sup>[76]</sup>.

Researchers have already studied the possible presence of polymorphisms in the area of *TLR3*. It was found that, at least in the chinese population, a +1234CT polymorphism is present which might contribute to increased susceptibility to HCC (specially 1234CT and TT genotypes)<sup>[78]</sup>. The presence of this SNP is responsible for a markedly diminished *TLR3* function, which may result in up-regulated vasculature remodelling and tumour growth and, in that way, contributing to HCC<sup>[78]</sup>.

The *TLR4* is probably the more extensively studied TLR and therefore, not an exception when it comes to having polymorphisms or variants capable of influence carcinogenesis. Growing evidence has shown that *TLR4* polymorphisms are related to chronic inflammation and inflammatory-related cancer. As a matter of fact, a polymorphism in microRNA-34a binding site in *TLR4* (rs1057317) was significantly associated with higher HCC risk, especially in HBsAg (+) patients and in the AA homozygous genotypes<sup>[79]</sup>. MicroRNA-34a is capable of inducing apoptosis, G1 arrest and senescence explaining why its down-regulation may be associated with malignancy. However, there are not only polymorphisms related to augmented risk. Indeed, some mutations

of *TLR4* gene - four SNPs in 5'-UTR (rs10759930, rs2737190, rs10116253 and rs1927914) and one intron polymorphism (rs1927911) - may allow a two-fold decrease in HCC risk, especially in heterozygous genotypes when compared to wild-type homozygous<sup>[80]</sup>. The justification can rely on the fact that 5'-UTR is involved in regulation of proteins concerned with growth and differentiation in normal tissues and these SNPs may, therefore, exert regulator effects in these proteins<sup>[80]</sup>. Therefore, according to the *TLR4*'s polymorphism observed, an augmented or diminished risk of HCC is possible, even though its magnitude is small.

## TLRS AS THERAPEUTIC TARGETS FOR HCC

So far we have seen that different TLRs could work as specific modulators of HCC. Therefore it is logical to think that its use as therapeutic targets could open the door to new promising strategies in the fighting against HCC. In fact, the modulation of TLRs' signalling, by targeting either the TLRs or their adaptors or downstream signalling molecules, is not new and they have already proved to be useful in ovarian, colorectal or head and neck cancer<sup>[81]</sup>.

*TLR4* modulators seem to be important chemotherapy adjuvants that enhance chemotherapy efficacy and prolong survival<sup>[81]</sup>. TAK-242 is a *TLR4* ligand capable of selectively suppress both ligand-dependent and independent signalling *via* the intracellular domain of *TLR4*, disrupting the TRAM and TIRAP interactions with *TLR4*<sup>[82]</sup>. This small molecule is, therefore, able to down-regulate NF- $\kappa$ B and consequently diminish inflammatory mediators such as nitric oxide, TNF- $\alpha$ , IL-1, -6 and with that, reduce the proliferation/invasion activity induced by LPS in the liver cancer cell lines<sup>[57,82,83]</sup>. Furthermore, TAK-242 might also show an efficacy against inflammation mediated by excessive expression of *TLR4*, what, in fact, has been shown to happen in HCC<sup>[82]</sup>. Independently, new studies are still required for better evaluating effects, doses and other characteristics of TAK-242.

To date, we still lack an effective systemic curative therapy for advanced cases of HCC and, in most cases the only alternative is palliative treatment.

Even though, sorafenib, a multi-kinase inhibitor, represents an important chemotherapeutic drug in the treatment of this type of cancer. Xu *et al.*<sup>[84]</sup> found that a combination of sorafenib with a *TLR3*-synergist (BM-06) results in a superior inhibition of tumour growth in HCC cell lines or rat models when compared to the two different agents alone. Their results were based on a significantly reduced proliferative capacity, invasion ability, tumour volume and an increased apoptotic rate<sup>[84]</sup>. Therefore, BM-06 emerges as a possible adjuvant agent in the therapeutic against HCC.

In the *TLR9* domain several studies were already conducted. It was reported that using *TLR9* antagonists

**Figure 6 Toll-like receptors influence on the pathway to hepatocarcinoma.** Several factors are known to contribute to the carcinogenic process including viral hepatitis, alcohol, auto-immune or metabolic diseases, among others and the link between all this factors is chronic inflammation which, in turn, is an important hepatocarcinoma's precursor. Moreover, innate immunity represents an important player in this equation with TLRs such as 4 and 9 having, mainly, a positive contribution to hepatocarcinogenesis and TLR3, essentially, a negative/protective one. TLR2 still presents an ambiguous role, possibly depending on liver's stage in the inflammation-cirrhosis-carcinoma axis to exert its pro-tumorigenic or anti-tumorigenic capacity. TLR: Toll-like receptor.

like chloroquine could be useful in several autoimmune diseases<sup>[2]</sup>. In fact, a markedly reduced proliferation is seen in a HCC cell line when TLR9 is inhibited by chloroquine<sup>[2]</sup>. This antimalaric agent works as a direct TLR9 antagonist, being proposed that its activity on HCC cells may be brought about *via* its effects on the protein kinase AKT, tumour-associated angiogenesis factor VEGF as well as NF- $\kappa$ B. Moreover, the same tumour growth restriction, followed by smaller volume and reduction in tumour's markers of aggressiveness was seen when this treatment was used in HCC cell lines intrahepatic implanted in mice<sup>[2]</sup>.

However, as it was said, sometimes, the only option is the palliation and radiofrequency ablation (RFA) which has already established an important role in this setting. Behm *et al.*<sup>[85]</sup> successfully demonstrated that, in a rabbit model, TLR9 agonists could work together with RFA in an anti-tumour response through a strong cytotoxic immune response mediated by increased tumour-specific lymphocytes. In fact, it was not only a good predictor of containment of tumour growth and spread but also of prolonged survival<sup>[85]</sup>.

Moreover, some studies focus on the use of TLRs as vaccine's adjuvants against HCV or HBV mediated hepatocarcinogenesis. There are also some proposals for using TLR4's antagonists in patients with septic shock<sup>[86]</sup>. Besides this, the use of TLR4's antagonists is being investigated in the prevention of alcoholic liver injury and Non Alcoholic Steato-Hepatitis<sup>[9]</sup>.

Despite the good results, when it comes to using TLRs as a novel HCC therapeutic it still has a long run before every mechanism is understood. TLRs' signalling pathways are too many and effects remain controversial but a lot is to be expected from these innate immunity receptors.

## CONCLUSION

HCC occupies the third place when it comes to mortality

in cancer<sup>[1]</sup>. Several factors are known to contribute to the carcinogenic process including viral hepatitis, alcohol, auto-immune or metabolic diseases, among others. The link between all these factors is inflammation or, more precisely, chronic inflammation.

However, despite all this malignant potential or this knowledge around the inflammatory causality, most of the pathways of carcinogenesis are still unknown or, at least, not entirely known.

TLRs' role in the tumour formation is part of a more recent concept that involves innate immunity but, despite all the advances, a lot is still waiting to be studied. The reasons for this lack of information include the range of responses that can be obtained from a single TLR signalling. Humans dispose of 11 TLRs capable of initiating a signal cascade from only five molecular adaptors. Consequently, some can be used by more than one receptor. Moreover, each of this activated adaptor molecules, depending on the initial TLR, elicit a response based on the production of several effectors, pro-inflammatory or anti-inflammatory cytokines, interferons and many others with countless results.

To understand the role of TLRs we must remember that HCC comes from an inflammatory background where a complex and progressive process appears with fibrosis and cirrhosis until the last stage, HCC, is reached. This review tried to show that, the path taken can be closely influenced by innate immunity/TLRs (Figure 6). TLR2 was shown to be an important stress manager so that, in its absence, an attenuated ASK1/p38 MAPK/NF- $\kappa$ B pathway and an increased JNK activity result in a larger and less differentiated HCC. Contrarily, TLR2's stimulation through HMGB1 and HSPA1A also indicates a tumour-promoter role. TLR3 may be responsible for driving HCC and endothelial cells to apoptosis and decreasing invasiveness and angiogenesis by mediating NF- $\kappa$ B, caspase-8 and INF- $\gamma$  up-regulation. TLR4 is closely related to LPS cytotoxic, which is diminished in TLR4-overexpressing HCC due to promoted ERK's and JNK's activity and limited NF- $\kappa$ B and p38 activation. Moreover, this receptor is tightly involved in EMT and progression of cancer based on non-LPS ligands like NANOG and HMGB1. TLR9 activity is different whether the membrane or the intracellular receptor is activated. The first promotes HCC through apoptosis inhibitors and oncogenic genes. The second augments apoptosis by increasing Interferons and interleukines. Consequently, initial findings attribute a pro-tumorigenic role to TLR4 and TLR9 and a protective capacity to TLR3. When it comes to TLR2, the available data suggests that its influence may go both ways (pro-tumorigenic and protective) depending on the liver's stage in the inflammation-cirrhosis-carcinoma axis. However this is not that simple or linear as a closer look easily reveals studies with interesting but opposing conclusions from the ones before.

Independently of this lack of knowledge, one thing is certain; TLRs can have a determining influence on the cancer's progression. Therefore, the usage of TLRs

as therapeutic targets has already been established, especially as adjuvants to other agents currently in use. However, the possibilities are many and with a deeper insight over the mechanisms involved new ways of dealing with HCC are expected to emerge.

In conclusion, we cannot say that TLRs came to facilitate our understanding of HCC mechanisms. Instead they came to open the door to a new reality and, with that, to possible new approaches, perhaps in a closer future than we might know.

### Abstract

Hepatitis C virus (HCV) infection is a serious problem worldwide. The use of interferon-based therapy has made HCV eradication challenging. The recent appearance of direct-acting antiviral agents (DAAs) has changed HCV therapy. Combining the use of DAAs with peginterferon and ribavirin has improved treatment efficacy. Furthermore, the combination of different orally administered DAAs has enabled interferon-free therapy with much higher efficacy and safety. In particular, sofosbuvir, a nucleotide-based NS5B inhibitor, prevents HCV RNA synthesis by acting as a "chain terminator". Treatment with sofosbuvir has attained an extremely high rate of sustained virologic response. The current review summarizes the efficacy and safety of sofosbuvir therapy.

**Key words:** Hepatitis C virus; Interferon; Interferon-free; Genotype; Sofosbuvir

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Sofosbuvir, a nucleotide-based NS5B inhibitor, is an effective treatment against pangenotypic strains of hepatitis C virus (HCV). Sofosbuvir-containing regimens have attained extremely high rates of sustained virologic response. Because regimens including sofosbuvir result in fewer adverse events than interferon-based regimens, sofosbuvir has taken a central role in HCV treatment.

## INTRODUCTION

Hepatitis C virus (HCV) infection is a global public health problem. Approximately 130 to 170 million people experience chronic HCV infection, which has a global prevalence of 2%-3%<sup>[1,2]</sup>. In 2002, worldwide, 27% of 783000 deaths from cirrhosis and 25% of 619000 deaths from hepatocellular carcinoma were attributed to HCV infection<sup>[3]</sup>.

The use of interferon-based therapy has made HCV eradication challenging, especially for patients infected with HCV genotype 1. Treatment with peginterferon plus ribavirin induces only about 50% of patients infected with HCV genotype 1 at high viral loads to achieve sustained virologic response (SVR)<sup>[4]</sup>, while about 80% of patients infected with HCV genotypes 2 and 3 achieve SVR<sup>[5]</sup>.

The appearance of direct-acting antiviral agents (DAAs), which specifically target HCV proteins, has provided insights into the current situation. The use of protease inhibitors, such as telaprevir, boceprevir, simeprevir, faldaprevir and vaniprevir, in combination with peginterferon and ribavirin has improved treatment efficacy in treatment-naïve patients (70% to 80% achieve SVR) and in patients infected with HCV genotype 1 who have relapsed post-treatment<sup>[6-10]</sup>. However, SVR rates in patients who exhibited no responses to previous treatments remain low<sup>[11,12]</sup>. Furthermore, patients who are ineligible for or intolerant to treatment with peginterferon plus ribavirin are contra-indicated from receiving the above treatment.

The use of combinations of different orally administered DAAs has enabled the realization of interferon-free therapy. DAA-based therapies generally have higher treatment efficacy and lower risk for adverse effects compared to regimens using interferon. In particular, sofosbuvir, a pyrimidine nucleoside analog inhibitor of HCV pangenotype NS5B polymerase, has produced extremely high rates of SVR when used in combination with other DAAs. In the current review, we discuss the use of treatment regimens that include sofosbuvir to combat HCV.

## STRUCTURE OF HCV GENOME AND DAAS

HCV is an enveloped, positive-stranded RNA virus. Its genome spans 9600 nucleotides in length and contains a 5' non-translated region (5' NTR), a single open reading frame and a 3' NTR. A single polyprotein is translated from HCV genome and is then cleaved into structural (core, E1, E2 and p7) and non-structural (NS2, NS3, NS4A, NS4B, NS5A and NS5B) proteins<sup>[4]</sup>. The

serine protease NS3 plays a key role in processing the HCV polyprotein. The phosphoprotein NS5A and RNA-dependent RNA polymerase NS5B are essential to the replication of HCV RNA. DAAs against HCV target these proteins and strongly inhibit HCV replication.

The first-generation NS3/4A protease inhibitors telaprevir and boceprevir are typically used in combination with peginterferon and ribavirin. This triple regimen has improved SVR rates in HCV genotype 1-infected patients<sup>[6,7]</sup> but often produces serious adverse events<sup>[13]</sup>. The second-generation NS3/4A protease inhibitors simeprevir, faldaprevir and vaniprevir have further improved treatment efficacy while resulting in fewer adverse effects<sup>[8-10]</sup>.

In Japan, daclatasvir, a first-in-class NS5A inhibitor, enabled effective interferon-free therapy for the first time. Interferon-free dual oral therapy with daclatasvir and asunaprevir, a NS3/4A protease inhibitor, led to high SVR rates (87.4% in interferon-ineligible or -intolerant patients, 80.5% in non-responders, 89.1% in treatment-naïve patients, and 95.5% in relapsers)<sup>[14,15]</sup>. However, the evolution of drug-resistant HCV variants has created new problems. For example, Y93H variants of the NS5A protein have markedly decreased SVR rates to as low as 43.3%<sup>[14]</sup>.

### Sofosbuvir

Sofosbuvir (formerly known as GS-7977; Gilead Sciences, Foster City, CA, United States) is a nucleotide NS5B inhibitor<sup>[16]</sup>. Sofosbuvir is converted into a pharmacologically active form (GS-461203) within hepatocytes<sup>[17]</sup>. GS-461203 inhibits RNA-dependent RNA polymerase activity by competing with uridine and prevents HCV RNA synthesis by acting as "chain terminator". Because the catalytic site of the NS5B protein is highly conserved, sofosbuvir is believed to have pangenotypic activity<sup>[18]</sup>.

Another favorable characteristic of sofosbuvir is its high genetic barrier. In an HCV replicon study, a S282T substitution in NS5B was reported to impart drug resistance<sup>[19]</sup>. However, in clinical trials, this NS5B variant was detected in only one patient after treatment with sofosbuvir monotherapy<sup>[16,20-22]</sup>. Foster *et al.*<sup>[23]</sup> reported that sofosbuvir treatment led to the emergence of drug-resistant variants in 9/78 (12%) of patients. An L159F variant was present both at baseline and at the time of virologic failure in 1 patient and at the time of virologic failure in 7 additional patients. The V321A variant emerged at the time of virologic failure in 2 patients.

Sofosbuvir also possess a noteworthy safety profile and high tolerability. In phase 3 trials of sofosbuvir, the frequency of serious adverse events ranged from 1% to 8% and the rate of treatment discontinuation because of adverse events range from 0% to 4.4%<sup>[24,25]</sup>.

## CLINICAL EFFICACY OF TREATMENT REGIMEN CONTAINING SOFOSBUVIR

More than 3000 patients have been assessed in clinical

**Table 1 Summary of phase 3 study for hepatitis C virus genotype 1-infected patients**

LC: Liver cirrhosis; SVR12: Sustained virologic response at 12 wk; Naïve: Treatment-naïve; Experienced: Treatment-experienced; SOF: Sofosbuvir; LDV: Ledipasvir; PEG-IFN: Peginterferon; RBV: Ribavirin.

studies of treatment regimens containing sofosbuvir. Below, we describe the efficacy of a sofosbuvir-containing regimen.

#### **HCV genotype 1-specific virologic response of sofosbuvir**

The results from phase 3 clinical trials evaluating the use of treatment regimens containing sofosbuvir against HCV genotype 1 are shown in Table 1. The NEUTRINO study was the first phase 3 trial to evaluate sofosbuvir-containing therapy<sup>[26]</sup>. In this single-group, open-label study, 291 treatment-naïve patients infected with HCV genotype 1 were treated with sofosbuvir plus peginterferon and ribavirin for 12 wk. The patients attained a high rate of SVR at 12 wk after completion of therapy (SVR12) (89%) and had a low rate of treatment discontinuation (2%) compared with historical controls. This study demonstrated the efficacy and safety of combining sofosbuvir with peginterferon and ribavirin; however, patients contraindicated for peginterferon or ribavirin were excluded.

Based on high rates of SVR in phase 2 studies, phase 3 ION studies (ION-1, ION-2 and ION-3 studies) were conducted to assess a fixed-dose combination of sofosbuvir and ledipasvir<sup>[27-30]</sup>. In the ION-1 trial, 865 treatment-naïve patients infected with HCV genotype 1 were randomly divided into four groups and received either 12 or 24 wk of sofosbuvir and ledipasvir with or without ribavirin. High SVR12 rates were attained in all groups (range: 97%-99%), and no patients in either 12-wk group discontinued therapy because of adverse events<sup>[28]</sup>.

The ION-2 trial was conducted to evaluate the combination of sofosbuvir and ledipasvir with or without ribavirin in treatment-experienced patients. In this trial, 440 patients were divided into groups and treated with either 12 or 24 wk of sofosbuvir and ledipasvir with

or without ribavirin. As in the ION-1 trial, high SVR12 rates were attained in all treatment groups (range: 94%-99%). No cases of treatment discontinuation owing to adverse events were reported<sup>[29]</sup>.

The ION-3 trial was conducted to evaluate the feasibility of shorter duration therapy in previously untreated patients without cirrhosis. The noninferiority of an 8-wk regimen was demonstrated by the similar SVR12 rates in all groups (range: 93%-95%)<sup>[30]</sup>. The results from the ION-3 trial also indicated that an 8-wk regimen of sofosbuvir plus ledipasvir is not generally equal to 12 wk of treatment; however, international guidelines recommend that an HCV RNA threshold of 6 million IU/mL is maintained.

Among Asian countries, Mizokami *et al.*<sup>[25]</sup> reported a phase 3 study conducted to evaluate Japanese patients. In this study, 166 treatment-naïve and 175 treatment-experienced patients received 12 wk of sofosbuvir and ledipasvir with or without ribavirin. High SVR12 rates (range: 96%-100%) were also attained in this study. This is noteworthy, as Japanese patients tend to be older, have more advanced fibrosis and are more frequently treated with previous therapy than patients in other countries. In the above studies, the inclusion of ribavirin in the treatment regimens produced no additional benefit. Furthermore, adverse events were more common in groups treated with ribavirin than in those without ribavirin.

The SOLAR-1 and SOLAR-2 studies showed the usefulness of sofosbuvir plus ledipasvir for decompensated cirrhosis<sup>[31,32]</sup>. In patients with cirrhosis and moderate or severe hepatic impairment who had not undergone liver transplantation, 86%-89% SVR12 rates were achieved<sup>[31]</sup>. In patients who had undergone liver transplantation, 96%-98%, 85%-88%, and 60%-75% SVR12 rates were achieved in patients without cirrhosis or with well-compensated cirrhosis, patients with

moderate hepatic impairment, and patients with severe hepatic impairment, respectively<sup>[31]</sup>. All 6 patients with fibrosing cholestatic hepatitis achieved SVR12. Response rates in the 12- and 24-wk treatment groups were similar<sup>[31]</sup>. The use of sofosbuvir plus simeprevir for 12 and 8 wk in HCV genotype 1-infected patients without cirrhosis resulted in 83% and 97% SVR12 rates, respectively<sup>[33]</sup>. Likewise, the use of sofosbuvir plus simeprevir for 12 wk resulted in an 83% SVR12 rate in HCV genotype 1 - infected patients with cirrhosis<sup>[34]</sup>.

#### **HCV genotype 2-specific virologic response of sofosbuvir**

The results from phase 3 clinical trials evaluating the use of treatments containing sofosbuvir against HCV genotype 2-infected patients are shown in Table 2. Three phase 3 trials have evaluated previously untreated patients (the FISSION, POSITRON and VALENCE studies)<sup>[23,29-31]</sup>. In the FISSION study, 12 wk of sofosbuvir plus ribavirin treatment and 24 wk of Peg-interferon  $\alpha$ -2a (Peg-IFN $\alpha$ 2a) plus ribavirin treatment produced comparable results in treatment-naïve patients. The SVR12 rate was 97% in a group of 70 patients who received sofosbuvir plus ribavirin and 78% in a group of 67 patients who received Peg-IFN $\alpha$ 2a plus ribavirin. The noninferiority of the sofosbuvir plus ribavirin regimen relative to interferon-based therapy was shown. Furthermore, adverse events were less frequent with the sofosbuvir plus ribavirin regimen<sup>[26,35]</sup>.

In the POSITRON study, 109 patients for whom treatment with Peg-IFN was not an option received 12 wk of sofosbuvir plus ribavirin, and 78% of these patients achieved SVR12<sup>[36]</sup>. These results were confirmed by the VALENCE study, in which 97% of 32 treatment-naïve patients achieved SVR12<sup>[37]</sup>.

In addition, the FUSION study<sup>[36]</sup> and the other arm of the VALENCE study evaluated the use of a sofosbuvir plus ribavirin regimen in treatment-experienced patients. In the FUSION study, 103 patients received sofosbuvir plus ribavirin for 12 wk, and 98 patients received the treatment for 16 wk. The rates of SVR12 were 86% and 94% in the 12 and 16-wk groups, respectively<sup>[36]</sup>.

Omata *et al.*<sup>[38]</sup> reported the efficacy and safety of a 12-wk sofosbuvir plus ribavirin treatment in Japanese

patients. The rates of SVR12 were 98% and 95% in treatment-naïve and previously treated patients, respectively. According to these trials, the use of sofosbuvir plus ribavirin has become a standard of care for the treatment of HCV genotype 2-infected patients.

#### **HCV genotype 3-specific virologic response of sofosbuvir**

HCV genotype 3 has become the most difficult genotype to cure in the era of interferon-free therapy. Although sofosbuvir is considered to have pangenotypic inhibitory activities, its treatment efficacy against HCV genotype 3 is lower than against the other genotypes. The results from phase 3 clinical trials evaluating treatments containing sofosbuvir to combat HCV genotype 3 are shown in Table 3.

In the FISSION study, SVR12 occurred in 56% of patients who received 12 wk of sofosbuvir plus ribavirin and in 63% of patients who received 24 wk of peginterferon plus ribavirin. These results were poor, as 97% of patients infected with HCV genotype 2 achieved SVR12 following treatment with sofosbuvir plus ribavirin in the same study<sup>[26,35]</sup>.

The results of the POSITRON study were similar to those of the FISSION study. In the FISSION study, 61% patients infected with HCV genotype 3 achieved SVR12 compared to 93% of patients infected with HCV genotype 2. The rate of SVR12 in patients with cirrhosis was especially low in the HCV genotype 3 group (21%)<sup>[36]</sup>.

Although the above results are somewhat disappointing, extending the duration of treatment might improve sofosbuvir's efficacy against HCV genotype 3. In the FUSION study, 16 wk of sofosbuvir plus ribavirin therapy resulted in higher SVR12 rates than 12 wk therapy (37% vs 63% in patients without cirrhosis; 19% vs 61% in patients with cirrhosis)<sup>[36]</sup>.

In addition, the VALENCE study was conducted to assess the efficacy of 24 wk of sofosbuvir plus ribavirin treatment in 250 HCV genotype 3-infected patients<sup>[37]</sup>. The rates of SVR12 were 95% and 92% in treatment-naïve patients with and without cirrhosis, respectively, and 87% and 62% in previously treated patients with and without cirrhosis. A longer treatment duration

was not associated with a higher frequency of adverse events or treatment discontinuation. However, further studies will be necessary to improve treatment efficacy in previously treated patients with cirrhosis.

Foster *et al.*<sup>[23]</sup> reported a 93% SVR12 rate following 12 wk of treatment with peginterferon, sofosbuvir and ribavirin vs an 84% SVR12 rate following 24 wk of treatment with sofosbuvir plus ribavirin vs an 88% SVR12 rate following 12 wk of treatment with peginterferon, sofosbuvir and ribavirin in cirrhotic patients. Treatment with daclatasvir plus sofosbuvir for 12 wk led to a 96% SVR12 rate in HCV genotype 3-infected patients without cirrhosis<sup>[39]</sup>.

#### Other HCV genotypes-specific virologic response of sofosbuvir

In the NEUTRINO study, 35 patients infected with HCV genotypes 4 through 6 were treated with sofosbuvir, ribavirin and peginterferon for 12 wk. The rates of SVR12 were 96% and 100% in patients infected with HCV genotypes 4 and 5-6, respectively<sup>[26]</sup>. A treatment regimen that contains sofosbuvir might therefore be efficient against these genotypes.

The use of a ribavirin- and interferon-free regimen of ledipasvir/sofosbuvir for 12 wk resulted in an SVR4 rate of 93% in genotype 4 and genotype 5 HCV-infected treatment-naïve and treatment-experienced patients with or without cirrhosis<sup>[40]</sup>.

#### HIV co-infection

The PHOTON-1 and -2 studies were conducted to evaluate the use of sofosbuvir plus ribavirin therapy to combat HCV-human immunodeficiency virus (HIV) co-infection<sup>[41,42]</sup>. The results of these trials are summarized in Table 4.

In the PHOTON-1 study, in patients infected with HCV genotype 1, 12 wk of sofosbuvir plus ribavirin led to a 78% SVR12 rate. Extending treatment to 24 wk tended to result in higher rates of SVR (85%)<sup>[41]</sup>.

The use of a longer treatment duration also appeared to be effective in treatment-naïve patients infected with HCV genotype 3. Similar to the results from the study against HCV genotype 3 infection alone, 12 wk of sofosbuvir plus ribavirin therapy attained low rates of SVR12 compared with other genotypes in the PHOTON-1 study (67%)<sup>[32]</sup>. Extending treatment from 12 to 24 wk improved the rate of SVR12 in the PHOTON-2 study (91%)<sup>[42]</sup>. Among patients infected with other HCV genotypes, high rates of SVR12 (83%-92%) were attained after 12 wk of sofosbuvir plus ribavirin treatment in treatment-naïve patients and 24 wk of the above treatment in previously treated patients<sup>[41,42]</sup>.

The ALLY-2 study examined the use of daclatasvir plus sofosbuvir in patients co-infected with HIV and HCV genotype 1. The results showed that SVR rates were 96.4% following 12 wk of treatment and 75.6% following 8 wk of treatment in treatment-naïve patients.

The SVR12 rate was 97.7% in treatment-experienced patients following 12 wk of treatment with the above regimen<sup>[43]</sup>.

The ION-4 study evaluated the use of ledipasvir plus sofosbuvir for 12 wk in HIV co-infected patients. The SVR12 rates were 96% in HCV genotype 1a-infected patients, 96% in HCV genotype 1b-infected patients, and 100% in HCV genotype 4-infected patients<sup>[44]</sup>.

## CONCLUSION

Sofosbuvir, a first-in-class NS5B inhibitor, has rapidly become the standard of care for the treatment of numerous HCV genotypes. However, its efficacy against HCV genotype 3, especially in patients with cirrhosis, has not been satisfactory. The optimal duration of treatment and use of novel combinations with other DAAs should be examined in the future.

Patients with severe renal impairment (estimated glomerular filtration rate < 30 mL/min per 1.73 m<sup>2</sup>) and on hemodialysis are contraindicated for sofosbuvir-containing regimens. This limitation of sofosbuvir should be recognized. Nevertheless, sofosbuvir is an important drug that possesses high efficacy and safety. Sofosbuvir-containing therapy has become a standard of care for the majority of patients with HCV infections.

### Abstract

Ablative treatment methods have emerged as safe

and effective therapies for patients with primary and secondary liver tumors who are not surgical candidates at the time of diagnosis. This article reviews the current literature and describes the techniques, complications and results for radiofrequency ablation, microwave ablation, cryoablation, and irreversible electroporation.

**Key words:** Liver; Ablation; Hepatocellular carcinoma; Metastasis; Radiofrequency; Microwave; Cryoablation

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Innovative ablation techniques, including radiofrequency ablation, microwave ablation, cryoablation and irreversible electroporation have become accepted as treatment modalities for patients with early stage tumor or for single metastases. This review paper describes the available ablation techniques and summarizes the evidence supporting the use of each modality.

### INTRODUCTION

The liver is a common site for both primary malignancy and metastatic disease. Hepatocellular carcinoma (HCC) remains the fifth most common malignancy in the world and its incidence is rising<sup>[1,2]</sup>. Traditionally, the first line therapy for hepatic tumors has been surgical resection or transplantation. However, many patients are not surgical candidates at the time of diagnosis<sup>[2]</sup>. For this reason interest in minimally invasive, ablative treatment methods has grown<sup>[3]</sup>. Percutaneous ablative techniques include radiofrequency ablation (RFA), microwave ablation, cryoablation, and irreversible electroporation (IRE).

**Figure 1** Sixty-eight-year-old male with hepatitis C and cirrhosis. A: Contrast enhanced CT shows a 16 mm HCC; B: RFA probe covering the lesion; C: Post contrast follow up CT shows capsular retraction at the site of the RFA and no residual tumor. HCC: Hepatocellular carcinoma; RFA: Radiofrequency ablation; CT: Computed tomography.

This review focuses on the use of percutaneous ablative techniques in the treatment of HCC, as well as of metastatic disease from colorectal, neuroendocrine, and breast carcinomas.

## TECHNIQUE AND COMPLICATIONS

### RFA

RFA is a low risk alternative treatment for HCC and liver metastases in patients who cannot undergo surgery or transplant<sup>[4]</sup>. Unlike other non-surgical strategies (TACE, Y90), the goal of RFA is curative<sup>[4]</sup>.

### Technique

RFA creates a closed loop circuit which results in an alternating electric field causing agitation of ions within the target tissue<sup>[5]</sup>. The circuit is created using an RF generator, an electrode, grounding pads, and the patient<sup>[3]</sup>. The resultant ionic agitation creates heat leading to cell death from coagulative necrosis<sup>[6]</sup>. In order to ensure tumor destruction, the mass needs to be treated to a temperature of 50 °C-100 °C for approximately 4-5 min<sup>[6]</sup>. Temperatures higher than 100 °C can cause gas formation, also known as carbonization, which can reduce ablation effectiveness, and char adjacent tissues<sup>[7]</sup>.

In order to achieve primary technical success, the entire tumor must be ablated as well as a sufficient margin around the tumor. Similar to surgical techniques, a 1 cm margin in all planes is needed to minimize the risk of residual disease or local recurrence<sup>[3]</sup>. Therefore, the planned target ablation diameter should be 2 cm larger than the tumor diameter<sup>[3]</sup>. If the tumor is small enough, this can be accomplished with one electrode (Figure 1). However, if the tumor is too large, multiple ablations can be performed<sup>[8]</sup>, although there is a risk of local recurrence due to inadequate tumor destruction from the error inherent in positioning electrodes<sup>[3]</sup>. Other causes of inadequate tumor ablation include heterogeneous tissue composition (*i.e.*, fibrosis, calcification) and adjacent blood flow, known as a "heat sink", which can cool the tissue and reduce the maximum achieved

temperature<sup>[9]</sup>.

RFA can be performed with guidance by ultrasound (US), computed tomography (CT), or magnetic resonance imaging (MRI) depending on lesion visibility and operator experience. Patients typically receive either conscious sedation or general anesthesia to control pain and minimize patient movement during the procedure. The decision to administer prophylactic antibiotics is somewhat controversial and institution dependent. A longer course of antibiotics may be warranted in patients who are at increased risk of liver abscess, including patients with a history of biliary-enteric anastomosis, biliary stents, or sphincterotomy<sup>[6]</sup>. This is thought to be due to retrograde movement of bacteria into the ablation cavity as a result of altered anatomy<sup>[10]</sup>.

### Complications

RFA has a low rate of major complications. The largest study on RFA complications by Koda *et al.*<sup>[11]</sup> evaluated 13283 patients (16346 treated lesions) with a total of 579 complications (3.5%) and 5 deaths (0.04%). The rate of liver injury was 1.69% (276 patients) which included 75 (0.47%) hepatic infarcts, 32 (0.19%) liver abscesses, 110 (0.67%) bile duct injuries, and 37 (0.23%) bile leaks<sup>[11]</sup>. A more recent study from Lee *et al.*<sup>[1]</sup> reported a similar major complication rate of 3.1% in 169 treated lesions, including 2 bile duct injuries. The overall reported complication rate ranges from 2.2% to 9.5%<sup>[6]</sup>.

The rate of extrahepatic injury is also extremely rare. Koda *et al.*<sup>[11]</sup> reported a total of 113 (0.69%) extrahepatic complications including, in order of decreasing frequency, pleural effusions, skin burns, pneumothorax, gastrointestinal injury, diaphragmatic injury, gallbladder injury, and cardiac tamponade. The risk of extrahepatic injury can be reduced by a technique called "hydrodissection", which involves injecting D5W to create space between adjacent organs. Saline infusions are not used for hydrodissection due to the theoretical risk of conduction of the electrical current through this type of fluid. Another potential complication is seeding, either in the peritoneum or along the ablation track. The

**Figure 2** Sixty-one-year-old with a history of alcohol abuse and cirrhosis. A: MRI demonstrates a 13 mm HCC in the left lobe; B: Two cryoablation probes covering the lesion; C: Post contrast follow up MRI shows capsular retraction at the site of the cryoablation and no residual tumor. MRI: Magnetic resonance imaging; HCC: Hepatocellular carcinoma.

reported risk of tumor seeding ranges from 0.04%<sup>[11]</sup> to 0.6%<sup>[12]</sup>. The risk (0.95%) of tumor seeding has been described to be slightly increased when concomitant biopsy is performed<sup>[12]</sup>.

### Cryoablation

Cryoablation involves rapid cooling of a cryoprobe resulting in cell death<sup>[13]</sup>. Cryoablation has been historically used for both HCC (Figure 2) and hepatic metastases.

### Technique

Cryoablation works by passing high pressure argon gas through a probe resulting in cooling of the metallic. As the probe cools, surrounding tissues are also cooled by convection and conduction<sup>[14]</sup>. Helium gas is then forced through the probe causing warming of the probe and thawing of the adjacent tissues. The cooling and subsequent thawing of the probe results in cell death by a variety of methods. The initial cooling results in intracellular ice crystal formation leading to cell membrane damage and death<sup>[15]</sup>. Larger ice crystals also form during slow thawing, resulting in a shearing effect and additional cell death<sup>[16]</sup>. Lastly, ice crystals develop in the small blood vessels feeding a tumor, leading to ischemia<sup>[16]</sup>. Like the other ablative techniques, cryoablation can be performed percutaneously or laparoscopically. Percutaneous cryoablation can be performed with CT, MRI or US guidance.

Although cryoablation has many uses for tumor ablation, including renal and osseous lesions, its utility in the liver is somewhat limited. The disadvantages of cryoablation include variable ablation size (resulting in the need for multiple cryoprobes), reduced cooling effect due to a heat sink from hepatic vessels, and the risk of major complications. An advantage of cryoablation over other ablative techniques is that the ice ball can be visualized during the procedure under both CT and ultrasound guidance, allowing for better adjustment.

### Complications

The risk of complication within the liver is higher with cryoablation compared to RFA. Complications include hemorrhage, injury to adjacent organs, biliary injury, and

“cryoshock”. Hemorrhage results from ice ball formation within the liver leading to shearing injury to the liver parenchyma and nearby blood vessels. Shearing forces can also cause biliary injury which can lead to late hemorrhage or hepatic abscess formation. Cryoablation of lesions near the liver edge risks damage to adjacent organs, usually bowel, kidney or adrenal glands. A complication unique to cryoablation is “cryoshock” which occurs due to the release of cytokines, resulting in a systemic syndrome characterized by fever, tachycardia, and tachypnea. A retrospective study by Adam *et al.*<sup>[17]</sup> found increased complication rates among patients treated with cryoablation (29%) compared to those who underwent RFA (8%). Additional studies have found similar results including a study demonstrating a 41% complication rate for cryoablation patients compared to 3% in patients who underwent RFA<sup>[18]</sup>.

However, a large study by Yang *et al.*<sup>[19]</sup> found very low rates of major complications with cryoablation. In this study of 300 patients who underwent cryoablation, the major complication rate was 6.3%<sup>[19]</sup>. Major complications included cryoshock (6 patients), extensive hemorrhage (5 patients), gastric bleeding (4 patients), liver abscess (1 patient), intestinal fistula (1 patient), and liver failure (2 patients)<sup>[19]</sup>. The risk of minor complications is reported to be 48.6%<sup>[19]</sup>. These include fever, pain, skin frostbite, pleural effusion, and arterial-portal venous fistula. Pneumothorax is rarely reported in treated tumors located near the diaphragm<sup>[19]</sup>.

## MICROWAVE ABLATION

### Background/indications

Microwave ablation is an emerging technology with particular applicability in treating hepatic tumors in patients who are not surgical candidates. It has been used for larger tumors than those treated by RFA<sup>[20]</sup>.

### Technique

Microwave ablation utilizes an antenna to locally deliver a high frequency (915 MHz or 2.45 GHz) oscillating electromagnetic field to induce rapid realignment of polar molecules (typically water molecules) in a lesion

**Figure 3** Sixty-two-year-old with hepatitis C cirrhosis. A: MRI shows an arterial enhancing lesion consistent with hepatocellular carcinoma; B: CT guided microwave ablation of the right hepatic lobe lesion; C: MRI shows an ablation zone and no evidence of residual tumor. MRI: Magnetic resonance imaging; CT: Computed tomography.

(Figure 3). This results in markedly increased kinetic energy and subsequent tissue heating<sup>[21]</sup>. Tissues with a larger concentration of water, such as tumors, are particularly susceptible to microwave heating<sup>[21]</sup>.

Microwave ablation can be performed with one or multiple antenna probes. Multiple antenna probes in close proximity allow for electrical and thermal synergy. Multiple probes can also be powered simultaneously which is not possible with RF ablation. Recent developments in microwave technology have produced high-powered water cooled systems which allow for smaller applicators and increased power.

Compared to RF ablation, microwave has several advantages. Microwave is capable of producing very high temperatures (greater than 150 °C) much faster than RF. In addition, microwave is more effective in propagating heating through charred and desiccated tissues which allows for a large ablation zone. Microwave does not require grounding pads or other similar devices<sup>[15]</sup>. Microwave ablation is not as susceptible to heat sink phenomena as RF ablation. This is particularly useful in the liver, which has a rich vascular supply. A recent study demonstrated larger zones of ablation and faster heating with microwave compared to RFA<sup>[22]</sup>. Additional studies have demonstrated larger and more consistent ablation zones with microwave without significant influence from adjacent hepatic vessels<sup>[23,24]</sup>. Ablation time is often less than 10 min, typically averaging 2-5 min, which improves overall efficiency and reduces anesthesia time.

Although microwave ablation is promising, several disadvantages have limited its widespread adoption. Compared to RFA, microwave power is more difficult to generate safely, mostly due to larger cables which are prone to heating issues<sup>[21]</sup>. In addition there remains still uncertainty about the size and shape of ablation zones with microwave<sup>[21]</sup>.

Microwave ablation is typically performed under general anesthesia to reduce patient discomfort and for better control of patient breathing and motion. As with RF ablation, microwave can be performed under CT or ultrasound guidance. Ultrasound allows for real time monitoring of the ablation and shorter procedure time. CT guidance allows for localization of lesions which are

difficult to visualize, and for better evaluation of adjacent structures. Hydrodissection can be used to displace adjacent structures, typically bowel or diaphragm.

### Complications

A systematic review of the literature by Lahat *et al.*<sup>[25]</sup> evaluated the safety of ablative techniques including microwave ablation. In the review of 16 studies, they reported a major complication rate of 4.6% for microwave ablation compared to 4.1% for RFA. The pooled mortality rate for microwave was 0.23% compared to 0.15% for RFA. The most common major complication was hemorrhage requiring blood transfusion. Additional complications included portal vein thrombosis, bile leak/biloma, liver abscess, pleural effusion, and tumor seeding.

### IRE

IRE is a relatively new non-thermal ablative technique approved by the Food and Drug Administration in 2006 for soft tissue ablation<sup>[26]</sup>. It has been used for liver, pancreas, kidney and lung ablations. IRE has several advantages over current, more proven ablative techniques.

### Technique

IRE utilizes multiple electrodes to deliver high voltage (2-3 kV) direct current pulses lasting microseconds to milliseconds<sup>[27]</sup>. The repeated electrical pulses cause damage to the cell membranes<sup>[26]</sup>. Initially the cell membrane damage is reversible, but it becomes irreversible after a period of time leading to apoptosis<sup>[26]</sup>. Because of the extremely short ablation time, care must be taken to ensure proper electrode positioning as mid treatment adjustment is not possible. Most IRE devices require simulation planning with the use of multiple probes placed in parallel to achieve the desired ablation zone.

IRE results in a well-defined ablation zone with sharp margins and relatively little damage to nearby tissues<sup>[27]</sup>. Because IRE does not utilize thermal methods for ablation, adjacent tissue architecture is well preserved<sup>[28]</sup>. The combination of fast ablation times

and minimal damage to nearby tissues makes IRE well suited for treatment of lesions in sensitive locations, including those adjacent to blood vessels and bile ducts. In addition, this eliminates the problems with heat sink seen in other thermal ablative techniques. However, the use of multiple parallel probes results in a significant increase in procedural cost and complexity<sup>[29]</sup>. One potential drawback to IRE is that imaging changes related to the ablation zone may take several minutes to manifest by ultrasound<sup>[30]</sup>. IRE also requires general anesthesia with paralytic agents as the electrical current generated during the procedure can cause muscle spasms and arrhythmias<sup>[31]</sup>. To lessen this risk, the IRE generator is connected to an ECG triggering device and pulses are delivered to the target/treatment zone during the cardiac refractory period<sup>[27]</sup>.

### Complications

A recent large systematic review investigated the safety and efficacy of IRE in several organs. The reported overall complication rate was 16% in 129 treated patients<sup>[26]</sup>. The most common complications included pneumothorax, portal vein thrombosis, biliary occlusion, pleural effusion, and cholangitis<sup>[26]</sup>. There was no periprocedural mortality reported in treated liver lesions, although 3 patients died after pancreatic IRE<sup>[26]</sup>. Self-reported post-procedural pain scores were similar between patients treated with IRE and RFA. Arrhythmias were reported in 4% of cases<sup>[26]</sup>. Ventricular arrhythmias were seen without synchronized pulse delivery while only atrial arrhythmias were seen in patients who received synchronized pulses<sup>[26]</sup>. No uncontrolled muscle spasms were reported in any of the reviewed studies in patients who received paralytic agents<sup>[26]</sup>.

## RESULTS OF INNOVATIVE ABLATION TECHNIQUES

### HCC

**Radiofrequency ablation:** Numerous studies support the usage of RFA as a first line treatment for HCC in patients who are poor surgical candidates. One of the largest studies by Tateishi *et al*<sup>[32]</sup> evaluated RFA of 2140 nodules measuring less than 3 cm in 664 patients. Survival rates at 1-5 years post-treatment were similar for patients with first line RFA alone compared with those who underwent RFA as part of a combination therapy<sup>[32]</sup>. In addition, the rate of local progression of disease was similar for RFA alone when compared to ethanol treatment or hepatectomy<sup>[32]</sup>. A study by Lencioni *et al*<sup>[33]</sup> evaluated patients with early stage HCC (single lesion < 5 cm or up to 3 lesions < 3 cm each) who underwent RFA alone or palliative TACE or ethanol injection. Overall survival rates at 5 years were 48% with a median survival of 57 mo for the RFA group, which was not significantly different from the TACE or ethanol groups<sup>[33]</sup>. Histologic analysis of tumors which underwent RFA and subsequent transplantation found that 74% of ablated tumors were treated successfully

by histologic criteria<sup>[34]</sup>. For tumors measuring less than 3 cm, the percentage successfully treated rose to 83%<sup>[34]</sup>. Another large study of 1502 HCC tumors in 1305 patients over 12 years by Kim *et al*<sup>[35]</sup> found survival rates of 59.7% and 32.3% at 5 and 10 years respectively. Additional studies have demonstrated similar overall recurrence and survival rates for patients who were poor surgical candidates using RFA as first line treatment<sup>[36]</sup>.

Several recent studies have evaluated RFA as a first line treatment in tumors measuring more than 3 cm. A study by Lee *et al*<sup>[1]</sup> evaluated 162 patients who underwent RFA for up to three tumors with a maximum diameter of 5 cm. Overall 5 year survival and recurrence-free survival rates were 67.9% and 25.9% respectively<sup>[1]</sup>. The most significant predictors of poor survival were Child-Pugh class B, elevated serum  $\alpha$ -fetoprotein level, and presence of portal-systemic collaterals<sup>[1]</sup>. The rate of local tumor progression at 5 years was 14.5% with tumor size being the only significant predictive factor<sup>[1]</sup>. Local tumor progression did have a significant negative effect on median recurrence free survival (28.0 mo vs 12.0 mo) and resulted in over two times more interventional procedures<sup>[1]</sup>. A study by Livraghi *et al*<sup>[37]</sup> evaluated RFA of 126 HCCs larger than 3 cm in 114 patients. Complete necrosis on follow up CT scan was observed in 47.6% of patients and near complete necrosis (90%-99%) was observed in 31.7% of patients. The observed complication rate was similar to other studies<sup>[37]</sup>.

More recent studies have called into question the conclusion that RFA is equivalent to surgery in the treatment of HCC. A recent meta-analysis by Qi *et al*<sup>[38]</sup> evaluated 3 randomized control trials. Surgical resection was found to be superior to RFA with respect to overall survival (HR = 1.41) and recurrence free survival (HR = 1.41)<sup>[38]</sup>. However, surgical patients had a significantly higher incidence of complications and a significantly longer hospital stay than patients treated with RFA<sup>[38]</sup>. A more recent study by Miura *et al*<sup>[39]</sup> investigated 2804 patients who underwent ablation or surgical resection for a solitary HCC < 3 cm. Overall survival at 3 and 5 years was higher in the resection group (67%, 55%) than in the RFA group (52%, 36%)<sup>[39]</sup>. There were baseline differences between the two groups which somewhat limited the analysis. However, after propensity matching, the overall survival rate was still higher in the resection group (54%) vs RFA (37%)<sup>[39]</sup>. Surgical resection was also independently associated with improved survival (HR = 0.62)<sup>[39]</sup>.

**Cryoablation:** Multiple studies have evaluated the utility of cryoablation in the treatment of HCC. Chen *et al*<sup>[40]</sup> performed percutaneous cryoablation in 76 lesions of unresectable HCC and 76 lesions of recurrent HCC. 1 and 3 year survival rates in the unresectable group were 81.4% and 60.3% while the disease-free survival rates were 67.6% and 20.8%<sup>[40]</sup>. Survival rates in the recurrent HCC group were 70.2% and 28.8% at 1 and 3 years respectively, while the disease-free survival

rates were 53.8% and 7.7%. There was a low overall complication rate (12.1%) and there were no peri-procedural deaths<sup>[40]</sup>. A similar study by Wang *et al.*<sup>[41]</sup> evaluated cryoablation of 156 patients with HCC < 5 cm in diameter. The reported 1, 2 and 3 years overall survival rates were 92%, 82% and 64%<sup>[41]</sup>. Disease free survival rates were 72%, 56% and 43% at 1, 2 and 3 years<sup>[41]</sup>.

One of the largest studies evaluating cryoablation and HCC was performed by Yang *et al.*<sup>[19]</sup> and looked at 300 patients with unresectable HCC. A total of 223 tumors were incompletely ablated while 185 tumors were completely ablated<sup>[19]</sup>. The rate of local progression of disease at a median 36.7 mo follow up time was 31%<sup>[19]</sup>. The most significant risk factors for tumor recurrence were size and tumor location. The mean survival of patients after cryoablation was 45.7, 28.4 and 17.7 mo, in increasing order of tumor stage<sup>[19]</sup>. A study by Adam *et al.*<sup>[17]</sup> looked at cryoablation vs RFA for unresectable HCC. Despite similar initial post-treatment results, they found a significantly higher rate of local progression of disease in patients treated with cryoablation vs RFA (53% vs 18%)<sup>[17]</sup>.

**Microwave:** Many studies have demonstrated the safety and effectiveness of microwave ablation in the treatment of HCC. Dong *et al.*<sup>[42]</sup> studied 234 patients who underwent microwave ablation, showing 1, 2, 3, 4 and 5 years survival rates of 92.7%, 81.6%, 72.9%, 66.4% and 56.7%. The reported local recurrence rate was 7%<sup>[42]</sup>. A more recent study from Ziemlewicz *et al.*<sup>[43]</sup> of microwave ablation in 107 HCC lesions found an overall survival rate of 76.0% at median 14 mo follow up. The primary effectiveness was 93.7% for tumors 4 cm or smaller and 75.0% for tumors greater than 4 cm<sup>[43]</sup>, with an overall primary effectiveness of 91.6%. This illustrates the ability of microwave to effectively treat larger tumors measuring more than 4 cm in diameter. No major complications or mortality were reported<sup>[43]</sup>. A study of microwave ablation in 182 patients with a single HCC was performed by Sun *et al.*<sup>[44]</sup>. The complete ablation rate was 93%<sup>[44]</sup>. The overall survival rates were 89%, 74% and 60% at 1, 2 and 3 years respectively, while the recurrence-free survival rates were 51%, 36%, 27% at 1, 2 and 3 years respectively. Tumor recurrence was associated with increasing patient age and tumor size. The major complication rate was 2.7%<sup>[44]</sup>.

Microwave ablation also compares favorably to treatment with RFA. A study of 102 patients with HCC found similar complete ablation rates of 94.9% for microwave and 93.1% for RFA<sup>[45]</sup>. The local recurrence rate was better with microwave ablation (11.8%) when compared to RFA (20.9%)<sup>[45]</sup>. A similar study by Shibata *et al.*<sup>[46]</sup> reported complete ablation rates of 89% for microwave ablation compared to 96% for RFA. Overall complication rates were also similar.

**Irreversible electroporation:** There is less data on the efficacy of IRE in comparison with other ablative

techniques because the procedure is relatively new. However, several studies have demonstrated the efficacy of IRE in treating hepatocellular carcinoma. Cheung *et al.*<sup>[47]</sup> evaluated IRE of 18 HCC lesions in 11 patients with a size range of 1.0-6.1 cm and a mean follow up of 18 mo. In tumors measuring less than 3 cm, complete ablation was achieved in 93%, with an overall 73% complete ablation rate. Cannon *et al.*<sup>[48]</sup> reported a primary efficacy of 97% in 14 HCC lesions ranging in size from 1.1-5.0 cm. Thomson *et al.*<sup>[31]</sup> performed IRE in 18 patients with HCC, achieving complete tumor ablation in 15 patients.

### Metastatic disease

**Radiofrequency ablation:** Percutaneous RFA is also increasingly used to treat hepatic metastases, including metastases from colorectal carcinoma (CRCLM), neuroendocrine tumors, and breast cancer<sup>[4]</sup>. The requirements for surgical resection of metastases are similar to HCC and therefore only 10%-20% of patients are surgical candidates at the time of presentation<sup>[49]</sup>. The ideal candidate for RFA has biopsy proven hepatic metastases without underlying liver disease. A study of patients with colorectal metastases who were not surgical candidates and underwent RFA found survival rates of 86%-99%, 46%-68%, and 24%-44% at 1, 3 and 5 years respectively<sup>[9]</sup>. A study by Oshowo *et al.*<sup>[50]</sup> of patients with a solitary CRCLM reported a 3-year survival rate of 52% in patients who underwent RFA vs 55% in patients who underwent surgery. Kim *et al.*<sup>[51]</sup> found similar overall and disease free survival rates in patients who underwent resection vs RFA for a solitary CRCLM < 3 cm. The disease free survival rate was significantly lower in patients with metastases > 3 cm<sup>[51]</sup>. There is additional data supporting the role of RFA as an adjunctive therapy in palliative treatment of CRCLM vs chemotherapy alone. Berber *et al.*<sup>[52]</sup> evaluated RFA in 135 patients with colorectal metastases and found a median survival of 28.9 mo, compared to 11-14 mo in patients who underwent chemotherapy alone.

RFA has also been successfully used in treating hepatic metastases from neuroendocrine tumors. As with HCC and colorectal metastases, only 10% of patients with neuroendocrine metastases are surgical candidates at the time of presentation. Berber *et al.*<sup>[53]</sup> evaluated the role of RFA in treating patients with carcinoid syndrome, as well as other neuroendocrine metastases. Two hundred and thirty-four tumors in 34 patients were treated with RFA<sup>[53]</sup>. Symptoms were improved in 95% of patients with significant or complete symptom control seen in 80% of patients<sup>[53]</sup>. This was compared to a response rate of 90% with surgery and 50%-88% with somatostatin analogues<sup>[53]</sup>. The rate of local progression of disease was 26% during the follow up period (1.6 years) while 41% of patients had no evidence of disease progression during the same period<sup>[53]</sup>. Another study by Elvin *et al.*<sup>[54]</sup> of 109 RFA treatments of neuroendocrine metastases showed a local recurrence rate of 10% during follow up (mean 3.2

years) with CT evidence of successful treatment in 90% of patients.

**Cryoablation:** The data on using cryoablation for metastatic disease is limited compared to the data for RFA since few centers use cryoablation for treating liver lesions. An older study by Kerkar *et al.*<sup>[55]</sup> in 2004 evaluated 56 patients who underwent cryoablation for colorectal metastases. The 3 and 5 years overall survival rates in the colorectal metastases group was 43% and 22% with a median survival of 30 mo<sup>[55]</sup>. A more recent and larger study by Ng *et al.*<sup>[56]</sup> reported the results of cryoablation in 293 patients with unresectable colorectal metastases. 1-, 3-, 5- and 10-year survival rates were 87%, 41.8%, 24.2% and 13.3%<sup>[56]</sup>. Disease-free survival rates were 37.9%, 17.2%, 13.4% and 10.8% at 1, 3, 5 and 10 years<sup>[56]</sup>. "Recurrences" were reported elsewhere in the liver in 73%, at the cryoablation site in 23%, and at the edge of the ablation cavity in 14%<sup>[56]</sup>.

Seifert *et al.*<sup>[57]</sup> reported results of cryoablation in 13 patients with metastatic neuroendocrine tumors. Twelve patients (93%) had complete ablations without reported local progression of disease on follow up imaging. Of additional clinical importance, 7 patients who had preoperative hormone-related symptoms experienced helpful palliative results<sup>[57]</sup>.

Zhang *et al.*<sup>[58]</sup> reported recent results with cryoablation of breast cancer metastases. They performed cryoablation of 39 liver metastases in 17 patients. Tumor response was 92% in the immediate post-op period and 87.1% at 1 mo. Local progression was seen in 6 lesions (15.4%) at 3 mo. The 1 year survival rate was 70.6%.

**Microwave ablation:** One of the first studies to evaluate microwave ablation in the treatment of metastatic disease was by Shibata *et al.*<sup>[59]</sup>. They compared microwave ablation to surgical resection in patients with metastatic colorectal cancer and found similar 1, 2 and 3 years survival rates (71%, 57% and 14% for microwave and 69%, 56% and 23% for resection), and mean survival rates (27 mo for microwave vs 25 mo for resection)<sup>[59]</sup>. A study by Tanaka *et al.*<sup>[60]</sup> also found similar survival and recurrence rates in patients who underwent microwave alone compared to microwave and eventual resection for colorectal metastases. Another study reported identical five-year survival rates (24%) for patients with colorectal metastases treated with microwave ablation vs microwave and surgery<sup>[61]</sup>.

**Irreversible electroporation:** Silk *et al.*<sup>[62]</sup> reported results of IRE in 9 patients with a total of 19 metastatic colorectal cancer lesions ranging from 1.0-4.7 cm. They reported an efficacy of 55% with local tumor recurrence in 5 of 9 patients at 9 mo<sup>[62]</sup>. Thomson *et al.*<sup>[63]</sup> reported a primary efficacy of 67% in a total of 45 metastatic lesions (including colorectal, breast, and neuroendocrine cancers) treated with IRE. Kingham *et al.*<sup>[63]</sup> evaluated IRE of 28 metastatic lesions including metastatic colorectal and neuroendocrine cancers. They reported

a total local failure rate of 7.5% with time to recurrence ranging from 66-230 d.

## ABLATION MODALITY

The choice of ablation modality is important to potential treatment success. While each case is unique and modality choice is often driven by local expertise and operator experience, several general concepts prevail. RFA is very safe and effective in smaller hepatic tumors. However, RFA is less effective with larger tumors and tumors near blood vessels. In contrast, microwave ablation has been shown to be more effective with larger tumor sizes and is affected less by the heat sink effect. Although cryoablation has historically been avoided with hepatic tumors due to concerns about complications, it has been used very safely more recently following the development of smaller probes. Lastly, in limited studies, IRE has been shown to be safe and effective in the treatment of both HCC and metastatic disease especially near sensitive structures such as blood vessels and bile ducts, although continued research is needed to demonstrate long term efficacy.

## CONCLUSION

Percutaneous ablation has become widely accepted as a curative technique in the treatment of HCC and hepatic metastatic disease. Specifically, ablation is useful in the treatment of patients who are not surgical candidates but in whom curative treatment is desired. Percutaneous ablation is safe and effective. Although additional studies are needed, percutaneous ablation continues to evolve as an option in the treatment of HCC and metastatic disease.

### Abstract

**AIM:** To describe the proportion of patients with cirrhotic cardiomyopathy (CCM) evaluated by stress echocardiography and investigating its association with the severity of liver disease.

**METHODS:** A cross-sectional study was conducted. Cirrhotic patients without risk factors for cardiovascular disease were included. Data regarding etiology and severity of liver disease (Child-Pugh score and model for end-stage liver disease), presence of ascites and gastro-esophageal varices, pro-brain natriuretic peptide (pro-BNP) and corrected QT (QTc) interval were collected. Dobutamine stress echocardiography (conventional and tissue Doppler imaging) was performed. CCM was considered present when diastolic and/or systolic dysfunction was diagnosed at rest or after pharmacological stress. Therapy interfering with cardiovascular system was suspended 24 h before the examination.

**RESULTS:** Twenty-six patients were analyzed, 17 (65.4%) Child-Pugh A, mean model for end-stage liver disease (MELD) score of 8.7. The global proportion of patients with CCM was 61.5%. At rest, only 2 (7.7%) patients had diastolic dysfunction and none of the patients had systolic dysfunction. Dobutamine stress echocardiography revealed the presence of diastolic dysfunction in more 6 (23.1%) patients and of systolic

dysfunction in 10 (38.5%) patients. QTc interval prolongation was observed in 68.8% of the patients and increased pro-BNP levels in 31.2% of them. There was no association between the presence of CCM and liver impairment assessed by Child-Pugh score or MELD ( $P = 0.775$ ,  $P = 0.532$ , respectively). Patients with QTc interval prolongation had a significant higher rate of gastroesophageal varices comparing with those without QTc interval prolongation (95.0% *vs* 50.0%,  $P = 0.028$ ).

**CONCLUSION:** CCM is a frequent complication of cirrhosis that is independent of liver impairment. Stress evaluation should always be performed, otherwise it will remain an underdiagnosed condition.

**Key words:** Dobutamine stress echocardiography; Cirrhotic cardiomyopathy; Cirrhosis; Corrected QT interval prolongation; Liver impairment

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Our study demonstrates that cirrhotic cardiomyopathy (CCM) is a frequent condition that is independent of the severity of liver disease. Furthermore, it shows that CCM is currently underdiagnosed, even after a comprehensive evaluation at rest. Consequently, a stress test should always be considered in the diagnostic approach to CCM, as it is here. Moreover, an association between corrected QT (QTc) interval prolongation and the presence of gastroesophageal varices was revealed, irrespective of the diagnosis of CCM. As such, the clinical significance of QTc interval prolongation is emphasized and it can be regarded as a marker of severe liver disease.

## INTRODUCTION

The presence of cardiac dysfunction related to chronic liver disease was first hypothesized by Kowalski *et al*<sup>[1]</sup> in 1953. Subsequent studies revealed that cirrhosis is associated with a hyperdynamic circulation (increased cardiac output and diminished systemic vascular resistance)<sup>[2-6]</sup>, which corresponds to a high-output heart failure under resting conditions<sup>[7,8]</sup>. This clinical entity, formally named cirrhotic cardiomyopathy (CCM), is unrelated to the etiology of cirrhosis<sup>[3-5,8-10]</sup> and is different from alcoholic disease<sup>[9]</sup>. It has been defined as a cardiac dysfunction in patients with cirrhosis characterized by impaired contractile responsiveness to stress and/or altered diastolic relaxation with electrophysiological abnormalities in the absence of other

known cardiac disease<sup>[11]</sup>. Some decades ago, this cardiac dysfunction was attributed to the effects of alcohol toxicity on the heart; however, data from studies performed since 1980s showed that the dysfunction at rest and the blunted cardiac response to stress was associated with cirrhosis *per se* rather than being an adverse effect of alcohol, which justify the specific cardiac disease term - "CCM"<sup>[3,8,12]</sup>.

The pathophysiology of diastolic dysfunction is an increased stiffness of the myocardial wall, most likely because of a combination of mild myocardial hypertrophy, fibrosis and subendotelial edema<sup>[3,9]</sup>. Systolic dysfunction relates to the inability of the heart to maintain an adequate arterial blood pressure and output<sup>[5-7]</sup>. QT interval prolongation is the main electrophysiological abnormality in cirrhosis<sup>[2-8,13,14]</sup>. Several mechanisms have been implicated in the impaired contractile function of the cardiomyocyte: Down-regulation of  $\beta$ -adrenergic receptors and impaired  $\beta$ -adrenergic signalling, altered cardiomyocyte plasma membrane biophysical characteristics, increased activity of the endocannabinoids, nitric oxide and cytokines systems, as well as abnormal myofilaments<sup>[3-5,7-9]</sup>. Though almost always clinically silent at rest, due to diminished preload and afterload that occurs in liver cirrhosis, CCM has been described as a blunted ventricular contractile response usually unmasked by physiological, pharmacological and/or surgical stress<sup>[3-9]</sup>. Consequently, overt congestive heart failure might result<sup>[4,5,9]</sup>. CCM has been linked to sodium and water retention, ascites formation and hepatorenal syndrome development<sup>[7,11,15-17]</sup>, mainly following infections such as spontaneous bacterial peritonitis<sup>[2,3,17-19]</sup>. The prevalence and natural history of CCM is not accurately known and studies that better describe it are still needed<sup>[4,5,8]</sup>. It has also been proposed that this condition has prognosis significance<sup>[5-7]</sup>. There is no specific treatment for CCM, the goal being the management of congestive heart failure<sup>[2-5,7,8]</sup>.  $\beta$ -blockers therapy reduce the prolonged QT interval towards normal values<sup>[20,21]</sup> but its impact on survival is not clear<sup>[12,22]</sup>. Though liver transplantation may initially aggravate the CCM, it remains the ultimate therapy for cardiovascular complications of cirrhosis, being associated with normalization of cardiac function with improvements in cardiac hypertrophy, diastolic and systolic functions and QT interval, several months after transplantation<sup>[5,7,23-25]</sup>.

The aims of our study were: (1) to describe the proportion of patients with CCM evaluated by stress echocardiography in a population of cirrhotic patients, defining blunted ventricular contractile response and/or impaired diastolic relaxation as predictors of CCM; and (2) to investigate whether CCM is related to severity of liver disease.

## MATERIALS AND METHODS

### Study population

A cross-sectional study was conducted during 2011 and 2012. Cirrhotic outpatients followed at our department

were included. The diagnosis of cirrhosis was based on clinical, biochemical, echographic, endoscopic, and, when available, histological criteria. Exclusion criteria were: Age under 18, known or suspected risk factors for cardiovascular disease (diabetes, systemic hypertension, smoking and obesity defined as body mass index  $> 30 \text{ kg/m}^2$ ), pulmonary major illness, severe anemia ( $\text{Hg} < 7 \text{ g/dL}$ ), severe systemic disease, hyperthyroidism and hypothyroidism, pregnancy and baseline electrocardiographic or echocardiographic evidence of structural heart disease, such as bundle branch block, regional wall motion abnormalities or valvular heart disease. Inclusion criteria were as strict as dictated by the definition discussed at the 2005 World Congress of Gastroenterology in Montreal and presented thereafter, so the cardiac dysfunction can be attributed to the CCM *per se*; moreover, they are similar to that described in other reports<sup>[26,27]</sup>. All the therapy interfering with cardiovascular system was suspended 24 h before the electrocardiographic and echocardiographic examinations not to alter the examinations' results. The study protocol was approved by the Ethics Committee of our hospital. Written informed consent was obtained from every patient included in the study.

### **Clinical and analytical data**

Data regarding gender, age, etiology and severity of liver disease (Child-Pugh classification and model for end-stage liver disease (MELD), presence of ascites, gastroesophageal varices, history of overt encephalopathy, heart rate and systolic and diastolic blood pressure were retrospectively recorded. Compensated disease refers to Child-Pugh class A and decompensated disease includes Child-Pugh class B or C patients.

Laboratory parameters - hematological, biochemical [including pro-brain natriuretic peptide (pro-BNP)] and clotting profiles were measured in fasting venous blood samples.

### **Electrocardiographic examination**

Patients were submitted to a 12-lead electrocardiogram and corrected QT interval (QTc interval), adjusted for heart rate, was calculated, according to Bazett's formula [ $\text{QTc} = \text{QTmax}/(\text{RR})^{1/2}$  interval]. A QTc interval  $> 440 \text{ ms}$  was considered prolonged.

### **Echocardiographic examination**

Transthoracic echocardiographic examination (standard 2D-echocardiographic imaging, pulsed Doppler interrogation of mitral inflow and tissue Doppler imaging (TDI) of the annular region of the left ventricle) using a General Electric™ Vivid 7, was performed by an experienced cardiologist in the echocardiography laboratory. Diastolic and systolic functions were evaluated at rest and after pharmacological stress with intravenous infusion of dobutamine. An initial dose of dobutamine at  $5 \mu\text{g/kg}$  per minute was administered and increased to 10, 20, 30 and  $40 \mu\text{g/kg}$  per minute every 3 min, in

order to achieve, at least, 85% of maximum heart rate predicted for age ( $220 - \text{age}$ ). In case maximum heart rate was not reached, atropine (0.25 mg every minute up to maximum dose of 1 mg) was added to the  $40 \mu\text{g/kg}$  per minute dobutamine infusion. After the examination, intravenous metoprolol (2.5 mg every 5 min up to a maximum dose of 10 mg) was administered until basal heart rate was achieved. Off-line analysis of echocardiographic images was performed by two investigators under blind conditions and agreement between the two observers was required.

Echocardiographic systolic left ventricular function parameters [left ventricular end-diastolic volume (LV EDV), LV end-systolic volume (LV ESV) and LV ejection fraction (LV EF) using Simpson's rule] were evaluated at rest and after a dobutamine inotropic dose perfusion ( $20 \mu\text{g/kg}$  per minute), as recommended to assess LV contractile reserve (LV CR). LV systolic dysfunction was considered present at rest when LV EF was below 50%. A reduced left ventricular contractile reserve was defined as an increase in LV EF  $< 10\%$  after dobutamine infusion.

To assess left ventricular diastolic function, peak early filling (E-wave) velocity, late diastolic atrial filling (A-wave) velocity and E-wave deceleration time (DT) were measured by pulsed Doppler examination and E/A ratio (early diastolic/atrial filling ratio) was calculated. Average early diastolic myocardial velocity (e'-septal and lateral sides of the mitral annulus average) was obtained by TDI. E/e' average ratio was calculated combining the parameter E from the pulsed wave Doppler and the parameter e' from the TDI. Left ventricular diastolic dysfunction at rest was diagnosed if septal e' velocity was  $< 8 \text{ cm/s}$  and lateral e' velocity was  $< 10 \text{ cm/s}$ , according to the American Society of Echocardiography recommendations<sup>[28]</sup> (patients whose e' velocities values were within normal limits for age were considered as not having diastolic dysfunction). Three categories of increasing severity of diastolic dysfunction were defined according to the following parameters: Grade I - E/e' average ratio  $\leq 8$ , E/A ratio  $< 0.8$  and DT  $> 200 \text{ ms}$ ; grade II - E/e' average ratio between 9 and 12, E/A between 0.8 and 1.5 and DT between 160 and 200 ms; and grade III - E/e' average ratio  $\geq 13$ , E/A  $\geq 1.5$ . E/e' average ratio at rest and after stress (using dobutamine maximum dose perfusion) has been applied in the diastolic stress test. If myocardial relaxation is normal, E and e' velocities increase proportionally, and the E/e' ratio remains unchanged or is reduced; in patients with impaired myocardial relaxation, the increase in e' with stress is much less than that of mitral E velocity and the E/e' ratio increases.

### **CCM**

CCM was diagnosed when LV diastolic dysfunction and/or systolic dysfunction was present, irrespective of the presence of other supportive criteria [electrophysiological abnormalities as QTc interval prolongation or increased

MELD: Model for end-stage liver disease.

cardiac biomarkers (pro-BNP)].

### Statistical analysis

Statistical analysis was performed using SPSS 16.0 for Windows (SPSS INC. Chicago, IL, United States). Variables with normal distribution were expressed as mean ± SD and variables with non-normal distribution as median and range. Student's *t*-test, Fisher's Exact Test and Pearson's correlation were used when appropriate. *P* values < 0.05 were considered as significant. The statistical review of the study was performed by the author Mara Barbosa.

## RESULTS

### Clinical and analytical data

Seventy-three cirrhotic patients were evaluated and only 26 fulfilled the inclusion criteria. The main reasons for exclusion were: Diabetes mellitus (51%), hypertension (26%), ischemic cardiac disease (9%) and arrhythmia (6%). Regarding included patients, 22 (85%) were men, with mean age 55 ± 10 years. The etiology of cirrhosis was predominantly alcoholic (77%). The majority of patients (65%) were compensated (Child-Pugh class A). Mean MELD score was 8.7 ± 5.3. Five (19.2%) patients had ascites and the vast majority (84.6%) had gastroesophageal varices. Baseline characteristics of

patients are listed in Table 1. Non selective β-blockers (propranolol) were suspended in 15 patients and diuretics (furosemide and/or spironolactone) in 12 patients.

Pro-BNP levels were 110.8 ± 110.6 μg/mL and were elevated in 8 (30.8%) patients (normal levels < 125 μg/mL). Pro-BNP values were not significantly different between alcoholic and non-alcoholic patients (*P* = 0.757). Pro-BNP levels were similar in Child-Pugh class B/C and Child-Pugh class A patients (*P* = 0.651). There was no correlation between MELD score and pro-BNP values (*P* = 0.950). The presence of ascites, gastroesophageal varices and history of overt encephalopathy was not significantly associated with more elevated pro-BNP levels (*P* = 0.525; *P* = 0.615 and *P* = 0.186, respectively).

### Electrocardiographic characteristics

QTc interval duration was 460 ± 23 ms. Prolongation of the QTc interval was found in 77% of the patients. The existence of a prolonged QTc interval or its duration was unrelated to the etiology of cirrhosis (alcoholic vs non-alcoholic) (*P* = 0.562 and *P* = 0.696, respectively). Regarding severity of disease, there was a significant correlation between QTc interval duration and MELD score (*P* = 0.453, *P* = 0.020) but not between QTc interval duration and Child-Pugh score (*P* = 0.322, *P* = 0.108); QTc interval prolongation was not more frequent in patients with decompensated (Child-Pugh class B/C) vs compensated cirrhotic patients (*P* = 0.380); however, patients with QTc interval prolongation tended to have higher MELD score (9.8 ± 3.7 vs 5.0 ± 8.2, *P* = 0.053). Patients with QTc interval prolongation had a statistically significant higher rate of gastroesophageal varices comparing with those without QTc interval prolongation (95.0% vs 50.0%, *P* = 0.028). However, the presence of QTc prolongation was not associated with the presence of ascites or history of overt encephalopathy (*P* = 0.678 and *P* = 0.438, respectively). Regarding QTc interval duration, there was no relation with ascites, gastroesophageal varices or history of encephalopathy. Although more elevated, pro-BNP levels were not significantly increased in patients with a prolonged QTc interval (*P* = 0.483). Furthermore, there was no correlation between pro-BNP levels and QTc interval duration (*P* = 0.125).

### Echocardiographic characteristics

Echocardiographic examinations were performed as planned, maximum heart rate predicted for age was achieved in all patients and no adverse events were recorded.

**Left ventricular systolic function:** At rest, none of the patients had LV EF below 50% (69.1% ± 8.1%) and LV EDV and LV ESV were within normal limits (94.2 ± 29.7 mL and 28.4 ± 9.5 mL, respectively). A reduced LV CR was observed in 10 (38.5%) patients with LV EF mean increment of 0.4% ± 7.6% vs 20.7% ± 10.4% in the other 16 patients with normal LV CR. Comparing the two groups, at rest, LV EF and LV ESV were similar (73.0% ± 7.1% vs 66.7% ± 7.9%, *P* = 0.051 and 30.1 ± 12.3

**Table 2** The characteristics of patients with and without cirrhotic cardiomyopathy

	CCM ( <i>n</i> = 16)	Non-CCM ( <i>n</i> = 10)	<i>P</i> value
Gender (male), <i>n</i> (%)	14 (87.5%)	8 (80.0%)	0.625
Age (yr)	52.8 ± 9.9	57.4 ± 11.2	0.284
Etiology (alcoholic/non-alcoholic), <i>n</i> (%)	14 (87.5)/2 (12.5)	9 (90.0)/1 (10.0)	0.677
Child-Pugh score (units)	6.3 ± 1.3	6.1 ± 1.2	0.775
Child-Pugh class (A/B + C), <i>n</i> (%)	9 (56.2)/7 (43.8)	8 (80.0)/2 (20.0)	0.399
MELD score (units)	8.1 ± 5.8	9.5 ± 4.6	0.532
Ascites, <i>n</i> (%)	4 (25.0)	1 (10.0)	0.617
Gastroesophageal varices, <i>n</i> (%)	14 (87.5)	8 (80.0)	0.625
History of overt encephalopathy, <i>n</i> (%)	1 (6.3)	2 (20.0)	0.538
Sodium (mEq/L)	140.7 ± 2.9	140.5 ± 2.3	0.865
Creatinine (mg/dL)	0.8 ± 0.2	0.9 ± 0.1	0.343
Albumin (g/dL)	3.6 ± 0.3	3.5 ± 0.4	0.446

CCM: Cirrhotic cardiomyopathy; MELD: Model for end-stage liver disease.

mL vs  $27.3 \pm 7.5$  mL,  $P = 0.466$ , respectively), but LV EDV was significantly increased in the group of reduced LV CR ( $111.4 \pm 32.8$  mL vs  $83.5 \pm 22.4$  mL,  $P = 0.016$ ). After pharmacological stress, LV ESV mean reduction was significantly inferior in the group of reduced LV CR ( $6.1 \pm 12.6$  mL vs  $44.0 \pm 21.8$  mL,  $P = 0.000$ ) and LV EDV mean reduction was similar in the two groups ( $0.53 \pm 11.6$  mL vs  $5.2 \pm 18.5$  mL,  $P = 0.481$ ).

**Left ventricular diastolic function:** At rest, 2 patients were diagnosed with diastolic dysfunction (grade I). In 8 (30.8%) patients, the E/e' average ratio increased from  $6.9 \pm 2.0$  to  $9.1 \pm 2.7$ ; in the others, the E/e' reduced from  $8.9 \pm 1.9$  to  $6.8 \pm 2.3$ .

### CCM

Sixteen (61.5%) patients were diagnosed with CCM: 10 patients had systolic dysfunction, 8 patients had diastolic dysfunction and 2 presented with both cardiac systolic and diastolic dysfunction. Among those patients with CCM, QTc interval prolongation was observed in 11 (68.8%) patients and increased pro-BNP levels were measured in 5 (31.2%) patients. QTc prolongation and elevation of pro-BNP were simultaneously present in 5 (31.2%) cases and none of the alterations was observed in 5 (31.2%) patients. The characteristics of patients with and without CCM are listed in Table 2. Of note, the presence of CCM was unrelated to the etiology and severity of cirrhosis and presence of ascites, gastroesophageal varices and history of overt encephalopathy. Moreover, sodium, creatinine and albumin values were similar between patients with and without CCM.

## DISCUSSION

In order to describe CCM prevalence, natural history and prognosis accurately, an effort to define diagnostic criteria has been made. However, universal consensus is still lacking and important points remain to be elucidated, such as: The minimum number of criteria required to make the diagnosis, the need to always

performing a stress test to unmask CCM and the most adequate stress test to use, as the disease is usually latent and revealed by stress. Moreover, recent studies have used tissue Doppler parameters to diagnose CCM<sup>[28,29]</sup>, as they are more sensitive and less dependent on loading conditions<sup>[30,31]</sup>, comparing with mitral inflow velocity variables. Consequently, there is a considerable heterogeneity in the results published in the literature.

Diastolic dysfunction relates to impaired myocardial relaxation<sup>[28]</sup> and elevated left ventricular filling pressures is the main physiological consequence of it<sup>[32]</sup>. During stress, left ventricular filling pressures change minimally in healthy subjects. However, if cardiac dysfunction is present, a rise in filling pressures is observed in order to maintain left ventricular filling and stroke volume<sup>[28]</sup>. The E/e' ratio was shown to relate significantly to left ventricular filling pressures during stress<sup>[33]</sup>. Diastolic dysfunction was present in only 2 cases at rest and in 8 after stress. In fact, stress dobutamine echocardiography could identify patients with diastolic dysfunction (average E/e' ratio increase) not recognized at rest. The observation of an impaired myocardial relaxation during stress provides a possible explanation for the frequent development of cardiovascular complications (such as pulmonary edema) after transjugular intrahepatic portosystemic shunt (TIPS) insertion and liver transplantation, as these interventions promote a sudden increase in the preload and, consequently, a rise in left ventricular filling pressures.

None of the patients was diagnosed with systolic dysfunction at rest, which is consistent with the data reported in the literature, when LV EF is used as diagnostic criteria. The pharmacological stimuli revealed the existence of a systolic dysfunction in a considerable number of patients (38.5%). Due to the hyperdynamic state, with central hypovolemia and diminished preload and afterload, it remains an underdiagnosed condition even after a careful echocardiographic evaluation at rest.

The proportion of patients with CCM in our population was 61.5%. A significant number of patients (68.8%) had concomitant QTc interval prolongation and a smaller fraction (31.2%) had increased levels of pro-BNP.

CCM was independent of the etiology of cirrhosis, as has already been described in previous studies<sup>[3-5,8-10]</sup>. Controversy exists regarding the relation between the CCM and the severity of the disease. Some studies suggest that CCM can be more severe in decompensated liver disease while others report CCM is not directly related to disease severity<sup>[7,26,29,33,34]</sup>. In our study, we did not find any relation between CCM and Child-Pugh classification or MELD. Furthermore, clinical markers of higher liver impairment (ascites, gastroesophageal varices and history of overt encephalopathy) did not predict the presence of CCM.

QTc interval prolongation was a very common finding in this population of cirrhotic patients. This result is in agreement with the data reported in the literature. It is already established that QTc interval prolongation is significantly related to the severity of the underlying liver disease<sup>[13,35,36]</sup>. In our study, QTc interval duration was positively correlated with the degree of liver dysfunction assessed by MELD score, but not by Child-Pugh classification, probably because of small sample size. Interestingly, patients who were diagnosed with QTc interval prolongation had more commonly gastroesophageal varices, the last being an established surrogate of more severe liver disease and increased risk. However, this could not be demonstrated in patients with ascites. Recently, Trevisani *et al.*<sup>[37]</sup> reported further QTc interval prolongation in the setting of acute gastrointestinal bleeding in cirrhotic patients. Although the clinical significance of QTc interval prolongation is not completely clarified<sup>[2,4-7,13,22]</sup>, it may increase the risk of cardiac events and be associated with a poorer survival<sup>[13]</sup>. Therefore, close monitoring during stressful events is advised<sup>[6]</sup>.

In summary, our study demonstrated that CCM is a frequent condition that is independent of the severity of liver disease. Furthermore, it showed that CCM is currently underdiagnosed, even after a comprehensive evaluation at rest. Consequently, a stress test should always be considered in the diagnostic approach to CCM, as it is highlighted in the current study. Moreover, an association between QTc interval prolongation and the presence of gastroesophageal varices was revealed, irrespective of the diagnosis of CCM. As such, the clinical significance of QTc interval prolongation is emphasized and it can be regarded as a marker of severe liver disease. A limitation of our study is its small sample size.

Hepatologists should be aware of this silent entity and actively search for it because it is of major importance in the management of the cirrhotic patient as it contributes to the high cardiovascular morbidity and mortality related to TIPS insertion and liver transplantation. It remains of the utmost importance to better define CCM diagnostic criteria, to suggest specific stress test protocols and to update echocardiographic criteria for the diagnosis, probably including TDI parameters which have already been used in several studies besides ours, in order to achieve more reproducible results.

Also, the performance of strain evaluation by speckle tracking analysis, a new sophisticated echocardiographic technique, might be a promising method to diagnose CCM in patients with advanced liver disease as it can detect subtle systo-diastolic dysfunction before left ventricular ejection fraction becomes impaired<sup>[12,29]</sup>. Data regarding the impact of CCM in the natural history of cirrhosis is also needed.

## COMMENTS

### Background

Cirrhotic cardiomyopathy (CCM) relates to a cardiac dysfunction in patients with cirrhosis characterized by impaired contractile responsiveness to stress and/or altered diastolic relaxation with electrophysiological abnormalities in the absence of other known cardiac disease. It is independent of the etiology of cirrhosis and is different from alcoholic disease. Although almost always clinically silent at rest, CCM is usually unmasked by physiological, pharmacological and/or surgical stress, such as transjugular intrahepatic portosystemic shunt or liver transplant. In this study, the authors aimed at describing the proportion of patients with CCM evaluated by stress echocardiography in a population of cirrhotic patients, and at investigating whether CCM is related to severity of liver disease.

### Research frontiers

Very few prior reports address the question of diagnostic evaluation of CCM in cirrhotic patients using accurate criteria and stress testing. The results of the authors' study contribute to the diagnostic approach to CCM in these patients.

### Innovations and breakthroughs

This study demonstrated that CCM is a frequent condition that is independent of the severity of liver disease. Also, it revealed that CCM is currently underdiagnosed at rest, even after a comprehensive electrocardiographic and echocardiographic evaluation. A substantial number of patients were diagnosed as having CCM only after the stress echocardiographic evaluation. Furthermore, an association between corrected QT (QTc) interval prolongation and the presence of gastroesophageal varices was revealed, irrespective of the presence of CCM. As such, QTc interval prolongation can be regarded as a surrogate of severe liver disease.

### Applications

This study suggests that a stress test should always be considered in the diagnostic approach to CCM, otherwise it will remain an underdiagnosed entity.

### Terminology

This study demonstrated that stress echocardiography was useful at revealing CCM. As such, it can identify patients at risk of cardiac decompensation and can be used as diagnostic tool of CCM in cirrhotic patients in clinical practice.

### Peer-review

This is an interesting manuscript, and especially interesting for the general gastroenterologists, hepatologists, cardiologists and the internist.

## Contents

Three issues per month Volume 8 Number 4 February 8, 2016

### EDITORIAL

- 207 Inflammasome activation in decompensated liver cirrhosis  
*González-Navajas JM*

### ORIGINAL ARTICLE

#### Basic Study

- 211 Lack of hepcidin expression attenuates steatosis and causes fibrosis in the liver  
*Lu S, Bennett RG, Kharbanda KK, Harrison-Findik DD*

#### Retrospective Study

- 226 Total hepatectomy and liver transplantation as a two-stage procedure for fulminant hepatic failure: A safe procedure in exceptional circumstances  
*Sanabria Mateos R, Hogan NM, Dorcaratto D, Heneghan H, Udupa V, Maguire D, Geoghegan J, Hoti E*

### SYSTEMATIC REVIEWS

- 231 Portal hypertensive gastropathy: A systematic review of the pathophysiology, clinical presentation, natural history and therapy  
*Gjeorgjievski M, Cappell MS*

### LETTERS TO THE EDITOR

- 263 Non-invasive evaluation of liver fibrosis by acoustic radiation force impulse and aminotransferase:platelet ratio index in chronic hepatitis C  
*Karagoz E, Ozturker C, Sivrioglu AK*

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Christos G Savopoulos, MD, PhD, Associate Professor, 1<sup>st</sup> Medical Propedeutic Department of Internal Medicine, AHEPA Hospital, Aristotle University of Thessaloniki, 54636 Thessaloniki, Greece

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/  
ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Inflammation participates in the pathogenesis of

many liver diseases, including liver cirrhosis. Certain inflammatory cytokines, such as interleukin (IL)-1 $\beta$  and IL-18, are produced after the activation of a multiprotein complex known as the inflammasome. Activation of the inflammasome has been documented in several liver diseases, but its role in the development and progression of liver cirrhosis or the complications associated with this disease is still largely unknown. We have recently studied the impact of the inflammasome in the sterile inflammatory response that takes place in the ascitic fluid of patients with decompensated cirrhosis, providing evidence that activation of the absent in melanoma 2 (AIM2) inflammasome is an important response in these patients. Ascitic fluid-derived macrophages were able to mount a very robust AIM2-mediated response even in the absence of a priming signal, which is usually required for the full activation of all the inflammasomes. In addition, high level of inflammasome activation in these patients was associated with a higher degree of liver disease and an increased incidence of spontaneous bacterial peritonitis. These results may help explain the exacerbated inflammatory response that usually occurs in patients with decompensated cirrhosis in the absence of detectable infections. Thus, inflammasomes should be considered as possible therapeutic targets in sterile inflammatory complications in patients with cirrhosis.

**Core tip:** In this Editorial I discuss the involvement of the inflammasome in the inflammatory reactions that occur in patients with liver cirrhosis and ascites. I focus on a recent work in which we observed that the absent in melanoma 2 inflammasome is highly activated in the ascitic fluid of patients with advanced cirrhosis and that its activation is linked to the severity of liver disease. These findings are important for the understanding of the sterile inflammatory reactions in these patients, and could have important therapeutic implications.

González-Navajas JM. Inflammasome activation in decompensated liver cirrhosis. *World J Hepatol* 2016; 8(4): 207-210 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i4/207.htm> DOI: <http://dx.doi.org/10.4254/wjgh.v8.i4.207>

Liver cirrhosis is the result of a long pathologic process initiated by chronic infection with hepatitis B virus or hepatitis C virus (HCV), excessive alcohol consumption, accumulation of fat in liver cells, and other metabolic alterations. The most important complications of liver cirrhosis include intestinal bleeding, encephalopathy, and ascites, and the development of any of these complications is clinically known as decompensated cirrhosis. Ascites is the most common cause of hepatic decompensation, and usually precedes the others. Decompensation of cirrhosis is usually associated with a systemic inflammatory response characterized by activation of innate immune cells and elevated expression of pro-inflammatory cytokines [tumor necrosis factor  $\alpha$ , interleukin (IL)-1 $\beta$ , IL-6] in the ascitic fluid. This inflammatory response is usually the result of bacterial translocation from the intestinal lumen to extra-intestinal sites, such as mesenteric lymph nodes and ascitic fluid. Bacterial translocation does not necessarily mean bacterial infection, since the translocating bacteria is often killed by the innate immune system. However, the sole presence of molecules of microbial origin [such as lipopolysaccharide (LPS) or bacterial DNA] is sufficient to mount a sterile inflammatory response in the ascitic fluid in the absence of active infection<sup>[1-3]</sup>.

Since its first description in 2002 by Martinon *et al*<sup>[4]</sup>, the inflammasome has been a key subject of research in multiple inflammatory diseases. Very comprehensive reviews of the expression, activation, and function of the inflammasomes have been published elsewhere<sup>[5-7]</sup>, and therefore these topics are discussed here only briefly. The inflammasome is a cytosolic multiprotein complex that controls the activation of the enzyme caspase-1<sup>[4,6]</sup>. Once activated, caspase-1 mediates the maturation and release of pro-inflammatory cytokines such as IL-1 $\beta$  and IL-18. Caspase-1 activity can also result in a highly inflammatory form of cell death called "pyroptosis" in some cells<sup>[8]</sup>, which occurs most frequently upon infection with intracellular pathogens<sup>[9]</sup>. Inflammasomes are assembled upon recognition of pathogen-associated molecular patterns (PAMPs), as well as host-derived signals known as damage-associated molecular patterns (DAMPs) that are released as a result of tissue damage or cellular stress. Several members of the NLR family (nucleotide-binding and oligomerization domain and leucine-rich-repeat-containing proteins) have been reported to exhibit inflammasome activity, including NLRP1, NLRP3, NLRP6 or NLRC4. In addition to NLRs, the HIN-200 domain-containing protein absent in melanoma 2 (AIM2) has also the ability to induce inflammasome activation. Full activation of the inflammasome requires two different signals. The first

signal is provided by the activation of pattern recognition receptors, such as Toll-like receptors, resulting in the accumulation of inactive pro-IL-1 $\beta$  and pro-IL-18 inside the cell. The second signal is then provided by the activation of NLRPs or AIM2 by different danger signals<sup>[5-7]</sup>. For example, NLRP3 is activated by a wide range of PAMPs and DAMPs (e.g., toxins, uric acid, ATP), whereas AIM2 is activated only by double-stranded DNA (dsDNA) of any origin<sup>[10,11]</sup> (Figure 1).

Recent studies have suggested that the inflammasome also plays an important role in chronic liver disease<sup>[12]</sup>. For example, the inflammasome is activated in response to HCV infection<sup>[13]</sup>, in drug-induced liver injury<sup>[14]</sup>, or in the pathogenesis of non-alcoholic steatohepatitis<sup>[15,16]</sup>. However, the inflammasome-mediated response in decompensated cirrhosis was unexplored until publication of our recent study by Lozano-Ruiz *et al*<sup>[17]</sup>. In this study we show that activation of the inflammasome is an important response in the ascitic fluid of cirrhotic patients. Macrophages from ascitic fluid showed high levels of pro-IL-1 $\beta$  and pro-IL-18 mRNA, constitutive activation of caspase-1 and enhanced expression of AIM2 protein and mRNA when compared to blood-derived macrophages from the same patients. Moreover, contrary to blood macrophages, activation of the AIM2 inflammasome did not require a priming signal in these cells, demonstrating the pre-activated state of the inflammasome in the ascitic fluid. This pre-activated state of the AIM2 inflammasome was associated with the presence of bacterial DNA fragments in the ascitic fluid of these patients, suggesting that translocation of bacteria and their products could be responsible for this priming<sup>[17]</sup>.

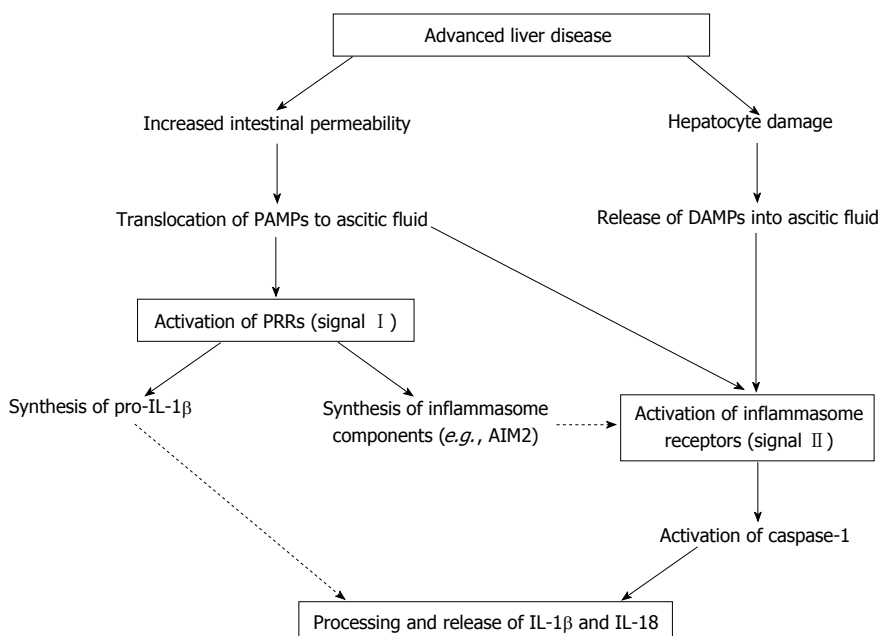

It was previously shown that bacterial translocation and inflammation increases depending on the degree of liver damage and the clinical stage of the disease<sup>[18]</sup>. Thus, it was conceivable that the severity of liver disease could affect the extent of inflammasome activation in cirrhosis. Indeed, activation of caspase-1 and AIM2-mediated production of IL-1 $\beta$  and IL-18 were increased in patients with Child-Pugh C score, compared to those with Child-Pugh B. Additionally, high level of IL-18 in ascitic fluid showed a significant association with the occurrence of spontaneous bacterial peritonitis (SBP) in these patients independently of the Child-Pugh score, suggesting that increased inflammasome activation might be a marker of increased risk of SBP.

In summary, these findings are important for the understanding of the sterile inflammatory reactions in patients with advanced cirrhosis. In these patients, complications associated with high mortality are normally accompanied by excessive inflammation, and therefore our results could have important translational implications. We propose that a two-hit process could explain the exacerbated inflammasome activation in advanced cirrhosis (Figure 2). First, bacterial translocation would lead to an abnormal influx of exogenous PAMPs (e.g., LPS or bacterial DNA) that induce a pre-activation state of the inflammasome in ascitic fluid cells.

**Figure 1 Basic representation of inflammasome activation.** Inflammasomes are formed after NLR or PYHIN family members recognize signals associated with tissue damage or infection. Receptors that have a CARD domain can recruit pro-caspase-1 directly (e.g., NLRC4), whereas those that contain a PYD domain (e.g., NLRP3 and AIM2) recruit pro-caspase-1 through the accessory protein ASC (which contains a PYD and a CARD). NLRP1 contains a CARD and can bypass the requirement for ASC, but also contains a PYD and its interaction with ASC enhances the activity of the NLRP1 inflammasome. CARD: Caspase-1 recruitment domain; PYD: Pyrin domain; ASC: Apoptosis-associated speck-like protein containing a CARD; LRR: Leucine rich repeat; HIN-200: Hematopoietic interferon-inducible nuclear antigen with 200 amino-acid repeat; PAMPs: Pathogen-associated molecular patterns; DAMPs: Damage-associated molecular patterns; AIM2: Absent in melanoma 2; dsDNA: Double-stranded DNA; IL: Interleukin; *S. aureus*: *Staphylococcus aureus*; *L. monocytogenes*: *Listeria monocytogenes*; *C. albicans*: *Candida albicans*; TLR: Toll-like receptor.

**Figure 2 Theoretical mechanism of inflammasome activation in ascitic fluid.** Advanced cirrhosis is typically associated with overgrowth of intestinal bacteria and increased intestinal permeability, which results in the translocation of bacterial products (e.g., DNA or LPS) to the ascitic fluid. The presence of these PAMPs activates PRRs in innate immune cells of the ascitic fluid, inducing the synthesis of IL-1 $\beta$  and IL-18 precursors and inflammasome components (signal I). At the same time, continuous liver damage (e.g., by virus or alcohol) would result in hepatocyte death and release of DAMPs (e.g., host dsDNA). These DAMPs (and probably new translocation events of PAMPs from the intestinal lumen) would activate inflammasome-forming receptors such as AIM2 (providing signal II), which in turn results in the activation of caspase-1 and the maturation and release of IL-1 $\beta$  and IL-18 into the ascitic fluid. IL: Interleukin; PAMPs: Pathogen-associated molecular patterns; DAMPs: Damage-associated molecular patterns; AIM2: Absent in melanoma 2; dsDNA: Double-stranded DNA; PRRs: Pattern recognition receptors; LPS: Lipopolysaccharide.

Second, endogenous DAMPs released from damaged liver cells (e.g., host dsDNA) would provide the second signal for the activation of the AIM2 inflammasome and the promotion of inflammation in the absence of active infection<sup>[17]</sup>. However, some questions remain that need to be further clarified. For example, it is not clear whether the inflammasome contributes to, or is a consequence of, cirrhosis progression. In addition, the use of the inflammasome as a therapeutic target in cirrhosis needs to be carefully addressed. Several IL-1 $\beta$  blocking agents are currently approved and used in patients suffering from different inflammatory diseases<sup>[19]</sup>, but the increased risk of infections would argue against using these immunosuppressive drugs in certain situations, such as in SBP. Therefore, more studies are needed to determine the exact role of the inflammasome in the pathogenesis of advanced cirrhosis and its potential use as a therapeutic target for the treatment or prevention of inflammatory complications.

### Abstract

**AIM:** To investigate the role of key iron-regulatory protein, hepcidin in non-alcoholic fatty liver disease (NAFLD).

**METHODS:** Hepcidin (*Hamp1*) knockout and floxed control mice were administered a high fat and high sucrose (HFS) or a regular control diet for 3 or 7 mo. Steatosis, triglycerides, fibrosis, protein and gene expression in mice livers were determined by histological and biochemical techniques, western blotting and real-time polymerase chain reaction.

**RESULTS:** Knockout mice exhibited hepatic iron accumulation. Despite similar weight gains, HFS feeding induced hepatomegaly in floxed, but not knockout, mice. The livers of floxed mice exhibited higher levels of steatosis, triglycerides and c-Jun N-terminal kinase (JNK) phosphorylation than knockout mice. In contrast, a significant increase in fibrosis was observed in knockout mice livers within 3 mo of HFS administration. The hepatic gene expression levels of sterol regulatory

element-binding protein-1c and fat-specific protein-27, but not peroxisome proliferator-activated receptor- $\alpha$  or microsomal triglyceride transfer protein, were attenuated in HFS-fed knockout mice. Knockout mice fed with regular diet displayed increased carnitine palmitoyltransferase-1 $\alpha$  and phosphoenolpyruvate carboxykinase-1 but decreased glucose-6-phosphatase expression in the liver. In summary, attenuated steatosis correlated with decreased expression of lipogenic and lipid storage genes, and JNK phosphorylation. Deletion of *Hamp1* alleles *per se* modulated hepatic expression of beta-oxidation and gluconeogenic genes.

**CONCLUSION:** Lack of hepcidin expression inhibits hepatic lipid accumulation and induces early development of fibrosis following high fat intake. Hepcidin and iron may play a role in the regulation of metabolic pathways in the liver, which has implications for NAFLD pathogenesis.

**Key words:** *Hamp*; Iron; Non-alcoholic steatohepatitis; Metabolic genes; Steatosis; Non-alcoholic fatty liver disease; Steatohepatitis

**Core tip:** Due to obesity epidemic the incidence of non-alcoholic fatty liver disease (NAFLD) is on the rise. Iron contributes to disease severity and the expression of key iron regulatory hormone, hepcidin is modulated in NAFLD patients. The underlying mechanisms are unknown. We have generated hepcidin knockout mice with iron overload phenotype. This study investigates the role of hepcidin in NAFLD by using high fat and high sucrose-fed knockout mice as an experimental model of NAFLD. Our findings showed attenuated steatosis and early fibrosis development suggesting a role for hepcidin in the regulation of metabolic processes in the liver, and in NAFLD.

## INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) encompasses a spectrum of liver disease ranging from simple benign steatosis to non-alcoholic steatohepatitis (NASH). NASH, a more aggressive form of disease, is characterized by the presence of lobular inflammation, fibrosis, hepatocellular ballooning and Mallory-Denk bodies<sup>[1,2]</sup>. NASH with progressive fibrosis can progress to cirrhosis and end stage liver disease<sup>[1,3,4]</sup>.

The precise mechanisms of NASH development

are not well understood. Although a so-called “two-hit hypothesis”<sup>[5]</sup> has been widely adopted<sup>[6,7]</sup>, NASH can also develop in the absence of insulin resistance and simple benign steatosis (*i.e.*, initial hit)<sup>[8]</sup>. The potential candidates regarded as the “second hit” include oxidative stress, inflammation and changes in mitochondrial function<sup>[7,9-12]</sup>. Iron is also considered as a “second hit” in liver injury<sup>[13]</sup> and a role for iron has been reported in NASH pathogenesis. Patients with NAFLD/ NASH frequently display elevated serum iron indices and hepatic iron content<sup>[14,15]</sup>. A strong correlation between hepatic iron content and the level of liver fibrosis in NAFLD/NASH patients has been shown<sup>[16-18]</sup>. Phlebotomy has also been suggested to alleviate insulin resistance in NAFLD patients<sup>[19]</sup>.

The mechanisms by which iron contributes to NAFLD/ NASH pathogenesis have mainly been attributed to oxidative stress, which can induce lipid peroxidation<sup>[20]</sup> and ultimately the activation of fibrotic signaling<sup>[21]</sup>. Studies with genetic haemochromatosis (GH) patients have shown the association of primary iron overload with fibrogenesis<sup>[22]</sup>. By using dietary experimental models, some studies have also suggested a reverse connection between iron and steatosis in rat livers<sup>[23,24]</sup>. In contrast, another study with a mouse dietary model of iron and high fat failed to show any significant effect of iron on steatosis<sup>[25]</sup>. The consequences of altered iron homeostasis for lipid metabolism in the liver are therefore unclear.

In this study, we employed hepcidin knockout mice with iron overload phenotype as an experimental model to further study the role of iron metabolism in NAFLD/NASH. Hepcidin is the central regulator of iron homeostasis, which is primarily synthesized in hepatocytes as a circulatory protein<sup>[26]</sup>. Unlike humans, which express only one hepcidin gene, *HAMP*, mice express two hepcidin genes, hepcidin (*Hamp1*) and *Hamp2*<sup>[27]</sup>. *Hamp1*, the human equivalent of mouse hepcidin gene, is by itself sufficient to regulate iron metabolism<sup>[28,29]</sup>. Hepcidin controls iron homeostasis by decreasing iron absorption from the absorptive enterocytes in the duodenum and the release of iron from the macrophages<sup>[30]</sup>. The lack of hepcidin expression in knockout mice and in human iron disorders results in iron accumulation both in the liver and other organs<sup>[30-32]</sup>. GH patients also display impaired hepcidin expression<sup>[33]</sup>. Although changes in both serum and liver hepcidin expression levels have been reported in NAFLD/NASH patients<sup>[14,34-38]</sup>, the significance of hepcidin in disease pathogenesis is unknown. Our findings in this study with *Hamp1* knockout mice administered a high fat diet for different time points suggest a role for hepcidin in NAFLD/NASH pathogenesis. This mouse model may also serve as a novel experimental model of NAFLD/NASH.

## MATERIALS AND METHODS

### Animal studies

Animal experiments were approved by the Institutional

**Table 1 SYBR green real-time quantitative polymerase chain reaction primer sequences of mouse genes**

Animal Care and Use Committee at the University of Nebraska Medical Center. *Hamp1* floxed mice and ubiquitous *Hamp1* knockout mice, lacking hepcidin expression in all the organs, were generated, as published previously<sup>[29]</sup>. All mice are on C57BL/6J genetic background. *Hamp* floxed mice have been donated to the Jackson Laboratory (Catalog No. 026872, 026873).

Male mice (4-6-wk-old) were randomly separated into groups to feed with custom-made regular control (17.2% kcal from fat, 100 g/kg sucrose) or high fat and high sucrose (HFS) [42% kcal from fat (54% saturated, 9.7% trans-fat), 0.4% cholesterol, 340 g/kg sucrose] diets for 3 or 7 mo (Harlan Laboratories; TD.97184; TD.120654). Water was given ad libitum, and contained sucrose (40 g/L) with HFS-fed groups to imitate the western diet with fat and soda consumption.

### Liver histology

Formalin-fixed, paraffin-embedded liver tissues were sectioned and stained with hematoxylin and eosin at UNMC Histology Core Facility. To determine fibrosis, sections were stained with Picrosirius Red, as published previously<sup>[39]</sup> and histomorphometric analyses were performed using ImageJ ROI manager software.

### Quantification of liver triglycerides

Triglycerides were isolated, as described<sup>[40]</sup> and quantified using a commercial kit (Thermo Scientific DMA kit 2750) according to manufacturer's instructions.

### Real-time polymerase chain reaction

cDNA was synthesized from liver tissue RNA with Superscript II reverse transcriptase (Invitrogen), as described<sup>[41]</sup>. Real-time polymerase chain reaction (PCR) reactions were performed using iTaq Universal SYBR Green Supermix (Bio-Rad) with a StepOnePlus instrument (Life Technologies). Glyceraldehyde 3-phosphate dehydrogenase (*Gapdh*) gene was used as the endogenous control and gene amplification was calculated using comparative Ct method, as described<sup>[41]</sup>. Primer sequences are shown in Table 1.

### Western blotting

Western blots using whole liver tissue lysate proteins were performed, as published previously<sup>[41]</sup>. Antibodies

were obtained commercially (Cell Signaling, Sigma) and immune-reactive bands were detected by the ImmunStar™ kits (Bio-Rad).

### Statistical analysis

The significance of differences between groups was determined by Student's *t*-test or one-way ANOVA by using SPSS software. A value of *P* < 0.05 was accepted as statistically significant.

## RESULTS

To study the interaction of hepcidin-induced iron overload and lipid metabolism, ubiquitous *Hamp1* knockout and floxed control mice were administered either high fat and HFS or regular (control) diets, as described in Material and Methods. Since NAFLD/NASH progression can occur over a long period of time, mice were fed up to 7 mo. We have previously shown that the deletion of both *Hamp1* alleles induces significant iron overload in the livers of *Hamp1* knockout mice by using inductively coupled mass spectrometry (ICP-MS)<sup>[29]</sup>. ICP-MS analysis did not detect any significant level of iron in the livers of homozygous *Hamp1* floxed control mice. Gradual iron deposition was also indicated macroscopically by the darker color of knockout mice livers compared to those of floxed control mice (Figure 1).

Macroscopic analyses have confirmed that HFS intake induced hepatomegaly and more pronounced visceral fat accumulation in floxed control mice compared to knockout mice (Figure 1). In agreement, the liver weights of floxed mice were significantly higher ( $3.5 \pm 0.46$  g) than those of knockout mice ( $2.42 \pm 0.54$  g) particularly following 7 mo of HFS administration (Figure 2A and B). However, HFS intake induced similar increases in body weights in both floxed (Figure 2C) and knockout (Figure 2D) mice after either 3 or 7 mo-long feeding, as compared to respective controls fed with regular diet.

To further understand these discrepancies between floxed and knockout mice, histological analysis were performed. Hematoxylin and eosin staining of livers showed significantly higher levels of steatosis in floxed than in knockout mice both after 3 and 7 mo-long HFS feeding (Figure 3). The quantification of hepatic triglycerides further confirmed that HFS intake signifi-

**Figure 1** Macroscopic changes in *Hamp1* floxed and knockout mice fed with either a high fat and high sucrose or a regular control diet for 3 or 7 mo. Representative images showing the abdominal cavity of mice were obtained with a digital camera (Nikon).

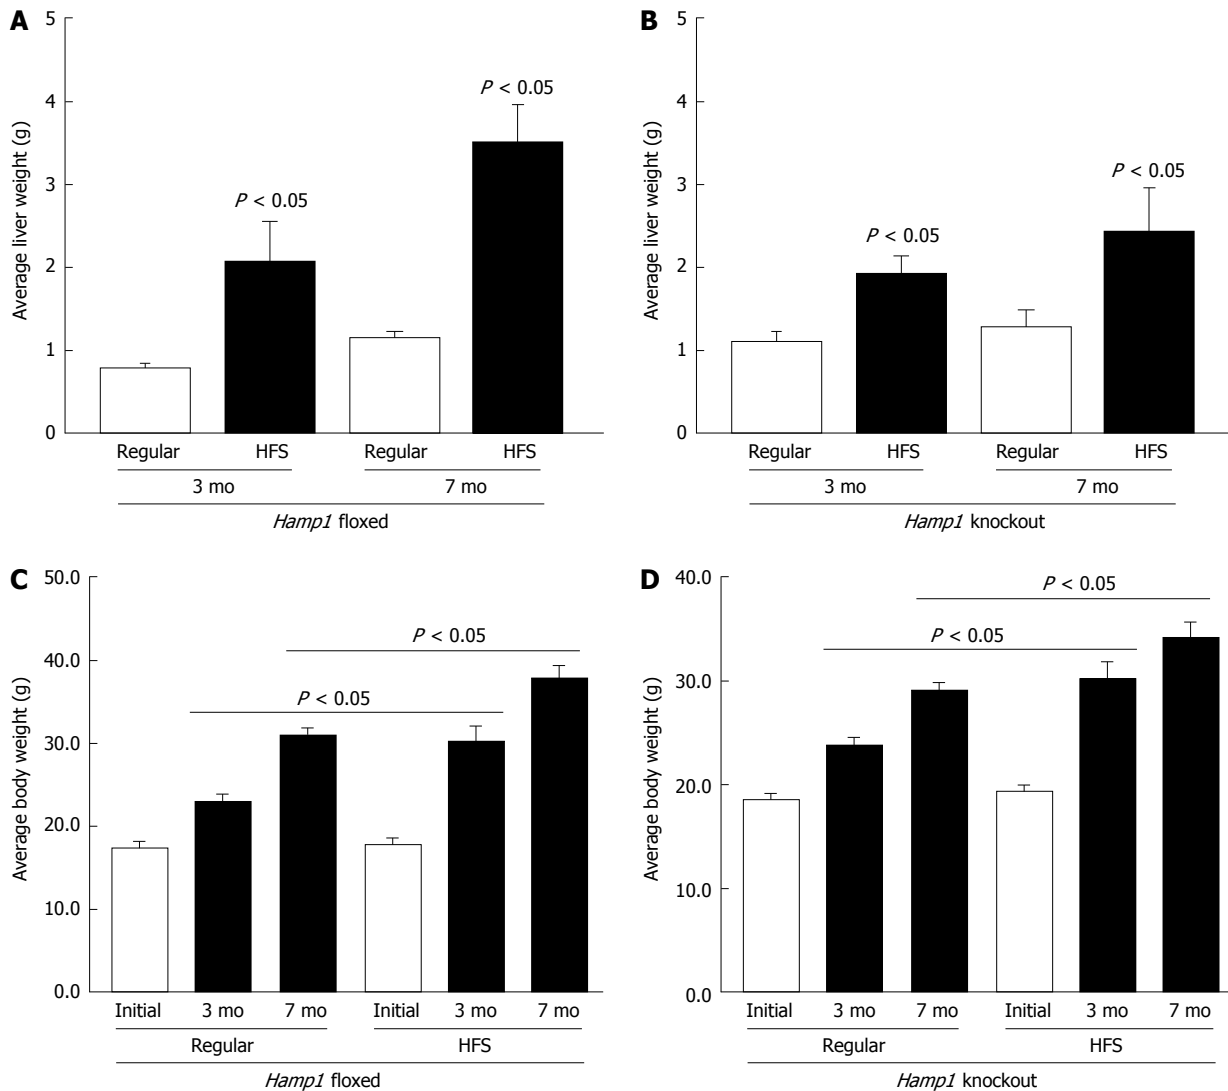

cantly increased hepatic triglyceride content to different extents in floxed and knockout mice (Figure 4). At the end of 3 mo-long high fat intake, the level of hepatic triglyceride accumulation was 2.85-fold higher in floxed mice compared to knockout mice ( $1876.64 \pm 370.84$  and  $657.98 \pm 186.89$   $\mu\text{mol/L}$  per 100 g BW) (Figure 4A). Seven mo-long feeding yielded 2.07-fold higher hepatic triglyceride content in floxed than in knockout mice ( $1837.71 \pm 118.12$  and  $886.91 \pm 89.51$   $\mu\text{mol/L}$  per 100 g BW) (Figure 4B).

Sirius Red staining of liver sections showed that knockout, but not floxed, mice developed fibrosis within 3 mo of high fat intake (Figure 5A). The deletion of both *Hamp1* alleles per se has also caused weaker but significant level of fibrosis in the livers of knockout mice (Figure 5A). Quantification by ImageJ analysis has shown a 2.56-fold higher level of fibrosis in the livers of high fat-fed knockout than regular diet-fed knockout mice at 3 mo (Figure 5B). In contrast to 3 mo, 7 mo of high fat intake induced fibrosis in the livers of floxed mice (Figure 6A). Compared to 3 mo, regular diet feeding for 7 mo slightly increased the level of fibrosis in knockout mice livers (Figure 6A). Knockout mice with 7 mo-long high fat intake developed the highest level of fibrosis, as shown by Image J quantification (Figure 6B). The hepatic expression patterns of alpha smooth

muscle actin ( $\alpha\text{SMA}$ ) protein, a marker for hepatic stellate cell activation, were in agreement with our histological analysis. Three months-long HFS feeding elevated liver  $\alpha\text{SMA}$  expression in knockout, but not floxed, mice, as shown by Western blotting (Figure 7A). The deletion of *Hamp1* alleles by itself increased hepatic  $\alpha\text{SMA}$  expression (Figure 7A). In contrast to 3 mo, 7 mo-long high fat intake increased  $\alpha\text{SMA}$  expression in the livers of both floxed and knockout mice (Figure 7A).

Studies with JNK knockout mice fed with methionine-choline-deficient diet (MCD) diets have indicated a role for c-Jun N-terminal kinase (JNK) in steatosis<sup>[42]</sup>. JNK is activated by phosphorylation on serine residues<sup>[43]</sup>. The expression levels of phosphorylated JNK protein in the livers of *Hamp1* transgenic mice were therefore determined by western blotting using specific anti-phospho JNK antibodies (Figure 7B). Three-month-long high fat intake significantly stimulated JNK phosphorylation in the livers of floxed, but not knockout, mice (Figure 7B). In contrast, the effect of high fat intake on JNK phosphorylation in the liver was weakened by 7 mo-long feeding (Figure 7B).

To further investigate the underlying mechanisms of attenuated fat accumulation in the livers of knockout mice with high fat intake, mRNA expression levels of genes, which are known to be involved in lipid meta-

**Figure 2** Liver and body weights of *Hamp1* floxed and knockout mice fed with high fat or regular diets. Average liver (A and B) and body (C and D) weights of floxed (A and C) and knockout (B and D) mice prior to (initial) and after feeding with high fat and sucrose (HFS) or regular control diets for 3 or 7 mo are shown as gram weight.

bolism, were examined by real-time PCR (Figure 8). The transcription factor, sterol regulatory element-binding protein-1c (*Srebp-1c*) is involved in *de novo* lipogenesis and its expression is also regulated at the transcriptional level<sup>[44,45]</sup>. The deletion of *Hamp1* alleles did not significantly alter basal hepatic expression levels of *Srebp-1c* (Figure 8A and B). Three months of high fat intake stimulated *Srebp-1c* expression by 13.39-fold in floxed and 7.40-fold knockout mice compared to controls (Figure 8A). In contrast, 7 mo of high fat intake elevated *Srebp-1c* expression only by 3.72-fold in floxed mice (Figure 8B). Furthermore, 7 mo-long high fat feeding did not significantly alter liver *Srebp-1c* expression in knockout mice (Figure 8B).

Fat-specific protein-27 (*Fsp27*) protein is involved in lipid droplet formation<sup>[46]</sup>. HFS feeding for 3 and 7 mo significantly induced *Fsp27* expression in the livers of floxed mice by 3.83- and 5.36-fold, respectively compared to regular diet-fed floxed mice (Figure 8C

and D). The livers of knockout mice fed with HFS for 3 or 7 mo displayed significantly lower induction of *Fsp27* expression than floxed mice, which was more prominent at 7 mo (Figure 8C and D). Liver *Fsp27* expression was not significantly altered in knockout mice fed with regular diets for 3 or 7 mo compared to respective floxed controls (Figure 8C and D).

Microsomal triglyceride transfer protein (*Mttp*) protein is responsible for the production and secretion of VLDL particles<sup>[47]</sup>. The mRNA expression level of *Mttp* in the liver was not significantly altered in floxed and knockout mice after 3 mo of high fat intake (Figure 8E). However, high fat exposure for 7 mo significantly suppressed *Mttp* expression in the livers of both floxed and knockout mice (Figure 8F).

Changes in fatty acid oxidation in the liver play an important role in NAFLD pathogenesis. Peroxisome proliferator-activated receptor- $\alpha$  (*Ppara*) activates the transcription of genes involved in the regulation of

**Figure 3** Liver histology in *Hamp1* floxed and knockout mice fed high fat or regular diets. Liver sections from floxed and knockout mice fed with high fat and sucrose (HFS) or regular diets for 3 and 7 mo were stained with hemotoxylin and eosin. Representative images obtained with a Nikon Eclipse E400 light microscope are shown (20 ×). Arrows indicate steatosis.

fatty acid  $\beta$ -oxidation<sup>[48]</sup>. The mRNA expression levels of Ppar $\alpha$  were up-regulated at similar levels in the livers of both floxed and knockout mice within 3 mo of high fat feeding (Figure 9A). In contrast, the livers of floxed

and knockout mice with 7 mo of high fat exposure displayed significantly inhibited Ppar $\alpha$  expression (Figure 9B). Carnitine palmitoyltransferase-1 (Cpt1) is the rate-limiting enzyme in mitochondrial  $\beta$ -oxidation pathway<sup>[49]</sup>.

**Figure 4** Liver triglyceride content in *Hamp1* floxed and knockout mice fed high fat or regular diets. Hepatic triglyceride content in floxed and knockout mice fed with regular or high fat sucrose (HFS) diets for 3 (A) or 7 (B) mo was quantified using 50 mg of wet liver tissue. Liver triglyceride amount was expressed as  $\mu\text{mol}$  per liver per 100 g body weight ( $\mu\text{mol/L}$  per 100 g BW).

Three month-long high fat administration did not exert a significant effect on hepatic *Cpt1a* expression in floxed and knockout mice (Figure 9C). On the other hand, the livers of knockout mice fed with regular diet for 7 mo expressed higher *Cpt1a* levels compared to floxed mice fed under similar conditions, suggesting a role for gradual iron deposition (Figure 9D). Seven month-long high fat intake did not alter hepatic *Cpt1a* expression in floxed mice (Figure 9D). In contrast, long-term high fat exposure significantly suppressed *Cpt1a* expression in the livers of knockout mice compared to knockout controls (Figure 9D).

Both phosphoenolpyruvate carboxykinase-1 (*Pck1*) and glucose-6-phosphatase (*G6pc*) are involved in gluconeogenesis. Similar to *Cpt1a*, the deletion of *Hamp1* alleles significantly up-regulated basal *Pck1* mRNA expression in the liver. In contrast, the absence of hepcidin expression suppressed basal hepatic *G6pc* mRNA expression (Figure 9E-H). Both 3 and 7 mo-long high fat exposure significantly inhibited *Pck1* and *G6pc* mRNA expression in the livers of both floxed and knockout mice (Figure 9E-H).

## DISCUSSION

Changes in iron metabolism contribute to liver injury<sup>[22,50]</sup>. The deposition of iron in the liver correlates with disease severity in NAFLD patients<sup>[15]</sup>. The mechanisms by which excess iron contribute to NAFLD pathogenesis is unclear. Although inconclusive, some studies suggested a role for iron in the regulation of lipid metabolism<sup>[23-25]</sup>. Since hepcidin is the central regulator of iron metabolism, we investigated its role in fatty liver disease. We and others showed iron accumulation in *Hamp1* knockout mice<sup>[29,31,51]</sup>. *Hamp1* knockout mice were administered high fat diets for different time periods to generate

pathological features in the liver, which are representative of NAFLD/NASH<sup>[2]</sup>. Collectively, our findings showed a strong correlation between hepcidin and lipid metabolism, and fibrosis in the liver.

The absence of hepcidin expression in *Hamp1* knockout mice exerted an inhibitory effect on hepatic lipid accumulation. This effect was not due to altered rates of diet consumption or weight gain and suggests the involvement of regulatory mechanisms. Previous studies showed a converse relationship between iron and lipid metabolism<sup>[22,23]</sup>. Since lack of hepcidin expression causes iron overload, elevated hepatic iron content may have interfered with fat accumulation in HFS-fed knockout mice. Furthermore, our findings suggest a role for JNK in this process. Namely, we showed a direct correlation between JNK phosphorylation and steatosis levels in floxed mice livers. In contrast, the livers of *Hamp1* knockout mice did not display significant JNK phosphorylation. Of note, the deletion of JNK1 reverses steatosis<sup>[52,53]</sup> and JNK is activated by phosphorylation<sup>[43]</sup>. Hepcidin-mediated changes in JNK activation may therefore be associated with attenuated steatosis in *Hamp1* knockout mice, particularly in early stages of high fat exposure.

Besides iron and JNK, altered metabolic gene expression in high fat-fed knockout mice may play a role in the inhibition of lipid accumulation. This is supported by our findings, which showed that the hepatic expression level of genes involved in lipogenesis and lipid storage do not adequately respond to high fat intake in *Hamp1* knockout mice. Namely, *Srebp-1c* and *Fsp27* expression were blunted in the livers of HFS-fed knockout, but not floxed, mice. These findings are significant because *Srebp-1c* and *Fsp27* expression are regulated at mRNA level<sup>[54]</sup>. Furthermore, the deletion of *Hamp1* alleles did not alter their basic expression levels.

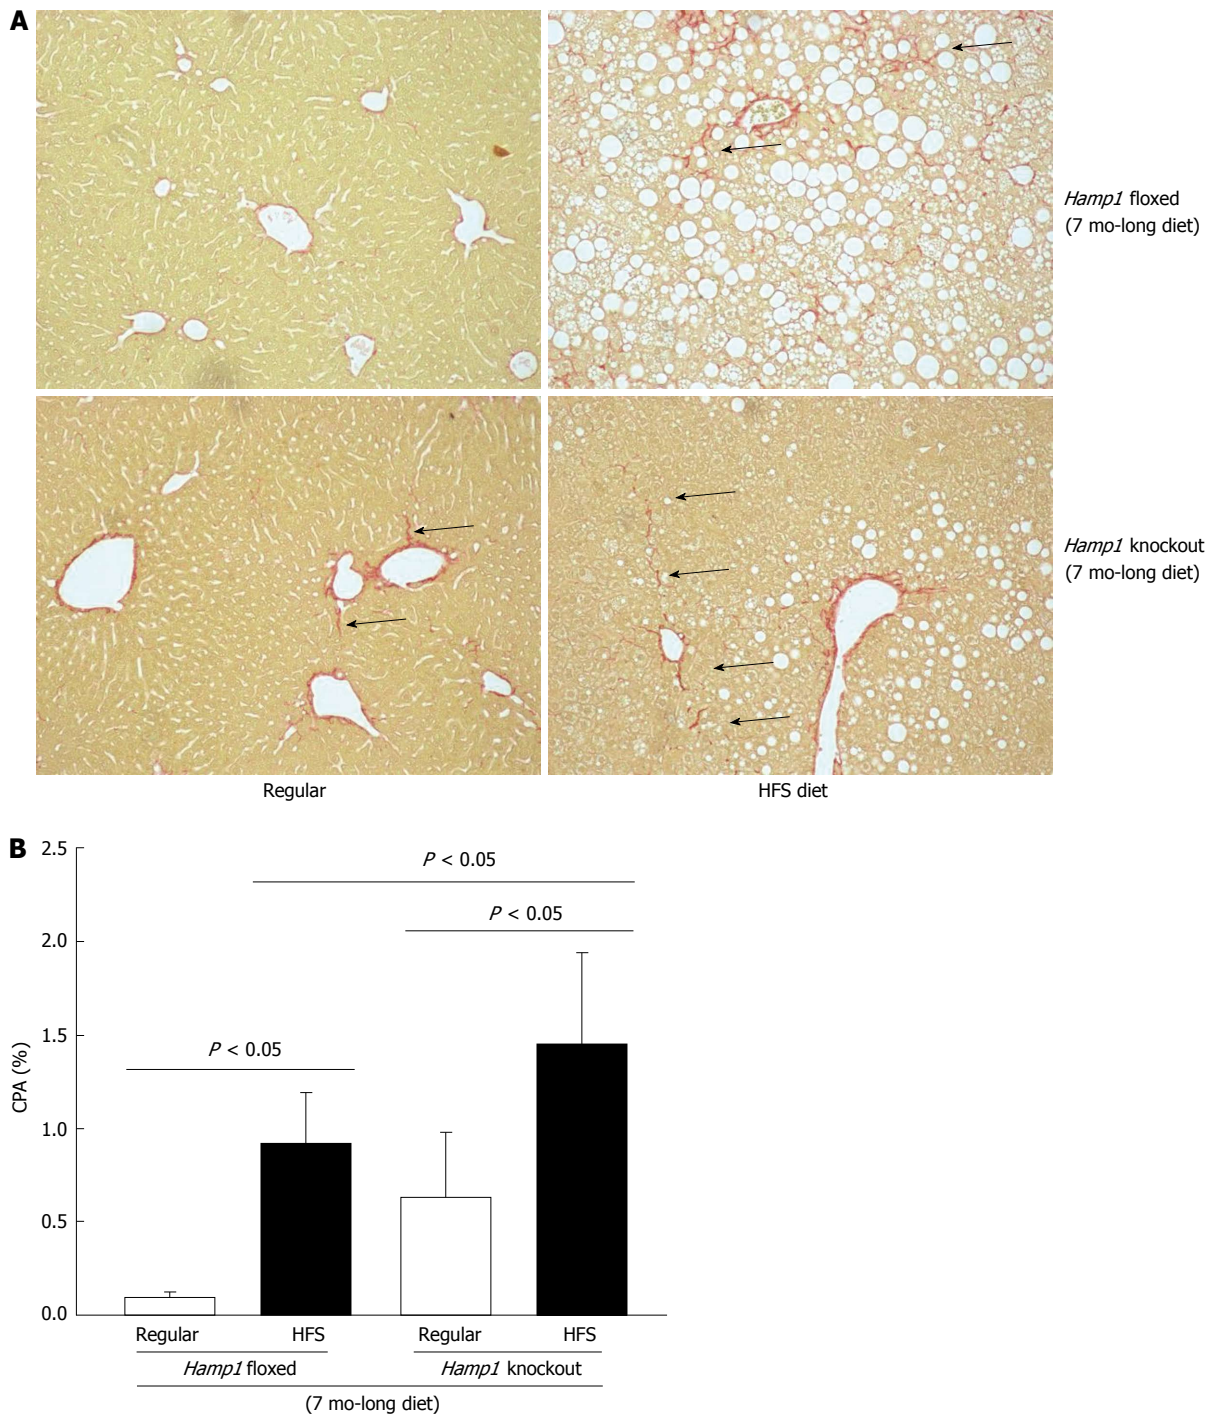

**Figure 5** Fibrosis in *Hamp1* floxed or knockout mice fed high fat or regular diets for 3 mo. A: Fibrosis in the livers of floxed and knockout mice fed on regular or high fat sucrose (HFS) diets for 3 mo was detected by Sirius Red staining of tissue sections. Representative images obtained with Nikon Eclipse E400 light microscope are shown; B: 10 independent images (10 x) taken from each group were quantified using ImageJ ROI manager software. The collagen proportional area (CPA) was determined by calculating the percentage of collagen-occupied pixels against the total pixel values.

Iron-deficient rodents have been reported to display elevated lipogenic gene expression, which indirectly supports our findings<sup>[55-57]</sup>. Hepatic lipid homeostasis is also regulated by lipid export *via* VLDL secretion. The hepatic expression levels of *Mttp*, which is important in this process, were comparable between control and knockout mice. Our findings therefore suggest that decreased lipogenesis and lipid storage, but not

increased lipid secretion, might lead to attenuated steatosis in high fat-fed *Hamp1* knockout mice.

Increased mitochondrial  $\beta$ -oxidation alleviates extra-hepatic fat burden in NAFLD by disposing of excess lipids<sup>[58]</sup>. Ppar $\alpha$ , which induces the transcription of genes involved in  $\beta$ -oxidation, is itself regulated at the transcriptional level<sup>[59,60]</sup>. However, Ppar $\alpha$  is not expected to contribute to liver pathology in *Hamp1*

**Figure 6** Fibrosis in *Hamp1* floxed or knockout mice fed high fat or regular diets for 7 mo. Liver fibrosis in floxed and knockout mice fed on regular or high fat sucrose (HFS) diets for 7 mo was detected (A) and quantified (B), as described above. CPA: Collagen proportional area.

knockout mice because HFS-fed floxed and knockout mice livers displayed similar levels of *Ppar $\alpha$*  expression. *Cpt1* is the rate-limiting enzyme in  $\beta$ -oxidation. Long-term high fat intake significantly suppressed *Cpt1a* expression only in knockout mice livers suggesting a role for it in attenuated steatosis in *Hamp1* knockout mice. Interestingly, *Hamp1* deletion by itself elevated hepatic *Cpt1a* expression. Besides  $\beta$ -oxidation, mitochondria is also important for iron metabolism<sup>[61]</sup>. It is feasible that iron accumulation caused by *Hamp1* deletion modulates

metabolic gene expression in mitochondria. Of note, mitochondrial changes contribute to NAFLD/NASH pathology<sup>[11]</sup>. *Hamp1* deletion also altered the expression of gluconeogenic genes, *Pck1* and *G6pc*. Hepcidin serves as a gluconeogenic sensor in mice during starvation<sup>[62]</sup>. The reasons for the differential regulation of *Pck1* and *G6pc* expression in knockout mice livers are unclear. *Pck1* and *G6pc* are however regulated by various transcription factors including *Foxo1*<sup>[54]</sup> and iron regulates *Foxo1* in adipocytes<sup>[63]</sup>. The net effect of hepcidin and

**Figure 7** Protein expression levels of phosphorylated Jun N-terminal kinase and alpha smooth muscle actin in *Hamp1* floxed and knockout mice fed with high fat or regular diets for 3 or 7 mo. The expression levels of alpha smooth muscle actin ( $\alpha$ SMA) (A) and phosphorylated Jun N-terminal kinase (p-JNK) (B) proteins in the livers of floxed and knockout mice fed with regular or high fat sucrose (HFS) diets for 3 or 7 mo was determined by western blotting, as described in Material and Methods. An anti-gapdh antibody was used as control to determine equal protein loading; Gapdh: Glyceraldehyde 3-phosphate dehydrogenase.

iron on metabolic processes in the liver requires further investigation.

Despite amelioration of steatosis, high fat administration caused injury in the livers of *Hamp1* knockout mice. In fact, knockout mice displayed an earlier and more pronounced development of fibrosis compared to control mice. Previous studies using MCD experimental models have shown that iron supplementation attenuates steatosis and triggers fibrosis<sup>[24,64]</sup>. Of note, MCD diet does not reproduce the metabolic changes observed in NAFLD/NASH patients and induces weight loss<sup>[65,66]</sup>. On the other hand, most high fat diet models induce metabolic changes but not fibrosis<sup>[66,67]</sup>. Furthermore, introduction of iron in the diet can create secondary effects by up-regulating liver hepcidin synthesis and thereby inhibiting the expression of iron exporter, ferroportin<sup>[68-70]</sup>. This will then lead to sequestration of iron in Kupffer cells and trigger inflammation. These artefacts are avoided in our experimental system because iron accumulation is directly caused by the lack of hepcidin expression. Our high fat-fed *Hamp1* knockout mice, which develop early fibrosis, may therefore be an advantageous NAFLD/NASH model.

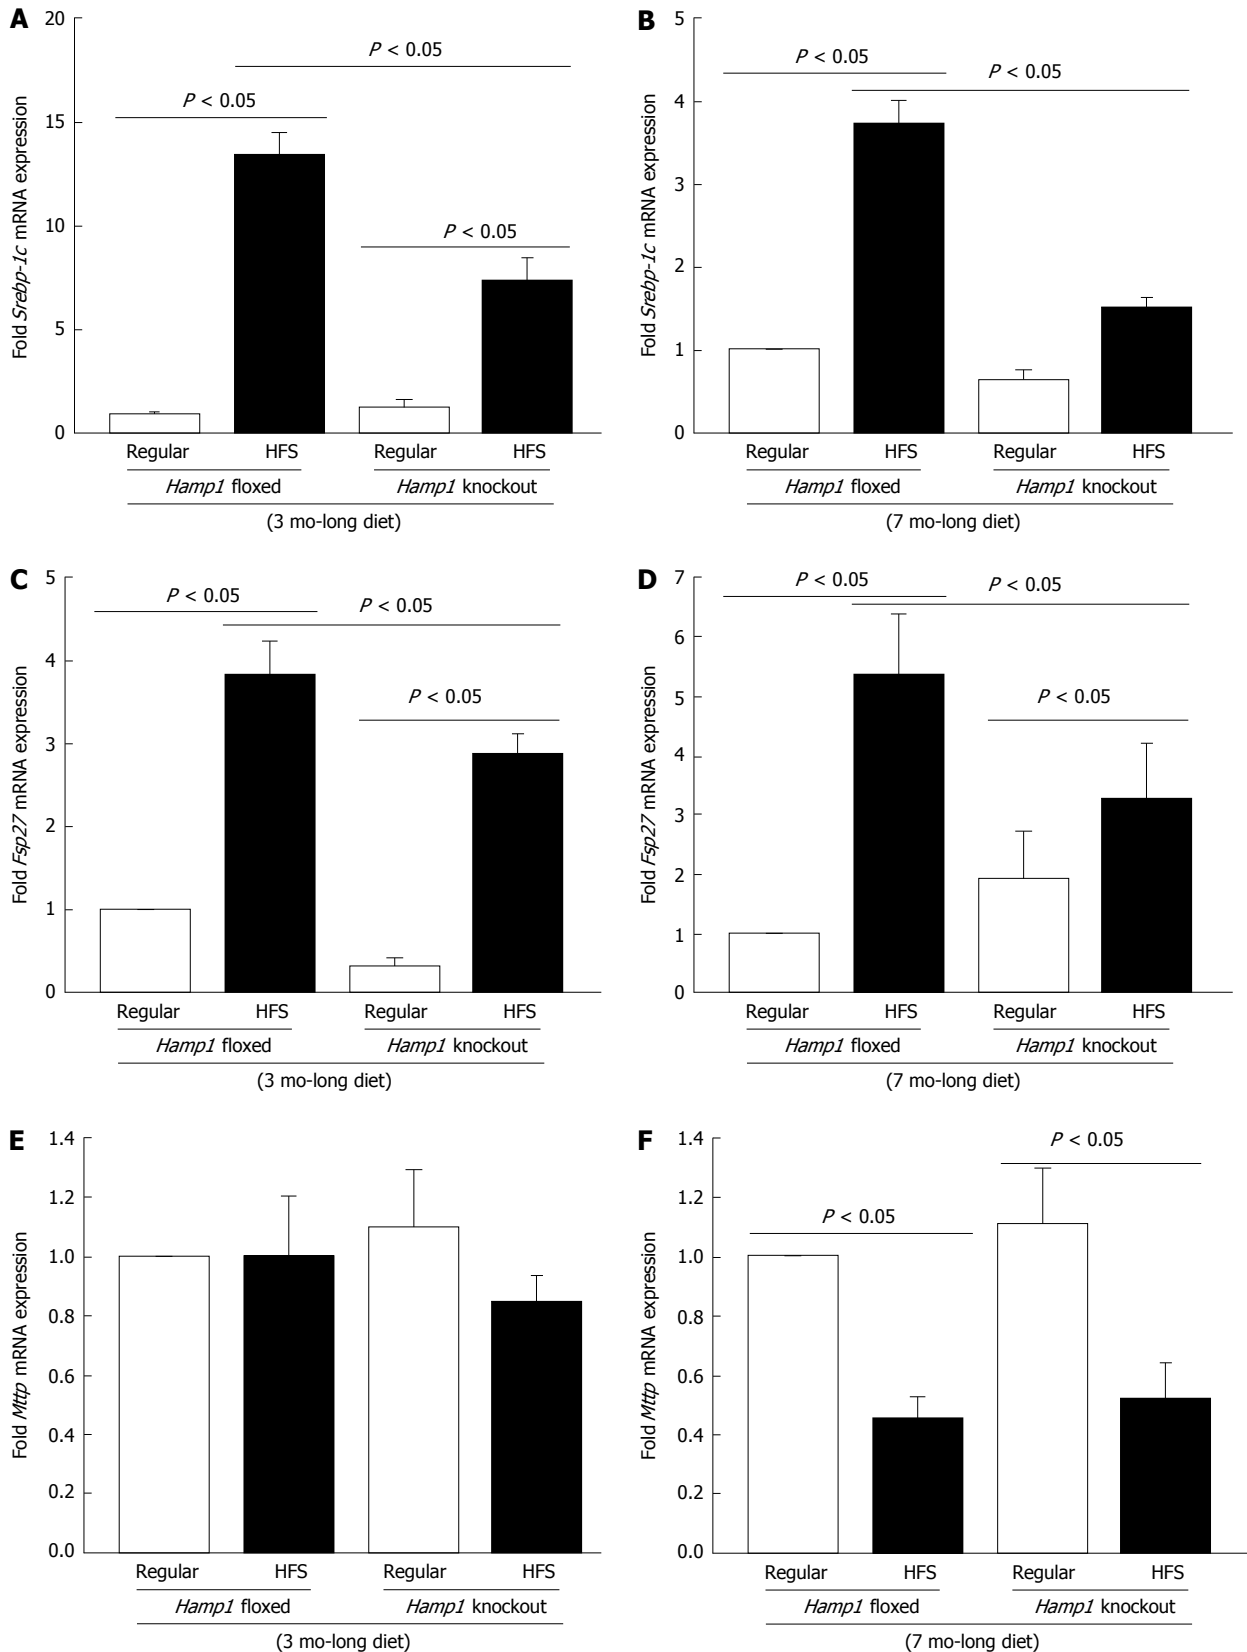

Simple steatosis is considered to be a benign condition in NAFLD patients. *In vivo* and *in vitro* studies have also shown this to be a beneficial process because triglycerides synthesis protects the liver from lipotoxicity induced by free fatty acid accumulation<sup>[64,71]</sup>. The de-

creased level of steatosis in synergy with iron might be responsible for early fibrosis development in the livers of HFS-fed *Hamp1* knockout mice.

In summary, our findings strongly suggest a role for hepcidin in the regulation of hepatic lipid and carbohydrate metabolism. There are currently a limited number of NASH experimental models<sup>[66]</sup>. *Hamp1* knockout mice will therefore be useful to investigate the molecular mechanisms of metabolic processes and fibrosis in NASH pathogenesis.

Lack of hepcidin expression due to the deletion of *Hamp1* alleles inhibited lipid accumulation in the liver following a high fat and high sucrose diet administration. Lack of c-jun kinase phosphorylation and the changes in the expression of metabolic genes, which are involved in lipogenesis and lipid storage, played a role in attenuated steatosis observed in hepcidin knockout mice. Knockout mice developed fibrosis within 3 mo of high fat exposure, which was more prominent at 7 mo. Deletion of *Hamp1* alleles by itself modulated hepatic expression of genes involved in mitochondrial fatty acid oxidation and gluconeogenesis. In summary, hepcidin is associated with the regulation of metabolic processes in the liver and the lack of hepcidin expression triggers early fibrosis development. High fat-fed hepcidin knockout mice may therefore serve as a useful animal model to study different aspects of fatty liver disease pathogenesis.

**Figure 8** Expression of genes involved in lipogenesis, lipid storage and secretion. The mRNA expression levels of *Srebp-1c* (A and B), *Fsp27* (C and D), and *Mttp* (E and F) in the livers of floxed and knockout mice fed with regular and high fat sucrose (HFS) diets, was determined by real-time polymerase chain reaction. Gene expression in high fat-fed floxed or knockout and regular diet-fed knockout mice for 3 (A, C and E) or 7 mo (B, D and F) was expressed as fold change of that in floxed mice fed with a regular diet for the same time period.

**Figure 9 Expression of genes involved in  $\beta$ -oxidation and gluconeogenesis.** The mRNA expression levels of *Pparα* (A and B), *Cpt1a* (C and D), *Pck1* (E and F) and *G6pc* (G and H), in the livers of *Hamp1* floxed and knockout mice fed with regular and high fat sucrose (HFS) diets, was determined by real-time polymerase chain reaction. Gene expression in high fat-fed floxed or knockout and regular diet-fed knockout mice for 3 (A, C, E and G) or 7 mo (B, D, F and H) was expressed as fold change of that in floxed mice fed with a regular diet for the same time period.

## COMMENTS

## Background

Obesity-related metabolic syndrome and its hepatic manifestation, non-alcoholic fatty liver disease (NAFLD) are important public health problems. Hepcidin, synthesized primarily by the liver, is the key iron-regulatory hormone. The authors have previously shown a role for hepcidin in alcoholic liver disease. Hepcidin expression is modulated in NAFLD patients but its significance is unknown. Furthermore, there are only a few animal models of NAFLD, which resemble human disease pathology. The authors are one of the few laboratories with hepcidin transgenic mice models, which were employed in this study to investigate NAFLD pathogenesis.

## Research frontiers

NAFLD is a wide spectrum of disease ranging from simple benign fat accumulation (steatosis) to non-alcoholic steatohepatitis (NASH), which is characterized by inflammation (steatohepatitis) and fibrosis in the liver. A correlation between hepatic iron levels and disease severity in NAFLD/NASH patients has been clearly demonstrated. Since hepcidin is the central iron regulator, it is essential to understand its role in NAFLD/NASH.

## Innovations and breakthroughs

The previously published studies with hepcidin knockout mice generated in the laboratory have demonstrated significant iron accumulation in the liver. To establish a novel NAFLD/NASH experimental model, hepcidin knockout mice were fed with a high fat diet for different time periods. By showing that hepcidin is directly involved in lipid storage and fibrogenesis in the liver following high fat intake, the authors underlined the importance of hepcidin and iron homeostasis in NAFLD/NASH pathogenesis.

## Applications

This study indicated a role for hepcidin in the regulation of metabolic processes and early fibrosis development in the liver. These findings will further understanding of the mechanisms involved in NAFLD/NASH progression and liver fibrosis. Furthermore, the high fat-fed hepcidin knockout mice, as a novel experimental NAFLD/NASH model, can be useful in the search for functional biomarkers and therapeutics for NAFLD/NASH.

## Terminology

Hepcidin is essential for systemic iron homeostasis. Chronic high fat intake and obesity ultimately lead to metabolic syndrome, which is characterized by dyslipidemia and insulin resistance. Obesity also impairs metabolic functions and histology of the liver causing fat accumulation (steatosis), inflammation (steatohepatitis) and scar tissue formation (fibrogenesis), as observed in patients with NAFLD/NASH.

## Peer-review

This manuscript investigated the role of key iron-regulatory protein, hepcidin in non-alcoholic fatty liver disease in hepcidin (*Hamp1*) knockout and floxed control mice administered a high fat and high sucrose or a regular control diet for 3 or 7 mo. The authors suggest that *Hamp1* and iron may play a role in the regulation of metabolic pathways in the liver, which has implications for NAFLD pathogenesis. This manuscript was well designed *in vivo* experiments and well written with all the results obtained.

## Abstract

**AIM:** To evaluate the outcomes of two-stage liver transplant at a single institution, between 1993 and March 2015.

**METHODS:** We reviewed our institutional experience with emergency hepatectomy followed by transplantation for fulminant liver failure over a twenty-year period. A retrospective review of a prospectively maintained liver transplant database was undertaken at a national liver transplant centre. Demographic data, clinical presentation, preoperative investigations, cardio-circulatory parameters, operative and postoperative data were recorded.

**RESULTS:** In the study period, six two-stage liver transplants were undertaken. Indications for transplantation included acute paracetamol poisoning ( $n = 3$ ), fulminant hepatitis A ( $n = 1$ ), trauma ( $n = 1$ ) and exertional heat stroke ( $n = 1$ ). Anhepatic time ranged from 330 to 2640 min. All patients demonstrated systemic inflammatory response syndrome in the first post-operative week and the incidence of sepsis was high at 50%. There was one mortality, secondary to cardiac arrest 12 h following re-perfusion. Two patients required re-transplantation secondary to arterial thrombosis. At a median follow-up of 112 mo, 5 of 6 patients are alive and without evidence of graft dysfunction.

**CONCLUSION:** Two-stage liver transplantation represents a safe and potentially life-saving treatment for carefully selected exceptional cases of fulminant hepatic failure.

**Key words:** Two-stage liver transplantation; Fulminant hepatic failure; Liver transplant; Survival

**Core tip:** We share our experience with selected cases of emergency total hepatectomy followed by liver transplantation for fulminant hepatic failure. This involves initial haemodynamic stabilization by recipient hepatectomy, creating a temporary porto-caval shunt to permit venous drainage during a variable anhepatic phase, then orthotopic transplantation once a suitable donor graft is available.

## INTRODUCTION

Liver transplantation is the treatment of choice for acute or chronic end-stage liver disease. In cases of acute liver failure, often the only life-saving intervention is a super-urgent liver transplantation. However, immediate allocation of a donor organ is not always achievable. Without urgent hepatectomy, some patients with fulminant hepatic failure develop a toxic hepatic syndrome with potentially catastrophic haemorrhage<sup>[1]</sup>. Toxic liver syndrome is defined as complete liver necrosis associated with critical multi-organ dysfunction<sup>[2]</sup>. In this grave circumstance, these critically-ill patients may benefit from a two-stage approach to transplantation; with urgent explantation of the toxic liver and creation of a temporary portocaval shunt, followed by transplantation as soon as a donor organ becomes available<sup>[2]</sup>. First reported in 1988 by Ringe *et al*<sup>[2]</sup> for a patient with primary graft failure causing multi-organ dysfunction, the goal of the first stage of this technique is haemodynamic and metabolic stabilisation. Subsequent to Ringe's description of this novel approach to retransplantation for primary graft failure, a wider variety of indications for this technique have been sporadically reported including liver trauma, spontaneous hepatic rupture, haemolysis elevated liver enzymes and low platelet syndrome associated with preeclampsia, and acute deterioration of chronic liver disease<sup>[2-11]</sup>. During the first stage of these two-stage transplantations, the inferior vena cava is

retained and a porto-caval anastomosis allows systemic and portal venous drainage during the subsequent anhepatic period<sup>[2-11]</sup>. Once an allograft becomes available, the second stage involves orthotopic liver transplantation using a modified piggyback technique without venovenous bypass<sup>[2-11]</sup>.

## MATERIALS AND METHODS

A retrospective review of a prospectively maintained database was undertaken to identify all patients who underwent two-stage liver transplantation at a single institution (a National Liver Transplant Unit) between January 1993 and March 2015. Demographic data, clinical presentation, preoperative investigations, operative details, postoperative course, and histopathological results were recorded. Data collection and analyses were performed with Statistical Package for the Social Sciences (version 16.0) (SPSS, Chicago, IL, United States). Descriptive statistics were computed for all variables. The Kolmogorov-Smirnov test was used to determine the variables' distribution. For nonparametric data, continuous variables are presented as median values (and range) and the Mann-Whitney *U* test was used for any two sample comparisons. Dichotomous variables were compared using the  $\chi^2$  test. All tests were two tailed and results with a *P*-value of < 0.05 were considered statistical significant.

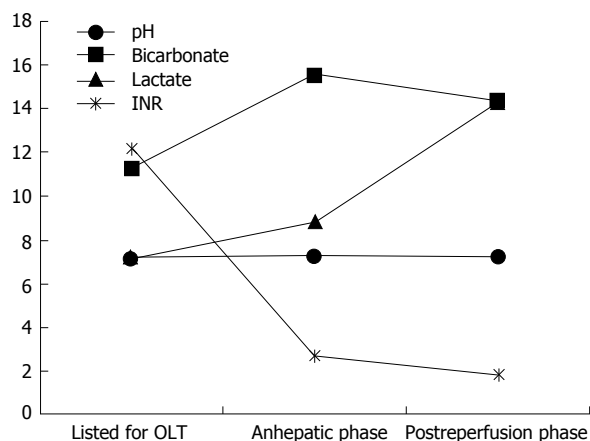

## RESULTS

During the study period, six cases of two-stage liver transplantation were undertaken in our centre. There was a male preponderance (4 males, 2 females). Median age at presentation was 28 years (range 20-47). Two patients had a past medical history of depression, no other co-morbidities were present. The most common indication for super-urgent transplantation was extensive liver necrosis secondary to paracetamol overdose (*n* = 3). One patient developed fulminant liver failure secondary to Hepatitis A infection. One patient had extensive haemorrhage secondary to liver trauma, and one patient developed exertional heat stroke causing ischemic hepatitis while running the final stages of an ultra-marathon. Five of six patients had evidence of toxic liver syndrome, as previously defined. The median model end stage liver disease was 39.50 (range 28-40). All patients had hypoglycemia and metabolic acidosis. In 50% of these cases, haemofiltration was initiated prior to hepatectomy, and all patients were intubated and mechanically ventilated before the procedure. The liver trauma case was the only patient who did not demonstrate signs of encephalopathy. Features of cerebral edema were present in 50% of cases. The anhepatic time ranged from 330 and 2640 min. In two patients, the hepatectomy was performed when a donor graft had been accepted for harvest but was not yet available. In one case, the hepatectomy was

undertaken prior to acceptance of a donor organ due to uncontrollable haemorrhage in the recipient and the patient was listed as “super-urgent” for transplantation. For the remaining three patients the hepatectomy was performed at the time of listing the patient for superurgent transplantation (Table 1).

All patients underwent total hepatectomy and end-to side portocaval anastomosis with temporary abdominal closure as the first of a two-stage transplantation. During the anhepatic phase, patients were managed in the intensive care unit and received haemofiltration with plasma separation treatment. Orthotopic liver transplantation was then performed as soon as an allograft became available. In all cases, histological evaluation of the native liver confirmed the indication for emergency liver transplantation (total liver necrosis regardless the etiology). The use of noradrenaline was required in 4 patients before total hepatectomy with a median of 67 µg/min (range 50-200). During the anhepatic period the inotropic requirements increased to 74 µg/min (10-120), however inotropic requirements decreased immediately after reperfusion of the donor grafts, with a median noradrenaline requirement of 26 µg/min (range 5-60).

Arterial blood gasometry parameters demonstrated increased levels of lactate during the anhepatic phase from a median of 7.2 mmol/L pre-hepatectomy to 8.8

mmol/L. However their acidosis improved during the anhepatic phase as reflected by an increase in pH from median of 7.14 to 7.25, and an increase in bicarbonate from 11.3 to 15.6 mmol/L (Figure 1). Coagulation parameters pre-hepatectomy, during the anhepatic phase, and post transplant are shown in Table 2. During graft implantation, median blood loss was 8.5 L (range 2.5-43 L). All patients received transfusion of blood products, pools of platelets (median of 4 pools), plasma products (median of 9.5 units) and packed red cells (median 8.5 units). During the anhepatic phase, three patients developed ventricular tachycardia which was treated with amiodarone infusion. One patient (liver trauma case) required repeated cardioversions during the anhepatic phase as well as after reperfusion of the donor graft.

All patients ( $n = 6$ ) fulfilled criteria for the diagnosis of systemic inflammatory response syndrome in the first post-transplant week, with 50% having a source of sepsis identified which required anti-microbial treatment with a single broad-spectrum agent. The median time to extubation was 7 d (range 5-15), haemodialysis duration was 20 d (range 6-28) and median hospital stay was 33 d (range 2-210). Two patients required re-transplantation secondary to arterial thrombosis (33%). One of these patients necessitated right hemicolectomy secondary to ileocolic arterial ischemia as well as the early hepatic artery thrombosis which required re-transplantation. There was a single mortality which was due to cardiac arrest and occurred 12 h after reperfusion of the graft, with a median follow-up of 112 mo.

## DISCUSSION

Acute liver failure is a rapidly devastating pathology due to its potential to precipitate multi-organ failure, sepsis and cerebral oedema. Despite advances in supportive care, liver transplantation remains the only potentially life-saving treatment. Although fulminant hepatic failure (FHF) is not a common indication for orthotopic liver transplantation, these patients nonetheless represent a significant challenge for transplant surgeons. Data suggests that the most important prognostic indicators for patients with FHF undergoing transplantation are the degree of encephalopathy, patient's age, the etiology of FHF, and the time to transplantation with the majority of

authors concurring that transplantation within 48-72 h is critical to reduce mortality<sup>[1]</sup>.

The anhepatic state requires considerable expertise in critical care to manage these gravely ill patients. In addition to cardiorespiratory support, haemofiltration and plasma separation are essential to prevent the development of severe lactate acidosis. The longest anhepatic period compatible with life is reported to be 66 h, which was recorded in a child with liver graft non-function after transplantation<sup>[12]</sup>. Herein we report a maximum anhepatic time of 44 h, in a patient who survived despite requiring re-transplantation secondary to hepatic artery thrombosis.

The number of cases of two-stage transplantation reported in the literature is scant and therefore survival rates vary widely<sup>[2-11]</sup>. However, advances in surgical techniques and supportive care appear to have exerted a beneficial effect on survival over time. In his seminal work almost two decades ago, Ringe *et al*<sup>[2,3]</sup> reported 32 patients treated with two-stage transplantation with 24 mortalities (75% mortality). In 2001, Domínguez Fernández *et al*<sup>[7]</sup> reported their outcomes from a series of eight patients who underwent emergency hepatectomy for FHF. Two patients died before a donor liver became available. A further five of six patients who underwent transplantation after an anhepatic period died postoperatively secondary to primary nonfunction or sepsis causing multiorgan failure (87.5% mortality). Herein, we report a series of six patients with a single death (16.6% mortality).

In conclusion, we report a series of cases of two-stage liver transplantation, which is a potentially life-

saving procedure in carefully selected patients in exceptional clinical circumstances.

## COMMENTS

### Background

In the setting of fulminant liver failure, immediate donor graft allocation for life-saving transplant may not always be possible and a two-stage approach may be necessary. This involves initial haemodynamic stabilisation by recipient hepatectomy - creating a temporary porto-caval shunt to allow circulation during a variable anhepatic phase. Once an allograft becomes available, orthotopic transplantation is undertaken using the standard technique. In this study, the authors evaluated the outcomes of two-stage liver transplant at a single institution, between 1993 and March 2015.

### Research frontiers

In cases of acute liver failure, the only life-saving procedure is frequently an emergency liver transplantation. However, immediate allocation of a donor organ is not always possible, particularly in the acute setting. Without urgent removal of the native liver, patients with fulminant hepatic failure, regardless of aetiology, can develop a life-threatening toxic hepatic syndrome. The results of this study suggest that in carefully selected patients a two-stage approach to super-urgent liver transplantation has utility, and can salvage these patients from the multi-organ failure arising from a toxic liver.

### Innovations and breakthroughs

In this study, two-stage liver transplantation appears to be a valuable, albeit exceptional, approach to the management of fulminant liver failure with associated toxic liver syndrome. The authors report a series of six patients treated with emergency hepatectomy and temporary portocaval shunt, followed by urgent orthotopic liver transplantation once a suitable donor graft became available. There was a single perioperative mortality in this series. Although two of the surviving five patients subsequently required re-transplantation for hepatic artery thrombosis, all are alive and without evidence of current graft dysfunction at a median follow-up of 112 mo. The number of cases of two-stage transplantation reported in the literature is scant, therefore mortality and

morbidity rates are largely unknown. This report contributes such data to the transplant literature.

## Applications

This study suggests that two-stage liver transplantation is a potentially life-saving procedure in carefully selected patients and in exceptional clinical circumstances.

## Terminology

Toxic liver syndrome: A critical systemic inflammatory syndrome-like response defined as complete liver necrosis associated with critical multi-organ dysfunction. Two-stage liver transplantation: A procedure which involves emergency hepatectomy and end-to-side portocaval anastomosis in the first stage, followed by liver transplantation when a donor organ becomes available in the second stage.

## Peer-review

The authors of this paper evaluated the outcomes of two-stage liver transplantation as an exceptional procedure in carefully selected patients with fulminant hepatic failure. Further reports of such cases are necessary to better evaluate its safety and utility in the management of acute liver failure.

## Abstract

**AIM:** To describe the pathophysiology, clinical presentation, natural history, and therapy of portal hypertensive gastropathy (PHG) based on a systematic literature review.

**METHODS:** Computerized search of the literature was performed *via* PubMed using the following medical subject headings or keywords: "portal" and "gastropathy"; or "portal" and "hypertensive"; or "congestive" and "gastropathy"; or "congestive" and "gastroenteropathy". The following criteria were applied for study inclusion: Publication in peer-reviewed journals, and publication since 1980. Articles were independently evaluated by each author and selected for inclusion by consensus after discussion based on the following criteria: Well-designed, prospective trials; recent studies; large study populations; and study emphasis on PHG.

**RESULTS:** PHG is diagnosed by characteristic endoscopic findings of small polygonal areas of variable erythema surrounded by a pale, reticular border in a mosaic pattern in the gastric fundus/body in a patient with cirrhotic or non-cirrhotic portal hypertension. Histologic findings include capillary and venule dilatation, congestion, and tortuosity, without vascular fibrin thrombi or inflammatory cells in gastric submucosa. PHG is differentiated from gastric antral vascular ectasia by a different endoscopic appearance. The etiology of PHG is inadequately understood. Portal hypertension is necessary but insufficient to develop PHG because many patients have portal hypertension without PHG.

PHG increases in frequency with more severe portal hypertension, advanced liver disease, longer liver disease duration, presence of esophageal varices, and endoscopic variceal obliteration. PHG pathogenesis is related to a hyperdynamic circulation, induced by portal hypertension, characterized by increased intrahepatic resistance to flow, increased splanchnic flow, increased total gastric flow, and most likely decreased gastric mucosal flow. Gastric mucosa in PHG shows increased susceptibility to gastrototoxic chemicals and poor wound healing. Nitrous oxide, free radicals, tumor necrosis factor- $\alpha$ , and glucagon may contribute to PHG development. Acute and chronic gastrointestinal bleeding are the only clinical complications. Bleeding is typically mild-to-moderate. Endoscopic therapy is rarely useful because the bleeding is typically diffuse. Acute bleeding is primarily treated with octreotide, often with concomitant proton pump inhibitor therapy, or secondarily treated with vasopressin or terlipressin. Nonselective  $\beta$ -adrenergic receptor antagonists, particularly propranolol, are used to prevent bleeding after an acute episode or for chronic bleeding. Iron deficiency anemia from chronic bleeding may require iron replacement therapy. Transjugular-intrahepatic-portosystemic-shunt and liver transplantation are highly successful ultimate therapies because they reduce the underlying portal hypertension.

**CONCLUSION:** PHG is important to recognize in patients with cirrhotic or non-cirrhotic portal hypertension because it can cause acute or chronic GI bleeding that often requires pharmacologic therapy.

**Key words:** Portal hypertensive gastropathy; Congestive gastropathy; Portal hypertension; Cirrhosis; Cirrhotic; Chronic liver disease; Nonvariceal upper gastrointestinal bleeding; Esophageal varices; Hepatic fibrosis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Portal hypertensive gastropathy (PHG) is diagnosed by characteristic endoscopic findings of variably erythematous, small, polygonal areas surrounded by a whitish, reticular border in a mosaic pattern in the gastric fundus/body in a patient with portal hypertension of any etiology. The pathophysiology of PHG is inadequately understood. Portal hypertension is a prerequisite to develop PHG. PHG increases in frequency with increasing portal hypertension, liver disease progression, duration of liver disease, presence of esophageal varices, and endoscopic variceal obliteration. Pathogenesis is related to a hyperdynamic circulation induced by portal hypertension. Gastric mucosa in PHG exhibits greater susceptibility to gastrototoxic chemicals and poor wound healing. Acute or chronic gastrointestinal bleeding are the only clinical complications. Bleeding is typically mild-to-moderate and rarely fatal. Endoscopic therapy is rarely useful. Pharmacotherapy for acute bleeding includes octreotide with concomitant proton-pump-inhibitor therapy, or alternatively vasopressin. Nonselective  $\beta$ -adrenergic receptor antagonists, particularly propranolol, are used

to prevent re-bleeding after acute bleeding or for chronic bleeding. Transjugular-intrahepatic-portosystemic-shunt and liver transplantation is ultimate therapies because they treat the underlying portal hypertension.

Portal hypertensive gastropathy: A systematic review of the pathophysiology, clinical presentation, natural history and therapy. *World J Hepatol* 2016; 8(4): 231-262 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i4/231.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i4.231>

## INTRODUCTION

Portal hypertensive gastropathy (PHG) is an important, but underappreciated, cause of morbidity in patients with cirrhotic or non-cirrhotic portal hypertension. Researchers have recently intensely focused on this inadequately understood disease. However, the research studies have been published in a wide spectrum of journals including basic or biomedical journals not readily accessible to clinicians and a review incorporating the recent basic and clinical advances in this rapidly evolving subject is needed. This work systematically reviews this entity including pathophysiology, clinical presentation, natural history, and established, evolving, or experimental therapy, with a focus on data relevant to clinicians and an emphasis on recent data. This work aims to describe what is known about the disease and to expose gaps, requiring further research, in our current understanding of this disease.

## MATERIALS AND METHODS

Computerized search of the literature was performed *via* PubMed using the following medical subject headings or keywords: "portal" and "gastropathy"; or "portal" and "hypertensive"; or "congestive" and "gastropathy"; or "congestive" and "gastroenteropathy". The following criteria were applied for study inclusion: Publication in peer-reviewed journals, and publication since 1980, except for publications from 1957-1980 of historical significance reviewed in the history section. Articles were independently evaluated by each author and selected for inclusion by consensus after a thorough discussion based on the following criteria: Well-designed, prospective trials; recent studies; large study populations; and study emphasis on PHG. However, data from retrospective series, reviews from internationally recognized authorities, and even case reports were included when prospective trials were unavailable.

## RESULTS

### History

Palmer<sup>[1]</sup>, in 1957, proposed that the pathogenesis of erosive gastritis in cirrhotic patients was different than that in non-cirrhotic patients and that erosive gastritis

PHG: Portal hypertensive gastropathy; EHPVO: Extrahepatic portal vein obstruction; TEE: Transesophageal echocardiogram.

in cirrhotic patients resulted from mechanical venous back-pressure from portal hypertension, rather than a circulating, mucosal, or intraluminal toxic factor. This proposal was supported by successful reversal of erosive gastritis in cirrhotic patients with portal decompression by surgical shunts<sup>[1]</sup>. In 1984, Sarfeh *et al*<sup>[2]</sup> recognized a distinct form of gastric mucosal hemorrhage in patients who had portal hypertension, demonstrated by cirrhosis and gastroesophageal varices, which they called "portal hypertensive gastritis". They proposed that gastric mucosa in portal hypertension reacts differently from gastric mucosa without portal hypertension and these patients with portal hypertension may benefit from portal decompressive surgery. One year later, McCormack *et al*<sup>[3]</sup> reported that the gastritis in patients with portal hypertension differed from that in patients without portal hypertension in mucosal histology, nonresponse to standard therapy for conventional gastritis, and in occasionally having very similar histological changes in other gastrointestinal (GI) organs such as the colon. They called these gastritis-like changes in patients with portal hypertension "congestive gastropathy"<sup>[3]</sup>, and classified it as "mild" or "severe", using criteria described by Taor *et al*<sup>[4]</sup>.

### Epidemiology

PHG can present at any age, including pediatric or adult patients. The reported prevalence of PHG varies greatly from 20% to 75% in patients with portal hypertension (Table 1)<sup>[3,5-23]</sup>, and varies greatly from about 35% to 80% in patients with cirrhosis (Table 2)<sup>[21,23-68]</sup>. For

example, in a study of 373 cirrhotic patients, 299 (80.2%) had PHG<sup>[34]</sup>. In the HALT-C trial, 374 (37%) of 1011 patients with biopsy-proven cirrhosis or bridging fibrosis from hepatitis C had PHG<sup>[69]</sup>. This wide variability likely reflects variability in classification criteria, interpretation of endoscopic lesions, study populations, and natural history of PHG<sup>[10,70,71]</sup>.

PHG is usually mild as reported by McCormack *et al*<sup>[3]</sup> or in the NIEC study<sup>[32,70]</sup>. The prevalence of mild PHG in patients with portal hypertension ranges from 29%-57%, and of severe PHG ranges from 9%-46%<sup>[71]</sup>.

### Risk factors for PHG

The main predictors of PHG are portal hypertension and severe liver disease<sup>[72]</sup>.

**Portal hypertension:** Most studies show that the frequency and severity of PHG is strongly correlated with the severity of portal hypertension, as indicated by multiple parameters, including hepatic venous pressure gradient (HVPG)<sup>[36,57]</sup>, esophageal intravariceal pressure<sup>[29]</sup>, and presence or size of esophageal varices<sup>[34,42,57,62,73]</sup>. Merkel *et al*<sup>[36]</sup> reported that the severity of PHG was correlated with the severity of portal hypertension as determined by HVPG, but this correlation was significant only for severe PHG (HVPG = 20.5 ± 4.0 mmHg) *vs* no PHG (HVPG = 17.4 ± 5.2 mmHg, *P* = 0.0004), and not for mild PHG (HVPG = 16.1 ± 3.2 mmHg) *vs* no PHG [17.4 ± 5.2 mmHg, not significant (NS)]. In a prospective study of 331 cirrhotic patients, Kim *et al*<sup>[57]</sup> found that patients with severe

**Table 2** Rates of portal hypertensive gastropathy in patients with cirrhosis

PHG: Portal hypertensive gastropathy.

PHG had significantly higher HVP (15.6 ± 4.6 mmHg) than patients with mild PHG (10.7 ± 4.1 mmHg) or no PHG (4.9 ± 1.7 mmHg) ( $P < 0.001$ ). Merkel *et al*<sup>[36]</sup> similarly reported in a small study that HVP was significantly higher in patients with severe PHG as compared to mild or no PHG.

Primignani *et al*<sup>[34]</sup> confirmed the correlation of PHG with severity of portal hypertension, by correlating PHG with presence and size of esophageal varices. The rate of PHG was significantly higher in patients with esophageal varices [80 of 104 patients (76.9%)]

than in patients without esophageal varices [51 of 84 (60.7%),  $P < 0.007$ ]. The rate of PHG also significantly increased with increasing variceal size ( $\chi^2 = 13.2$ ;  $df = 1$ ,  $P = 0.0003$ ). Abbasi *et al*<sup>[62]</sup> reported a significantly positive correlation between esophageal variceal size and rate of PHG ( $r = 0.46$ ;  $P < 0.001$ ). Taranto *et al*<sup>[29]</sup> reported more severe PHG in cirrhotic patients with more severe portal hypertension, as measured by esophageal intravariceal pressure. Iwao *et al*<sup>[28]</sup> reported that patients with severe PHG had elevated HVP, high hepatic sinusoidal resistance, and low hepatic blood

flow, all markers of severe portal hypertension. For example, patients without PHG had hepatic sinusoidal resistance of  $1218 \pm 528 \text{ dyne} \times \text{s}^{-1} \times \text{cm}^{-5}$ , patients with mild PHG had resistance of  $1968 \pm 944 \text{ dyne} \times \text{s}^{-1} \times \text{cm}^{-5}$  ( $P < 0.05$ ), and patients with severe PHG had resistance of  $2082 \pm 672 \text{ dyne} \times \text{s}^{-1} \times \text{cm}^{-5}$  ( $P < 0.01$ ). Presence of PHG was independent of patient age, sex, or cirrhosis etiology<sup>[28]</sup>.

As discussed below, other data supporting an association between PHG and portal hypertension include resolution of PHG after intervention to decrease portal hypertension, including pharmacotherapy<sup>[74-78]</sup>, transjugular intrahepatic portosystemic shunt (TIPS), or liver transplantation<sup>[74]</sup>.

Contrariwise, a decided minority of studies showed no significant association between severity of portal hypertension and rate of PHG<sup>[8,9,16,26,28,30,31,47,54,67]</sup>. Curvêlo *et al*<sup>[54]</sup> found no significant difference in HVP in cirrhotic patients with vs without PHG. Bellis *et al*<sup>[47]</sup> demonstrated similar findings. Among patients with portal hypertension from cirrhosis without esophageal varices, Zardi *et al*<sup>[67]</sup> reported that patients with PHG vs patients without PHG had similar mean portal vein diameter, splenic vein diameter, and portal flow volume, all markers of severity of portal hypertension. Erden *et al*<sup>[16]</sup> showed that the mean diameters of the left gastric, paraesophageal, and azygos veins, which are markers of portal hypertension, were not significantly different between patients with vs without PHG. The preponderance of data strongly suggest that the severity of portal hypertension is associated with the severity or frequency of PHG.

#### **Cirrhotic vs non-cirrhotic portal hypertension:**

Primary liver disease usually occurs in PHG, but is not a prerequisite for PHG provided another cause of portal hypertension exists. PHG can occur among patients with non-cirrhotic portal fibrosis (NCPF), extrahepatic portal vein obstruction (EHPVO), hepatic veno-occlusive disease, and schistosomiasis<sup>[8,14,35,75,79]</sup>.

The frequency of PHG appears to be higher in portal hypertension with cirrhosis than in portal hypertension without cirrhosis. Sarin *et al*<sup>[8]</sup> reported that patients with cirrhosis had a significantly higher frequency of PHG (37.1%) than that in patients with NCPF (16.7%;  $P < 0.05$ ), or non-cirrhotic EHPVO (8.7%;  $P < 0.01$ ) and had a more aggressive course of PHG with progression to more severe PHG with time. These phenomena are attributed to the worse liver function in patients with cirrhosis as compared to patients with NCPF or EHPVO<sup>[8]</sup>. Chaves *et al*<sup>[35]</sup> similarly reported a higher incidence of PHG in patients with cirrhosis vs patients with portal hypertension from etiologies including schistosomiasis or postsinusoidal hypertension. Chaves *et al*<sup>[35]</sup> reported that PHG occurred in 18 (81.8%) of 22 patients with cirrhosis vs only 7 (33.3%) of 21 patients with portal hypertension from schistosomiasis ( $P < 0.05$ ). Parikh *et al*<sup>[9]</sup> reported a non-significant trend of more frequent PHG in patients with cirrhosis [64 of 102 patients (63%)]

vs NCPF [7 of 16 patients (44%)], but the lack of statistical significance may have resulted from the small number of patients with NCPF.

Chaves *et al*<sup>[35]</sup> reported that the mosaic pattern was significantly more prevalent in patients with cirrhosis [12 of 22 patients (54.5%)] than in patients with schistosomiasis [2 of 21 patients (9.5%);  $P < 0.05$ ]. Sarin *et al*<sup>[6]</sup> in a study of 50 patients with portal hypertension from various etiologies undergoing endoscopy, reported 6 (16.6%) of 36 patients with underlying cirrhosis had a mosaic pattern of PHG, whereas only 1 (8.5%) of 12 patients with EHPVO had a mosaic pattern of PHG (NS).

**Cirrhosis etiology:** Several research groups reported that the underlying etiology of cirrhosis did not affect PHG frequency or severity<sup>[13,71,80]</sup>. For example, Abbasi *et al*<sup>[62]</sup> reported among 217 patients with cirrhosis that PHG was unassociated with cirrhosis etiology ( $r = 0.056$ ;  $P = 0.414$ ), among 144 patients with hepatitis C, 36 patients with hepatitis B, 21 patients with cryptogenic cirrhosis, 15 patients with hepatitis C and hepatitis B coinfection, and 1 patient with hepatitis B and hepatitis D coinfection. Kim *et al*<sup>[57]</sup> similarly did not find a correlation between cirrhosis etiology and severity of PHG in a prospective study of 331 patients with cirrhosis, including cirrhosis etiologies of alcohol in 250, hepatitis B in 68, hepatitis C in 15, and cryptogenic cirrhosis in 8. Gupta *et al*<sup>[30]</sup> in a study of 230 patients with cirrhosis and esophageal varices found no significant difference in the rate of PHG between patients with cirrhosis from alcohol [32 of 52 patients (62%)] vs cirrhosis from other causes [110 of 178 patients (62%),  $P = \text{NS}$ ]. Iwao *et al*<sup>[31]</sup> in an endoscopic study of 47 patients with histologically-proven cirrhosis reported no significant differences in etiology of cirrhosis between patients without PHG vs patients with mild or severe PHG.

Iwao *et al*<sup>[31]</sup> reported no association between etiology of cirrhosis and PHG severity. The etiologies of cirrhosis in this study included 7 from alcoholism vs 8 from chronic hepatitis in patients without PHG, 5 from alcoholism vs 10 from chronic hepatitis in patients with mild PHG, and 8 from alcoholism vs 9 from chronic hepatitis in patients with severe PHG (NS).

**Liver disease duration:** Generally, duration of liver disease positively correlates with development of PHG<sup>[5]</sup>. Merli *et al*<sup>[37]</sup> reported a cumulative incidence of 3% at 1 year, 10% at 2 years, and 24% at 3 years. Most cases were mild, with only 10% of cases reported as severe PHG in cirrhotic patients undergoing esophagogastroduodenoscopy (EGD) to screen for esophageal varices. Primignani *et al*<sup>[34]</sup> reported that the prevalence of PHG was only 56% in patients with newly diagnosed cirrhosis, rose to 75% in patients with previously diagnosed cirrhosis and no prior variceal bleeding, and rose further to 91% in patients with previously diagnosed cirrhosis and prior variceal bleeding treated with sclerotherapy ( $\chi^2 = 34.25$ ;  $df = 1$ ;

$P < 0.0001$ ). The frequency of PHG increased by 46% after 5 years of follow-up in patients with cirrhosis<sup>[34]</sup>. In 30%-60% of cases, preexistent PHG remained stable with time<sup>[72]</sup>, but it can fluctuate in severity with time, with progression in 30%, and regression in 20% of cases<sup>[25,34,37]</sup>. Child-Pugh stage C cirrhosis was associated with faster progression of PHG<sup>[34]</sup>.

**Liver disease severity:** Numerous studies reported PHG is correlated with liver disease severity, as measured by Child-Pugh stage<sup>[8,9,29,35,37,55,57,67]</sup>. The reported strength of this correlation is variable. Some studies showed correlation between all stages of cirrhosis and PHG, whereas other studies showed correlation only for specific stages of cirrhosis. Sarin *et al.*<sup>[8]</sup> reported an 87% prevalence of PHG in patients with Child-Pugh stage C, vs only 13% prevalence in patients with Child-Pugh stage A. Another study reported that only Child-Pugh stage C was independently associated with PHG (OR = 2.68; 95%CI: 1.16-6.20,  $P = 0.021$ )<sup>[56]</sup>. Merli *et al.*<sup>[37]</sup> reported, in a study of 48 patients with PHG among 222 patients with cirrhosis, that Child-Pugh stage B or C, and presence of esophageal varices were independent risk factors for developing PHG. De Lisi *et al.*<sup>[58]</sup> reported a significantly higher prevalence of PHG in Child-Pugh stages B or C, as compared to stage A. Zardi *et al.*<sup>[67]</sup> reported that cirrhotic patients without esophageal varices with severe PHG had significantly more frequently Child-Pugh stage C than patients with mild PHG. In another study, the MELD (model for end-stage liver disease) score was significantly correlated with PHG severity (mean MELD score in patients without PHG =  $7.6 \pm 1.7$ , in patients with mild PHG =  $10.2 \pm 4.0$ , and in patients with severe PHG =  $11.3 \pm 3.5$ ;  $P < 0.001$ )<sup>[57]</sup>. In the HALT-C trial, hypoalbuminemia and hyperbilirubinemia, biochemical markers of advanced liver disease, were independent predictors of PHG in a logistic regression model (OR = 0.53, 95%CI: 0.37-0.76 for hypoalbuminemia; OR = 1.77, 95%CI: 1.25-2.51, for hyperbilirubinemia). Markers of portal hypertension (thrombocytopenia) and of insulin resistance (hyperglycemia) were also significant independent predictors of PHG.

Contrariwise, a minority of studies found no correlation between liver disease severity, as determined by Child-Pugh stage, and presence or severity of PHG<sup>[34,36,40,47,54,62,70,79]</sup>. For example, Primignani *et al.*<sup>[34]</sup> reported the prevalence of severe PHG was lowest in Child-Pugh stage C. In the NIEC study, patients with Child-Pugh stage B had a higher prevalence of PHG than patients with stages A or C. Zardi *et al.*<sup>[67]</sup> reported no significant differences in Child-Pugh stage or in MELD score among cirrhotic patients with vs without PHG. The preponderance of the data, however, suggest that severity of cirrhosis, as measured by Child-Pugh score, is correlated with frequency of PHG.

**Correlation with varices:** Many studies report a correlation between the presence and size of esopha-

geal varices and severity of PHG. For example, among the 188 of 373 patients with cirrhosis not undergoing variceal sclerotherapy in the NIEC study, the prevalence of PHG was significantly higher in patients with esophageal varices [80 of 104 patients (77%)] than in patients without esophageal varices [51 of 84 patients (61%);  $P = 0.007$ ]; and the prevalence of PHG significantly increased with increasing variceal size ( $\chi^2 = 13.2$ ;  $P < 0.0003$ )<sup>[34]</sup>. Numerous other studies also demonstrated significant correlation between presence of esophageal varices and PHG, and several studies also demonstrated significant correlations between variceal size and PHG<sup>[9,13,29,42,56,57,62]</sup>. For example, Abbasi *et al.*<sup>[62]</sup> reported that esophageal variceal size was significantly correlated with PHG frequency among 217 cirrhotic patients ( $r = 0.46$ ;  $P < 0.001$ ).

However, a few studies showed no correlation between presence or size of varices and PHG<sup>[26,28,30,47]</sup>. All these negative studies but one were relatively small. Gupta *et al.*<sup>[30]</sup> reported no significant association between frequency of PHG and size of esophageal varices among 230 cirrhotic patients. Similarly, in a study of 59 patients with cirrhosis, Bellis *et al.*<sup>[47]</sup> showed a non-significant trend towards more severe PHG in patients with large vs small varices. For example, three (50%) of 6 patients without esophageal varices had PHG, 6 of 10 patients (60%) with small varices had PHG, 19 of 25 patients (76%) with medium-sized varices had PHG, and 16 of 18 patients (89%) with large varices had PHG (NS). Iwao *et al.*<sup>[28]</sup> further reported that the frequency of PHG was not correlated with esophageal variceal size. The mean grade of gastroesophageal varices was  $1.4 \pm 0.9$  for no PHG,  $2.0 \pm 0.9$  for mild PHG, and  $1.9 \pm 1.0$  for severe PHG (all NS), and the mean grade of gastric varices was  $0.5 \pm 0.8$  for no PHG,  $1.3 \pm 1.3$  for mild PHG, and  $0.9 \pm 1.2$  for severe PHG (all NS).

**Location of varices:** Regarding variceal location, Sarin *et al.*<sup>[8]</sup> reported in a study of 107 patients with cirrhosis, NCPF or EHPVO, that PHG was significantly more common in patients with coexistent gastric and esophageal varices as compared to solely esophageal varices. PHG occurred in 15 (42%) of 36 patients with concomitant esophageal and gastric varices, but occurred in only 8 (11%) of 71 patients with solely esophageal varices ( $P < 0.01$ ). Likewise, Gupta *et al.*<sup>[30]</sup> reported a significantly higher prevalence of PHG in patients with esophageal and gastric varices [74 of 107 patients (69%)] compared to solely esophageal varices [68 of 123 patients (55%),  $P < 0.05$ ].

Iwao *et al.*<sup>[31]</sup> reported a significantly higher incidence of PHG in cirrhotic patients with esophageal varices as compared to fundal gastric varices. Merkel *et al.*<sup>[36]</sup> reported that patients with severe PHG localized to the gastric body or fundus had significantly higher HVPG than patients with severe PHG localized to the gastric antrum.

Portal hypertension is usually associated with porto-

**Table 3** Effects of variceal ligation on frequency of portal hypertensive gastropathy

Ref.	No. of patients and etiology	Study type	PHG rate before variceal ligation	PHG aggravation after variceal ligation	P value of pre vs post EVL
Hou <i>et al</i> <sup>[73]</sup>	90 patients with cirrhosis and recent variceal bleeding, 46 patients underwent EVL	Randomized, controlled trial	No PHG-4, mild PHG-33, severe-PHG-9	At eradication: 17/37; 17/37 (45.9%) in EVL; at 3 mo: 17/30 (56.7%); at 6 mo 18/29 (62.1%)	$P > 0.05$
Elnaser <i>et al</i> <sup>[80]</sup>	125 patients with upper GI bleeding undergoing variceal ligation, followed for mean of 31 mo	Retrospective study	22/125 (17.6%)	50/125 (50%)	$P < 0.05$
Yüksel <i>et al</i> <sup>[41]</sup>	114 patients with cirrhosis and portal hypertension undergoing EVL in 85 patients	Retrospective study	27/85 (31.8%) none; 28/85 (32.9%) mild; 30/85 (35.3%) severe	14/85 (16.5%) none; 30/85 (35.3%) mild; 41/85 (48.2%) severe	$P < 0.05$
Lo <i>et al</i> <sup>[81]</sup>	77 patients with bleeding from EV underwent variceal ligation and were randomized to receive propranolol (37/77) or control (40/77); patients with severe PHG prior to treatment excluded from the study	Prospective, randomized, controlled trial	Control group: 7/40 (17%); propranolol group: 8/37 (22%)	At variceal ligation: Control group: 67% (does not state number); Propranolol group: 31% (number not stated); 6 mo after treatment: Control group: 85% (number not stated) propranolol group: 48% (number not stated)	Pre vs post ligation, both groups; $P < 0.05$ ; frequency of PHG significantly higher in control group post ligation when compared to propranolol group; $P = 0.002$
de la Peña <i>et al</i> <sup>[82]</sup>	93 patients with history of variceal hemorrhage and cirrhosis, randomized to receive either EVS (46/88) or EVL (42/88); 5 patients excluded due to diagnosis of hepatoma, non-cirrhotic portal hypertension or portal vein thrombosis	Randomized, prospective study	Not reported	PHG significantly worsened in 23 patients, including 17 patients undergoing EVL	$P < 0.01$

PHG: Portal hypertensive gastropathy; EVL: Endoscopic variceal ligation; EVS: Endoscopic variceal sclerotherapy.

systemic collateral circulation, commonly including esophageal varices, gastric varices, and abdominal or umbilical or hemorrhoidal vein dilatation; and uncommonly including splenorenal, gastric, renal, retroperitoneal, or cardiac angle venous shunts. Wu *et al*<sup>[68]</sup> reported that the rate of moderate or severe PHG was higher in patients with common collaterals [296 of 439 patients (67.4%)] vs uncommon collaterals [70 of 118 patients (59.3%)], but this difference was not statistically significant.

In 2007, Zardi *et al*<sup>[45]</sup> proposed that PHG is promoted by minimal collateral circulation because a significant collateral circulation would otherwise reduce portal pressure and gastric mucosal congestion. They found that the portal vein diameter in cirrhotic patients was larger in patients with PHG and no esophageal varices ( $13.0 \pm 2.6$  mm) than in patients with F1 esophageal varices ( $12.6 \pm 2.3$  mm) or F2 esophageal varices ( $12.9 \pm 2.0$  mm) (NS). They further supported this concept by finding that patients with portal vein diameter  $< 12$  mm have a significantly higher prevalence of F1 and F2 esophageal varices than patients with a portal diameter between 12–13 mm, and argued that the absence of hepatofugal collateral circulation created by flow inversion, in patients without esophageal varices, left the entire pressure gradient over the portal vein<sup>[45]</sup>.

**Esophageal variceal eradication:** Numerous studies demonstrated that PHG increased in incidence and that preexistent PHG increased in severity after eradication of esophageal varices by either endoscopic variceal ligation

(Table 3)<sup>[41,73,80–82]</sup> or endoscopic variceal sclerotherapy (Table 4)<sup>[8,10,11,25,30,41,73,81–83]</sup> in cirrhotic patients with portal hypertension. Both phenomena also occurred after endoscopic variceal eradication in patients with non-cirrhotic portal hypertension, as shown in two studies in pediatric patients with EHPVO. For example, Poddar *et al*<sup>[83,84]</sup> reported in a prospective study of 274 children undergoing surveillance EGD after endoscopic sclerotherapy for EHPVO that the number of patients with PHG increased from 46 (24.7%) at baseline to 95 (51.6%) after sclerotherapy among 186 patients completing the study ( $P < 0.001$ ). Likewise, Itha *et al*<sup>[11]</sup> reported that the rate of PHG increased from 12% to 41% after endoscopic sclerotherapy ( $P < 0.001$ ) in a prospective study of 163 children undergoing surveillance EGD at 3 and 6 mo after endoscopic sclerotherapy. In the study by Sarin *et al*<sup>[10]</sup>, 86 (9%) of 967 patients with prior variceal bleeding treated with endoscopic sclerotherapy, had PHG at EGD, of whom 22 (26%) had PHG before variceal eradication and 64 (74%) developed PHG after variceal eradication.

PHG also increases in frequency after angiographic variceal obliteration. Duan *et al*<sup>[85]</sup> reported *de novo* PHG developed in 13 of 34 patients (38%) after percutaneous transhepatic variceal embolization for massive esophago-gastric variceal hemorrhage.

These phenomena are attributed to increased portal pressure and flow after eradication of esophageal varices because of redistribution of residual blood flow that had passed through the previously patent varices<sup>[5,41,45,81,86–90]</sup>. Itha *et al*<sup>[11]</sup> concluded that the significant increase in

**Table 4** Effects of variceal sclerotherapy on frequency of portal hypertensive gastropathy

Ref.	No. of patients and etiology	Study type	PHG before procedure	PHG aggravation after procedure	P value
Hou <i>et al</i> <sup>[73]</sup>	90 cirrhotic patients with recent variceal bleeding; EVS 44, EVL 46	Randomized, controlled trial	Pre EVS group: 6 none/24 mild/14 severe; pre EVL group: 4 none/33 mild/9 severe; total: 10 none/57 mild/23 severe	At eradication: 14/29 (48.3%) in EVS; 17/37 (45.9%) in EVL; at 3 mo: 15/26 (57.7%) in EVS; 17/30 (56.7%) in EVL; at 6 mo 15/25 (60%) in EVS; 18/29 (62.1%) in EVL	Non-significant difference in PHG aggravation between EVS and EVL; $P > 0.05$
Itha <i>et al</i> <sup>[11]</sup>	163 children with extrahepatic portal vein obstruction presenting with variceal bleeding underwent endoscopic injection sclerotherapy	Not reported	12% overall PHG (actual number not stated), 1 patient with severe PHG	41% overall PHG (actual number not stated), 12 patients with severe PHG	$P < 0.001$ for overall PHG; $P < 0.001$ for severe PHG
Poddar <i>et al</i> <sup>[83]</sup>	186 children with extrahepatic portal vein obstruction presenting with variceal bleeding undergoing endoscopic sclerotherapy, and mean follow up of $38 \pm 30$ mo	Retrospective study	PHG: 46/186 (24.7%), severe PHG: 6/186 (3.2%)	PHG: 96/186 (51.6%), severe PHG: 29/186 (15.6%)	$P < 0.001$ for overall PHG; $P < 0.05$ for severe PHG
Yüksel <i>et al</i> <sup>[41]</sup>	114 patients with cirrhosis and portal hypertension undergoing EVS (29/114) or EVL (85/114)	Retrospective study	Pre EVS group: 11/29 (37.9%) none; 10/29 (24.5%) mild; 8/29 (27.6%) severe; pre EVL group: 27/85 (31.8%) none; 28/85 (32.9%) mild; 30/85 (35.3%) severe	Post EVS group: 4/29 (13.8%) none; 8/29 (27.6%) mild; 17/29 (58.6%) severe; post EVL group: 14/85 (16.5%) none; 30/85 (35.3%) mild; 41/85 (48.2%) severe	Pre EVS <i>vs</i> post EVS; $P < 0.05$ ; pre EVL <i>vs</i> post EVL; $P < 0.05$ ; pre EVS <i>vs</i> pre EVL; $P > 0.05$ ; post EVS <i>vs</i> post EVL; $P > 0.05$
Sarin <i>et al</i> <sup>[10]</sup>	967 patients with variceal bleeding underwent endoscopic sclerotherapy; out of whom 88 patients fulfilled the inclusion criteria (including presence of endoscopic lesions consistent with PHG or GAVE, before or within 4 wk after obliteration) were prospectively followed (out of whom 2 had only GAVE)	Prospective study	22 patients had PHG prior to EVS; 2/22 transient (9%); 17/22 persistent (77%); 3/22 progressive (14%)	Additional development in 64 patients post procedure, 28/64 transient (44%), 31/64 persistent (48%), 5/64 progressive (8%)	Only statistically significant difference was the transient PHG that disappeared in 28 (44%) of patients in the group that developed PHG post procedure; $P < 0.05$
Gupta <i>et al</i> <sup>[30]</sup>	230 patients with liver cirrhosis; of which 44 underwent variceal eradication with sclerotherapy	Prospective study	24/44 (54%)	33/44 (75%)	$P < 0.05$
Sarin <i>et al</i> <sup>[8]</sup>	107 patients with portal hypertension presenting with variceal bleeding that underwent sclerotherapy with mean follow-up of $23.2 \pm 3.4$ mo	Prospective study	4/107 (3.7%)	21 additional patients, 25/107 (23%)	Does not state if this was statistically significant
de la Peña <i>et al</i> <sup>[82]</sup>	93 patients with history of variceal hemorrhage and cirrhosis, randomized to receive either EVS (46/88) or EVL (42/88); 5 patients were excluded due to diagnosis of hematoma, non-cirrhotic portal hypertension or portal vein thrombosis	Prospective study	Not reported	PHG worsened in 23 patients total; statistically significantly more in EVL group than EVS group (17 <i>vs</i> 6 patients respectively)	$P < 0.01$
D'Amico <i>et al</i> <sup>[25]</sup>	212 cirrhotic patients of which 75 had an episode of variceal bleeding and were treated with sclerotherapy; 137 without bleeding were not treated with sclerotherapy	Prospective study	No EVS group at admission: 104/137 (75%) none; 28/137 (20%) mild; 5/137 (4%) severe; EVS group at admission: 50/75 (66%) none; 17/75 (22%) mild; 8/75 (11%) severe	No EVS group at end of study: 69/137 (50%) none; 61/137 (45%) mild; 7/137 (5%) severe; EVS group at end of study: 13/75 (17%) none; 49/75 (65%) mild; 13/75 (17%) severe	The conclusion was that sclerotherapy is a significant indicator of the risk of PHG in a multivariate analysis ( $P = 0.00032$ )

PHG: Portal hypertensive gastropathy; EVL: Endoscopic variceal ligation; EVS: Endoscopic variceal sclerotherapy.

frequency and severity of PHG after variceal eradication resulted from decreasing collateral blood flow through esophageal varices causing increasing PHG from gastric mucosal congestion. This mechanism is supported by

finding that gastric mucosal blood flow increases after variceal ligation<sup>[91]</sup>. Another theory is that delayed gastric emptying after sclerotherapy from extravasation of sclerosant, may cause development of PHG<sup>[69]</sup>. No direct

evidence exists for delayed gastric emptying in PHG<sup>[71]</sup>.

Data on which technique of endoscopic variceal eradication leads to quantitatively more *de novo* PHG is contradictory. Most studies showed no differences in frequency or severity of PHG after variceal ligation vs sclerotherapy<sup>[19,34,41,73,92,93]</sup>, but some studies showed worse outcomes after variceal ligation<sup>[82,93,94]</sup>, while some other studies showed worse outcomes after sclerotherapy<sup>[95]</sup>.

*De novo* PHG after variceal obliteration is often transitory and less severe than PHG that predated the variceal obliteration<sup>[10,73]</sup>. For example, Sarin *et al.*<sup>[10]</sup> reported in a study of 84 patients followed for a mean of  $25 \pm 14$  mo that PHG resolved in 28 (44%) of 64 patients who developed PHG after sclerotherapy, but resolved in only 2 (9%) of 22 patients who had PHG present before sclerotherapy ( $P < 0.05$ ). Hou *et al.*<sup>[73]</sup> similarly reported that the increased severity of PHG after variceal obliteration was generally transitory and returned to baseline status. The return to baseline severity of PHG was significantly faster after variceal ligation than after sclerotherapy ( $P = 0.03$ ), attributed to ligation achieving subtotal variceal obliteration and permitting faster redistribution of blood flow<sup>[10]</sup>.

Some investigators believe the higher rate of PHG in patients undergoing endoscopic variceal sclerotherapy merely reflects a longer duration of portal hypertension, more advanced liver disease, or more severe portal hypertension in patients selected to undergo variceal sclerotherapy compared to controls rather than the performance of sclerotherapy *per se*<sup>[34,78,96]</sup>. Primignani *et al.*<sup>[34,97]</sup> demonstrated an almost identical increase in frequency of PHG with time in patients undergoing vs not undergoing sclerotherapy, and suggested that PHG evolved identically with time regardless of performance vs nonperformance of sclerotherapy.

**Additional risk factors:** PHG severity is significantly associated with thrombocytopenia or splenomegaly<sup>[42,57,58]</sup>. In a prospective study of 331 cirrhotic patients performed in South Korea, PHG severity was correlated with splenic diameter: Splenic diameter with

severe PHG =  $13.1 \pm 2.4$  cm, diameter with mild PHG =  $12.2 \pm 2.5$  cm, and diameter with no PHG =  $10.7 \pm 2.9$  cm,  $P < 0.001$ <sup>[57]</sup>. In this study, PHG severity was inversely correlated with platelet count: count with no PHG =  $174600 \pm 109400$  platelets/mm<sup>3</sup>, count with mild PHG =  $132000 \pm 100700$  platelets/mm<sup>3</sup>, count with severe PHG =  $102800 \pm 68800$  platelets/mm<sup>3</sup> ( $P < 0.001$ ). Among 1016 patients with bridging fibrosis or compensated cirrhosis undergoing EGD in the HALT-C trial, including 374 (37%) with PHG, PHG was negatively correlated with platelet count in a logistic regression model (negative estimate: -0.00407, OR = 0.99, 95%CI: 0.99-0.998;  $P = 0.0007$ )<sup>[42]</sup>.

In one study, PHG in patients with chronic liver disease was correlated with increasing thickness of the lesser omentum, and presence of a splenorenal shunt<sup>[22]</sup>. This study found that PHG frequency was not associated with severity of hypersplenism<sup>[62]</sup>. The HALT-C trial showed no association between prevalence or severity of PHG and lifetime alcohol consumption, nonsteroidal anti-inflammatory drugs (NSAIDs) use, COX- (cyclooxygenase-) 2 inhibitor use, or smoking<sup>[42]</sup>. The lack of association with alcoholism may reflect the need for near abstinence from alcohol to have enrolled in the clinical trial; at study enrollment 86% of patients reported abstinence and 14% reported minimal drinking of alcohol. Table 5<sup>[8,9,11,14,34,41,55,62,67,71,83,85]</sup> lists well-established risk factors for PHG; Table 6<sup>[11,41,44,55,75-77,83,85,98-107]</sup> lists therapies that affect the severity of PHG or the risk of bleeding from PHG, and Table 7<sup>[8,14,28,30,35,42,84,108-110]</sup> lists the factors that do not affect the risk of PHG.

### Pathogenesis

**Hemodynamic changes:** The pathogenesis of PHG is inadequately understood<sup>[96]</sup>. Hemodynamic changes, especially increased portal pressure, are the suspected underlying cause because PHG develops only with established portal hypertension<sup>[72]</sup>. However, portal hypertension cannot be the sole factor because many patients with portal hypertension do not develop PHG<sup>[36,111]</sup>. Hemodynamic changes in patients with portal hypertension lead to hyperdynamic congestion with a change in gastric mucosal blood flow<sup>[112]</sup>, that leads to activation of cytokines, growth factors, and hormones that perpetuate this hyperdynamic gastric circulation<sup>[113]</sup>. Vascular congestion in PHG alters the gastric microcirculation, but the nature and extent of this alteration is somewhat controversial. The hyperdynamic circulation of portal hypertension is characterized by increased intrahepatic vascular resistance, generalized splanchnic vasodilatation, decreased mean arterial pressure, decreased systemic vascular resistance, increased gastric blood flow, and most likely decreased gastric mucosal flow<sup>[110,114,115]</sup>. Hashizume *et al.*<sup>[116]</sup> reported that cirrhotic patients have dilated small gastric blood vessels, including arterioles, precapillaries, capillaries, submucosal veins, and subserosal veins, with decreased arteriovenous resistance and straightening of arterioles.

**Table 6** Therapies affecting the severity or the risk of bleeding from portal hypertensive gastropathy

Therapies reducing severity of PHG	Ref.
TIPS	[76,77,98]
Transcatheter splenic arterial embolization	[99]
Surgical shunt	
Portocaval shunt	[100]
Central splenorenal shunt	[101]
Laparoscopic splenectomy (in patients with hypersplenism)	[55]
Liver transplantation	[44]
Therapies reducing risk of bleeding from PHG	
TIPS	[75,98,102]
Surgical shunt (portocaval or splenorenal)	[100,101]

Variceal sclerotherapy	[11,83]
Interventional angiography	
Percutaneous transhepatic variceal embolization	[85]

TIPS: Transjugular intrahepatic portosystemic shunt; PHG: Portal hypertensive gastropathy.

This hyperdynamic circulation impairs gastric mucosal defense mechanisms, causes release of proinflammatory mediators, and inhibits growth factors which render gastric mucosa more susceptible to injury<sup>[67,117]</sup> and impair mucosal healing<sup>[113,114,118,119]</sup>. This vulnerable mucosa becomes predisposed to bleeding<sup>[117,120]</sup>. Decreased gastric mucosal perfusion may explain the increased rate of erosions, ulcers, and bleeding in PHG<sup>[118]</sup>. Abnormal regulation of the gastric microcirculation in PHG may render gastric mucosa more vulnerable to hypoxia<sup>[112,122]</sup>, and more susceptible to noxious gastric factors, such as aspirin and ethanol<sup>[123-125]</sup>.

Misra *et al.*<sup>[126]</sup> showed that gastric mucosal capillaries, obtained by endoscopic mucosal biopsies, have a much thicker wall in patients with cirrhosis than in healthy volunteers. Ichikawa *et al.*<sup>[127]</sup> reported a narrower diameter in gastric mucosal capillaries and less capillary angiogenesis, measured as percentage of buds in microvessels, after exposure to ethanol in individuals with PHG as compared to healthy controls. Tarnawski *et al.*<sup>[121]</sup> reported prominent cytoplasm in endothelial cells of mucosal microvessels, that narrowed the capillary lumina, in rats with PHG. This finding was confirmed by electron microscopy which showed significantly larger cytoplasmic and pinocytic vesicular areas and increased capillary basement membrane thickness. Additionally, there was arterIALIZATION of submucosal veins and thickening of arterioles in the muscularis mucosae and submucosa<sup>[121]</sup>.

**Table 7** Factors not affecting risk of portal hypertensive gastropathy

Factors not affecting risk of portal hypertensive gastropathy	Ref.
Etiology of cirrhosis	[8,28,30]

Alcoholism	[30,42]
NSAID use	[42]
Use of COX-2 inhibitors	[42]
Smoking tobacco	[42]
Gastric infection with <i>Helicobacter pylori</i>	[109,110]

NSAID: Nonsteroidal anti-inflammatory drug; COX-2: Cyclooxygenase-2.

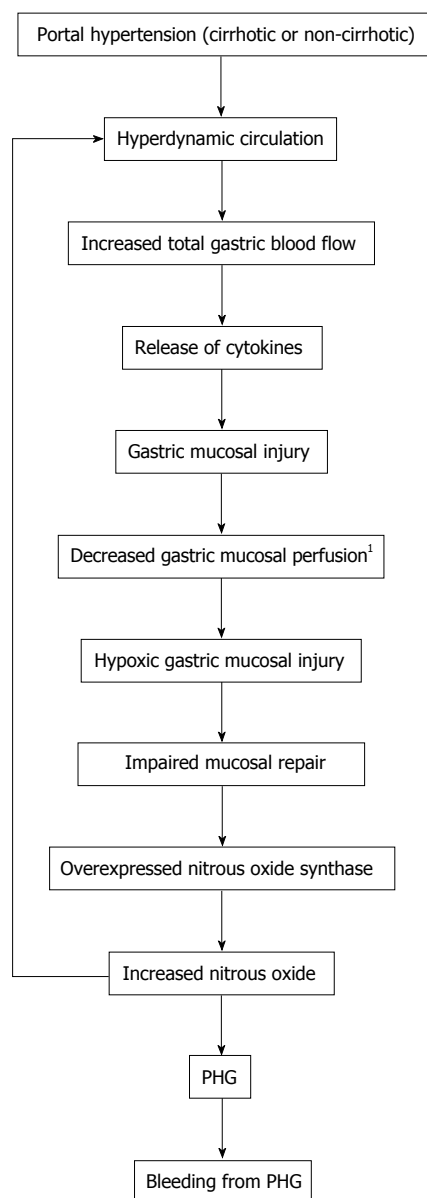

The level of gastric mucosal blood flow in PHG is controversial. Most studies reported decreased mucosal blood flow in patients with PHG<sup>[76,128-131]</sup>, whereas several studies reported increased gastric mucosal blood flow in experimental animals and in humans with PHG<sup>[132-136]</sup>. Makhija *et al.*<sup>[118]</sup> described in PHG a decrease in gastric mucosal blood flow, an increase in the submucosal and muscular layer blood flow, and a net increase in total gastric blood flow. Mezawa *et al.*<sup>[76]</sup> using a laser Doppler flowmeter to measure gastric mucosal blood flow and near-infrared endoscopy to measure total gastric blood flow, reported decreased mucosal blood flow and increased total blood flow in patients with PHG. These results reversed after undergoing TIPS, with an increase in mucosal blood flow and a decrease in total blood flow. These findings support the hypothesis of decreased mucosal blood flow in patients with PHG. Ohta *et al.*<sup>[113]</sup> reported a decrease in superficial mucosal blood flow rendering mucosa more susceptible to injury, but noted a net increase in total gastric blood flow. Variability in study results arise from study biases including chronic anemia in some patients, variable measurement techniques, different techniques of applying endoscopic probes in laser-Doppler flowmetry, and differences in gastric mucosal angioarchitecture<sup>[113]</sup>. Laser-Doppler flowmetry, moreover, has limited utility in clinical practice<sup>[137,138]</sup>.

Portal hypertension increases the splenic circulation<sup>[139]</sup>. Pan *et al.*<sup>[79]</sup> reported that PHG severity was strongly correlated with hypersplenism ( $P = 0.003$ ). However, Abbasi *et al.*<sup>[62]</sup> did not show this correlation. The difference between these studies may reflect use of different classifications for PHG. Figure 1 describes the hypothesized pathophysiology of PHG. This current mechanism is currently sketchy and likely incomplete.

Patients with secondary polycythemia A have decreased blood flow and oxygen carrying capacity because of sluggish movement of viscous blood; this phenomenon produced endoscopic and histopathologic findings of congestive gastropathy similar to those in PHG that reversed after the patient underwent serial phlebotomies to reverse the polycythemia<sup>[140]</sup>.

**Molecular mechanisms:** Numerous molecular and cellular mechanisms have been investigated regarding

**Figure 1** Hypothesized mechanism of portal hypertensive gastropathy.

<sup>1</sup>The finding of decreased gastric mucosal perfusion in PHG is somewhat controversial (see text). PHG: Portal hypertensive gastropathy.

the pathogenesis of PHG.

**Apoptosis:** Wu *et al.*<sup>[141]</sup> showed that rats with PHG had increased gastric mucosal apoptosis and decreased mucosal proliferation. Recently, a p53-upregulated modulator of apoptosis (PUMA) was reported markedly induced in gastric mucosa in patients or mouse models of PHG. PUMA is modulated by endoplasmic reticulum - stress-induced mucosal epithelial apoptosis in PHG<sup>[142]</sup>. This effect could promote mucosal injury in PHG.

**Free radicals and antioxidants:** Kaur *et al.*<sup>[143]</sup> showed elevated levels of injurious free radicals and lysosomal enzymes and decreased levels of protective antioxidant enzymes in gastric mucosal homogenates from rats with portal hypertension. Kawanaka *et al.*<sup>[144]</sup> showed impaired endoplasmic reticulum serine/

threonine kinase-2 (ERK2) activation after oxidative stress in rat gastric mucosa; ERK2 normally protects against cellular stress by inducing cell proliferation in gastric mucosa. Kinjo *et al.*<sup>[145]</sup> showed that enhanced nitration of ERK by peroxynitrite is involved in impaired MAPK (ERK) signaling in PHG, which impairs mucosal healing and promotes mucosal injury. The levels of lipid peroxide and nitrotyrosine that tend to promote gastric injury increased significantly in rats with PHG as compared to controls.

**Mucin:** Wang *et al.*<sup>[146]</sup> reported significantly reduced expression of mucin mRNA in rat models of portal hypertension induced by partial portal vein ligation. Decreased mucin production may impair gastric mucosal protection. Rats with portal hypertension had significantly greater injury to gastric mucosa than healthy controls after exposure to gastrototoxic compounds. Tomikawa *et al.*<sup>[135]</sup> reported decreased mucosal gel layer thickness, surface epithelial cell intracellular pH, and oxygenation of gastric mucosal surface in rats with PHG.

**Angiogenesis:** As aforementioned, the number of angiogenic buds decreased after injury to PHG mucosa. This phenomenon may decrease the reparative capacity of PHG mucosa<sup>[127]</sup>. However, Tsugawa *et al.*<sup>[136]</sup> reported humans with PHG had increased vascular endothelial growth factor (VEGF), a potent angiogenic factor. Additionally, rats with PHG had a significant decrease in the SaO<sub>2</sub> and PaO<sub>2</sub> of the arterial blood gas, and increased levels of VEGF, proliferating cell nuclear antigen (PCNA) expression, and gastric mucosal blood flow in gastric mucosa. They proposed that gastric mucosal hypoxia in portal hypertension and elevation of VEGF and PCNA levels might accelerate mucosal angiogenesis and increase blood flow<sup>[147]</sup>.

**Tumor necrosis factor alpha:** Tumor necrosis factor alpha (TNF- $\alpha$ ) may directly contribute to the hyperdynamic circulation in PHG. Patients and animal models with portal hypertension had an elevated TNF- $\alpha$  level which stimulated release of nitric oxide (NO) and prostacyclin, important mediators of a hyperdynamic circulation<sup>[148]</sup>. For example, in one study, 96 healthy rats were injected with either anti-TNF- $\alpha$  polyclonal antibodies or placebo before surgically creating portal vein stenosis (PVS) to induce portal hypertension and 4 d after in the short-term inhibition group and 1, 4, 7 and 10 d after PVS in the long term-inhibition group. Anti-TNF- $\alpha$  treated PVS rats exhibited lower serum levels of TNF- $\alpha$ , which normally stimulates the synthesis of NO and prostacyclin, and exhibited lower serum levels of nitrates and nitrites and of 6-keto-PGF<sub>1- $\alpha$</sub>  (6-keto-PGF<sub>1 $\alpha$</sub> ), used to monitor NO and prostacyclin release, respectively. The combined nitrate and nitrite level was significantly reduced from 68  $\pm$  9 nmol/mL in controls to 42  $\pm$  8 nmol/mL in the short-term inhibition group ( $P < 0.05$ ), and from 66  $\pm$  6 nmol/mL in controls to 44  $\pm$  4 nmol/mL in the long-term inhibition group ( $P$

< 0.05). Similarly the 6-keto-PGF<sub>1α</sub> was significantly reduced from 484 ± 92 pg/mL in the controls to 174 ± 12 pg/mL in the short-term inhibition group ( $P < 0.05$ ), and from 522 ± 98 pg/mL in the controls to 169 ± 18 (SD) pg/mL in the long-term inhibition group ( $P < 0.05$ ). Kaviani *et al.*<sup>[149]</sup> reported that TNF-α increased by 50% and inducible nitric oxide synthase (iNOS) mRNA levels increased by 300% in gastric strips after ligating the portal vein in rats ( $P < 0.01$  for both). These data are consistent with TNF-α playing a role in the hyperdynamic circulation in PHG via NO and prostacyclin.

Baseline constitutional NOS (cNOS) mRNA expression increased by 75% in the PHG group as compared to placebo ( $P < 0.01$ )<sup>[149]</sup>. NOS was significantly reduced after injecting a TNF-α neutralizing antibody during incubation of mucosal strips from portal hypertensive rats; the expression of inducible NOS mRNA levels was incrementally decreased by 40%, 70% and 80% after 1, 2, and 6 h of incubation, respectively ( $P < 0.05$ )<sup>[149]</sup>. Ohta *et al.*<sup>[150]</sup> similarly successfully used TNF-α antibody to normalize gastric mucosal blood flow in rats with PHG and to significantly reverse overexpression of gastric NOS isoform 3. In PHG rats, treatment with TNF-α antibody significantly reduced the elevated NOS isoform 3 mRNA expression by 48% ( $P < 0.01$ ). Moreover, administration of thalidomide, which enhances TNF-α mRNA degradation, decreased levels of TNF-α and NOS in animals with portal hypertension produced by partial portal vein ligation<sup>[114]</sup>.

**Nitric oxide:** Patients with portal hypertension and PHG have increased serum levels of NO, a potent vasodilator released by endothelial cells. Ohta *et al.*<sup>[151]</sup> demonstrated gastric cNOS significantly increased, by 67%, in portal hypertensive rats, experimentally produced by portal vein and splenic vein occlusion, as compared to sham-operated rats at 14 d after surgery ( $P < 0.05$ ). In portal hypertensive rats, cNOS fluorescence intensity was significantly higher in endothelia of submucosal veins [ $96.2 \pm 5.9$  (SD) U] as compared to endothelia of mucosal collecting veins [ $69.5 \pm 1.7$  (SD) U,  $P < 0.01$ ], or endothelia of veins of muscularis mucosae [ $55.7 \pm 10.0$  U,  $P < 0.01$ ]. The average fluorescence area in submucosal vein endothelia was significantly higher in portal hypertensive rats than in normal controls [ $1038.5 \pm 459.5$  (SD)  $\mu\text{m}^2$  vs  $372.4 \pm 180.3$  (SD)  $\mu\text{m}^2$ ,  $P < 0.01$ ]. This finding may provide a molecular mechanism for submucosal vascular dilation in the hyperdynamic circulation in PHG. In another study, gastric mucosal cNOS levels were significantly higher in patients with cirrhosis and severe PHG compared to healthy controls [ $125.4 \pm 4.3$  (SD) pmol/mg protein/minute vs  $88 \pm 8.6$  (SD) pmol/mg protein/minute,  $P < 0.002$ ]. Likewise, gastric mucosal iNOS levels were significantly higher in patients with cirrhosis and severe PHG than in healthy controls [ $259.7 \pm 5.5$  (SD) pmol/mg protein/min vs  $130.8 \pm 6.6$  (SD) pmol/mg protein/min,  $P < 0.0001$ ]<sup>[152]</sup>. Serum nitrate/nitrite levels were  $30.1 \pm 3.2$  nmol/mL in the first group vs  $15.5 \pm 0.09$  (SD) nmol/mL in the

second group ( $P < 0.001$ )<sup>[152]</sup>. In another study, iNOS and cNOS levels were also higher in gastric mucosa of patients with PHG than in controls<sup>[153]</sup>, and were significantly higher in patients with severe PHG as compared to patients with mild or no PHG<sup>[154]</sup>. Nitrous oxide may underlie the gastric vascular dilation<sup>[152]</sup>, and hyperdynamic circulation in PHG<sup>[148]</sup>.

However, Lee *et al.*<sup>[155]</sup> reported administration of aminoguanidine, an iNOS inhibitor, successfully corrected the hyperdynamic circulation without affecting PHG, suggesting that iNOS and NO are important in the hyperdynamic circulation in portal hypertension, but play a limited role in PHG development. They argued that PHG should be treated by reducing portal pressure rather than reversing the hyperdynamic circulation<sup>[155,156]</sup>.

**Glucagon:** Glucagon levels are elevated in patients with portal hypertension<sup>[118]</sup>. Curvêlo *et al.*<sup>[54]</sup> found in 43 patients with PHG from portal hypertension with cirrhosis, that the mean serum glucagon level after an overnight fast was significantly higher than the level in healthy controls. Serum glucagon levels were significantly correlated with high systemic vascular resistance index ( $r = -0.523$ ;  $P = 0$ ) and HVP (G) ( $r = 0.34$ ;  $P = 0.019$ ). Glucagon significantly increases portal pressure<sup>[157-159]</sup>, and causes splanchnic vasodilation<sup>[148]</sup>. Geraghty *et al.*<sup>[158]</sup> found a strong correlation between portal pressure and glucagon levels ( $r = 0.85$ ). Tsui *et al.*<sup>[160]</sup> reported that glucagon significantly increased portal pressure in rats with portal vein ligation, but did not alter portal pressure in sham-operated rats. The effect of glucagon occurred only in rats with preexisting portal hypertension. Exogenous glucagon rendered gastric mucosa more susceptible to injury from toxins, such as ethanol, which was attenuated by somatostatin<sup>[160]</sup>. For example, the lesion area was significantly higher at > 60% of gastric mucosa after glucagon administration, compared to somatostatin or glucagon and somatostatin administration ( $P < 0.05$ , ANOVA)<sup>[160]</sup>.

**Prostaglandins:** Studies in patients or animal models with portal hypertension failed to show significant differences in prostaglandin E2 (PGE2) levels as compared to healthy controls<sup>[125,141,161-163]</sup>. Low prostaglandin levels significantly decreased gastric perfusion velocity in cirrhotic rats, whereas misoprostol, a PGE2 analogue, significantly increased gastric perfusion in cirrhotic rats as compared to controls<sup>[125]</sup>. For example, Beck *et al.*<sup>[125]</sup> found that administration of indomethacin did not affect gastric perfusion velocity in healthy control rats, despite reducing gastric PGE2 synthesis by > 95%, but reduced gastric perfusion velocity by 30% within 10 min in cirrhotic rats achieved by ligating the common bile duct ( $P < 0.05$ ). The hyperemic response to application of ethanol was significantly reduced in cirrhotic rats compared to healthy rats ( $56.3\% \pm 21.7\%$  (SD) vs  $66.1\% \pm 17.1\%$  (SD) increase,  $P < 0.05$ ). Misoprostol applied to gastric mucosa caused

concentration-dependent increase in perfusion velocity, with a significantly greater increase in perfusion velocity in cirrhotic rats with concentrations of misoprostol  $> 0.8$  mcg/mL ( $P < 0.05$ ).

Beck *et al.*<sup>[164]</sup> further reported that administration of misoprostol to cirrhotic rats for 1 mo restored the hyperemia in response to ethanol that sham-operated, non-cirrhotic rats showed, whereas placebo-treated cirrhotic rats failed to increase gastric blood flow in response to ethanol. PGE2-treated cirrhotic rats exhibited significantly less spontaneous gastric mucosal damage [ $0.2\% \pm 0.07\%$  (SD)] than placebo-treated cirrhotic rats [ $3.0\% \pm 0.8\%$  (SD);  $P < 0.05$ ]. The mean microscopic gastric injury score was significantly less in PGE2-treated cirrhotic rats [ $0.7 \pm 0.3$  (SD)] than in placebo-treated cirrhotic rats [ $2.1 \pm 0.4$  (SD);  $P < 0.05$ ].

Rats with PHG exhibited suppression of gastric mucosal COX-1 levels, but exhibited normal COX-2 levels compared to healthy controls<sup>[141]</sup>. Nonselective COX inhibitors, such as aspirin, decrease PGE2 levels resulting in more apoptosis of cells. Payen *et al.*<sup>[123]</sup> reported that gastric mucosal potential difference, an index of mucosal integrity, decreased with increasing severity of PHG, suggesting greater vulnerability of gastric mucosa in patients with PHG. Payen *et al.*<sup>[123]</sup> further reported a significantly greater decline of potential difference after aspirin administration of  $11.1 \pm 3.6$  (SD) mV in 9 patients with severe PHG, vs  $9.2 \pm 3.6$  mV in 21 patients with moderate PHG ( $P < 0.05$ ), and vs  $6.4 \pm 1.9$  (SD) mV in 10 healthy controls ( $P < 0.05$ ). Also, PGE2 administration suppressed the increased apoptosis which occurred in rats with PHG.

**Prostacyclin:** Prostacyclin, a vasodilator that inhibits gastric acid secretion, has been proposed as a mediator of the hyperdynamic circulation in PHG from portal hypertension<sup>[148,163]</sup>. Ohta *et al.*<sup>[161]</sup> found significantly elevated serum levels of 6-keto-PGF<sub>1 $\alpha$</sub> , a metabolite of prostacyclin, in cirrhotic patients with PHG. They also reported that these patients had significantly elevated levels of 6-keto-PGF<sub>1 $\alpha$</sub>  in the mucosa of the gastric fundus.

**Other cytokines and growth factors:** Several studies have analyzed the roles of endothelin-1, VEGF, and other cytokines in PHG, but further research is required<sup>[165]</sup>. The gastric concentrations of epidermal growth factor were comparable between patients with and without PHG, and its significance in PHG remains unclear<sup>[166]</sup>. A high serum level of autotaxin, involved in liver fibrosis, was associated with advanced stage of cirrhosis, presence of esophageal varices, and PHG<sup>[167]</sup>.

**Helicobacter pylori:** Numerous studies demonstrated that *Helicobacter pylori* (*H. pylori*) infection is not associated with PHG<sup>[7,9,25,79,109,110,154,168-172]</sup>. Indeed, several studies reported that patients with PHG less frequently have *H. pylori* infection than controls. *H. pylori* does not appear to play a pathogenic role in

ulcers associated with PHG<sup>[173]</sup>. Contrariwise, Sathar *et al.*<sup>[174]</sup> reported an association between *H. pylori* infection and PHG in cirrhotic patients, but this study apparently had limitations, including low specificity and low sensitivity of *H. pylori* serology in cirrhotic patients, potential selection bias, and underreporting of *H. pylori* seroprevalence<sup>[174-178]</sup>.

## Diagnosis

**Endoscopy:** PHG is diagnosed by EGD<sup>[72]</sup>. The characteristic endoscopic appearance is a mosaic-like pattern or a diffuse, erythematous and reticular cobblestone pattern of gastric mucosa consisting of small polygonal areas, with superimposed red punctate lesions,  $> 2$  mm in diameter and a depressed white border<sup>[78,96,177]</sup>. The red lesions vary in size and in color depending on PHG severity. The lesions range from pink speckled lesions within a mosaic or snakeskin pattern in mild cases, to localized small areas of intense erythema, resembling a scarlatina rash, in severe cases<sup>[70,71,112,139]</sup>. These findings occur predominantly in the gastric body and fundus, and rarely in the antrum<sup>[71,72,139]</sup>. Figure 2 illustrates a patient with classic endoscopic findings of portal hypertensive gastropathy. Toyonaga *et al.*<sup>[178]</sup> reported in a meta-analysis of 6 studies that the mosaic-like pattern had high specificity at 98% (range: 93%-100%), but low sensitivity at 38% (range: 7%-94%) for PHG, with an accuracy of 78% (range: 63%-98%). In severe PHG numerous petechiae and bleeding spots present as a diffuse hemorrhagic gastropathy<sup>[112,139]</sup>.

**Endoscopic classification:** Endoscopic classification of PHG severity is clinically important because severity is correlated with bleeding risk<sup>[31,71,72,179]</sup>. PHG can be simply categorized as mild with a mosaic-like pattern without red spots, or as severe, with superimposed red lesions present<sup>[78,96]</sup>. Multiple formal endoscopic classifications exist (Table 8<sup>[3,7,8,70,180-183]</sup>), with no consensus as to which classification is the best<sup>[5,182-184]</sup>. The following classifications are commonly used: Classifications by McCormack *et al.*<sup>[3]</sup>, Tanoue *et al.*<sup>[180]</sup>, the New Italian Endoscopic Classification (NIEC)<sup>[70]</sup>, and the Baveno scoring system<sup>[181]</sup>.

In 1985, McCormack *et al.*<sup>[3]</sup> classified PHG according to presence of red spots into mild and severe disease. In 1991, McCormick *et al.*<sup>[7]</sup> divided the prior single category of mild PHG into mild and moderate PHG based on absence vs presence of erythema, respectively. This moderate category is infrequently used<sup>[7]</sup>. In 1992 Tanoue *et al.*<sup>[180]</sup> and Parker *et al.*<sup>[185]</sup> also expanded the scoring system by providing a grade between mild and severe. This classification is rendered cumbersome by a lack of sharply defined differences between the added intermediate category and the original categories<sup>[71]</sup>. This system is, however, simple and can help predict bleeding risk<sup>[71,182]</sup>. Iwao *et al.*<sup>[186]</sup> found McCormack's classification was accurate for fine pink speckling in 54%, for snakeskin pattern in 76%, and for cherry-red spots in 64%. The NIEC produced a better definition in

**Figure 2** A 60-year-old man presented for routine endoscopic screening for esophageal varices due to a history of Child-Pugh class B cirrhosis, with a model for end-stage liver disease score = 18, from hepatitis C secondary to former intravenous drug use. The patient denied a history of gastrointestinal bleeding. The hematocrit was 40.1%. Esophagogastroduodenoscopy revealed the classic findings of portal hypertensive gastropathy, including a pale white reticular (mosaic) pattern surrounding small polygonal areas of mucosa, with variable erythema, in the entire stomach, but most prominently in the gastric fundus and body. B is a relatively close-up view of the lesions seen in A.

**Table 8** Different classification systems for portal hypertensive gastropathy

Ref.	Mild	Moderate	Severe
McCormack <i>et al</i> <sup>[3]</sup>	Fine pink speckling (scarlatina type rash) Superficial reddening, especially on rugal surface (striped appearance) Fine white reticular pattern separating areas of raised edematous mucosa (snake skin)		Discrete red spots (analogous to cherry red spots in esophagus)  Diffuse hemorrhagic gastritis
McCormick <i>et al</i> <sup>[7]</sup> Tanoue <i>et al</i> <sup>[180]</sup>	Mosaic or snake skin appearance Mild reddening, congestive mucosa, no mosaic-like pattern	Presence of erythema Severe redness and a fine reticular pattern separating the areas of raised edematous mucosa (mosaic-like pattern) or a fine speckling	Presence of erosions or hemorrhagic gastritis Grade III (severe) Point bleeding + grade II (moderate)
Spina <i>et al</i> <sup>[70]</sup> (NIEC)	Mosaic-pattern: Presence of small, polygonal areas surrounded by a whitish-yellow depressed border		Red point lesions (1 mm in diameter, flat) Cherry-red spots (2 mm, slight protrusion) Black-brown spots (irregularly shaped, persistently present after washing)
Sarin <i>et al</i> <sup>[8]</sup>	Discrete cherry red spots, with or without mosaic pattern		Presence of confluent red spots, diffusely distributed in a large portion of the stomach
Sarin <i>et al</i> <sup>[181]</sup> (Baveno II Consensus Workshop) <sup>[181]</sup>	Mild $\leq 3$ points <sup>1</sup>		Severe $\geq 4$ points <sup>1</sup> Gastric antral ectasia Absent (0) Present (2)
Yoo <i>et al</i> <sup>[182]</sup> 2-category classification	Fine pink speckling (scarlatina type rash) Superficial reddening Mosaic pattern		Discrete red spots Diffuse hemorrhagic lesion
Yoo <i>et al</i> <sup>[182]</sup> 3-category classification	Mild reddening Congestive mucosa Diffuse pink areola	Flat red spot in center of a pink areola Severe redness and a fine reticular pattern	Diffusely red areola Pinpoint bleeding Discrete or confluent red mark lesion

<sup>1</sup>Points assigned for Baveno II consensus according to the following: Mild mucosal mosaic pattern = 1 point, severe mucosal mosaic pattern = 2 points; isolated red markings = 1 point, confluent red markings = 2 points; gastric antral ectasia present = 2 points.

1992 of mild and severe HPG<sup>[32,34,70]</sup>. Elementary lesions of PHG according to the NIEC classification include: (1) mosaic-like pattern defined as small, polygonal areas surrounded by a whitish-yellow, depressed border. This mosaic pattern is mild when the areola is uniformly pink, moderate if the center is red, and severe if the areola is uniformly red; (2) red-point lesions defined as small, flat, 1-mm-wide, punctate, red lesions; (3) cherry-red spots defined as red, 2-mm-wide, round lesions which protrude slightly into the gastric lumen;

and (4) black-brown spots defined as irregularly shaped flat black or brown spots from intramucosal hemorrhage that remain after endoscopic irrigation. PHG is defined as mild when only a mosaic-like pattern of any degree was present, and severe when red-point lesions, cherry red spots, or black-brown spots were present. Due to variable data on the classification systems, Hashizume *et al*<sup>[184]</sup> proposed a simplified classification that divides PHG into three stages by presence of: Non-specific redness, a mosaic pattern, and red spots.

Yoo *et al.*<sup>[182]</sup> demonstrated substantial limitations in intra-observer and inter-observer reproducibility in the most common 2-scoring and 3-scoring systems. Nevertheless, the 2-scoring system by McCormack *et al.*<sup>[3,7]</sup> produced better and more reproducible results than the 3-scoring system by Tanoue *et al.*<sup>[180]</sup>. The mean inter-observer kappa value was 32% higher and mean intra-observer kappa value was 15% higher for the 2-scoring system compared with the 3-scoring system. However, both inter-observer and intra-observer kappa values in both classification systems were below the desirable value of  $> 0.75$ <sup>[187]</sup>. Kappa values represent the degree of agreement as compared with that expected by chance alone, with one being perfect agreement, and zero being no greater agreement than expected by chance alone<sup>[182]</sup>.

The Baveno scoring system uses point calculations to define PHG as mild ( $\leq 3$  points) vs severe ( $\geq 4$  points)<sup>[181]</sup>. This system adds gastric antral vascular ectasia (GAVE) into the classification<sup>[179]</sup>. Stewart *et al.*<sup>[179]</sup> showed that this scoring system was reproducible and accurately reflected the risk of PHG-related bleeding in cirrhotic patients. Kappa values for mucosal mosaic pattern, red marks, and GAVE were  $> 0.75$ , indicating good reproducibility. Kappa values for lesion severity were lower, attributed to loss of details in endoscopic photographs.

de Macedo *et al.*<sup>[187]</sup> proposed analyzing binary criteria such as presence vs absence of mosaic-like pattern, red punctate lesions, and cherry-red spots, without subdivisions or classification systems. These binary criteria were associated with high inter-observer reliability and accuracy (94%, 81% and 83% respectively). Mosaic-like pattern was associated with high sensitivity (100%). The previously used classifications and subdivisions showed unsatisfactory reliability and low inter-observer agreement.

Current classification systems are suboptimal. The ideal classification system should be simple, clinically useful, accurate, and reproducible with high levels of intra-observer and inter-observer agreement<sup>[183]</sup>. The 2-scoring system is most commonly used due to relative simplicity and reasonable reproducibility<sup>[71]</sup>.

**Capsule endoscopy:** Several studies evaluated the diagnostic accuracy of capsule endoscopy. In a study using the PillCam ESO capsule, capsule endoscopy had an overall concordance with EGD of 90.6% for PHG<sup>[188]</sup>. This study included only 32 patients of whom 19 had PHG, and a large trial is underway to confirm these findings. In another study, PHG was identified by capsule endoscopy in 13 (68.4%) of 19 patients with cirrhosis, portal hypertension, and chronic anemia, but the 19 patients did not undergo EGD to determine capsule endoscopy test sensitivity and specificity<sup>[49]</sup>. In a study of 50 patients with cirrhosis undergoing both EGD and capsule endoscopy for screening or surveillance of esophageal varices, capsule endoscopy had an accuracy of 57%, sensitivity of 96%, and specificity of

17% compared to EGD. Inter-observer reliability was 0.61. The researchers concluded that more data are required to assess accuracy of capsule endoscopy for diagnosis and staging of PHG<sup>[52]</sup>. In another study of 50 patients with portal hypertension undergoing EGD and capsule endoscopy, only 24 of 35 patients with PHG diagnosed by EGD had PHG detected by capsule endoscopy (sensitivity = 69%)<sup>[23]</sup>. Capsule endoscopy was somewhat more sensitive at detecting severe than mild PHG (82% vs 63%), but this difference was not significant ( $P = 0.44$ ). The accuracy was significantly higher in diagnosing PHG in the gastric body (100%) than the fundus (48%) ( $P = 0.0009$ ).

**Dynamic CT:** Kim *et al.*<sup>[150]</sup> proposed using dynamic CT to diagnose PHG by demonstrating the transient perfusion defect sign, defined as the presence of transient segmental or subsegmental hypo-attenuating mucosa in the gastric fundus or body during hepatic arterial imaging that returns to normal attenuation on portal venous or equilibrium-phase imaging. This sign had a sensitivity of 75%, specificity of 88.6%, positive predictive value of 90%, and negative predictive value of 72.1% for diagnosing PHG in patients with cirrhosis. Further prospective trials are required to validate this diagnostic modality.

Screening for PHG is currently not recommended in patients with liver disease<sup>[189]</sup>. To identify predictors of PHG and varices noninvasively in patients with chronic liver disease to increase the cost-benefits of EGD, Min *et al.*<sup>[190]</sup> combined three independent parameters in a multivariate analysis into a "Varices and PHG" (VAP) score. The score = platelets/ $\text{mm}^3 \times$  albumin in g/dL/multidimensional index for spleen volume (M-Index) in  $\text{cm}^3$ . The M-Index is calculated from spleen length, width, and thickness, as determined by helical computerized tomography, which is designed to reflect splenomegaly as a predictor of esophageal varices and PHG. A VAP cut-off value of 861 had a sensitivity of 85%, positive likelihood ratio of 3.17, and negative predictive value of 86%. This scoring system requires prospective validation<sup>[190]</sup>.

**Differentiation from GAVE:** Differentiation of PHG from GAVE is important because they have distinct pathologic, clinical, and endoscopic characteristics, and different therapies (Table 9)<sup>[34,37,71,72,75,77,103,106,191-213]</sup>. Treatments that reduce portal pressure are effective for PHG but ineffective for GAVE<sup>[193]</sup>. PHG and GAVE also affect different gastric locations. PHG generally affects the proximal stomach, whereas GAVE generally affects the distal stomach<sup>[139]</sup>. A mosaic-like pattern surrounding polygonal areas of erythema is typical for PHG, but GAVE has erythema most commonly arranged linearly along folds in the antrum, less commonly arranged as diffuse erythema in the antrum, and least commonly arranged as diffuse gastric erythema<sup>[75,78,96]</sup>.

PHG is usually diagnosed by endoscopic criteria. When endoscopic features are uncertain, histologic

**Table 9** Differences between portal hypertensive gastropathy and gastric antral vascular ectasia

Parameter	Portal hypertensive gastropathy	Gastric antral vascular ectasia	Ref.
Associated conditions	Conditions associated with portal hypertension: cirrhotic or non-cirrhotic portal hypertension	Cirrhosis, autoimmune disorders, and connective tissue diseases (scleroderma, pernicious anemia, hypothyroidism)	[72]
Association with portal hypertension	Strong association	Only 30% of cases	[191,192]
Sex	Mildly more common in males (alcoholic cirrhosis more common in males than females)	Much more common in females (80%)	[193,194]
Age	Can occur at any age in patients with portal hypertension or cirrhosis	Typically elderly (average age > 70 years old)	
Location	Proximal stomach: Fundus, body	Distal stomach: Antrum	[72,192]
Diagnosis	Endoscopy (endoscopic biopsy sometimes useful). Radiologic imaging usually not helpful	Endoscopy (endoscopic biopsy sometimes useful)	[72,195]
Appearance at endoscopy	Mosaic/snakeskin mucosa with red or brown spots	Tortuous columns of ectatic vessels in "watermelon" or diffuse pattern; erythematous or hemorrhagic	[191]
Histology	Ectatic capillaries, mildly dilated mucosal and submucosal veins; no vascular inflammation, no vascular thrombi	Marked dilation of capillaries and venules in gastric mucosa and submucosa with areas of intimal thickening, fibrin thrombi, fibromuscular hyperplasia and spindle cell proliferation	[72,191,196,197]
Clinical presentation/ complications	Gastrointestinal bleeding: Usually chronic, but sometimes acute	Almost exclusively chronic gastrointestinal bleeding with guaiac positive stools	[37,193]
Primary prophylaxis	Not indicated	Not indicated (unless associated with large varices)	[198]
Medical therapy	Non-selective $\beta$ -adrenergic receptor antagonists (propranolol), octreotide (for acute bleeding)	No benefit of $\beta$ -adrenergic receptor antagonists Oral contraceptive pills to temporarily control bleeding Questionable benefit of octreotide	[103,106,198-201]
Endoscopic therapy	Occasionally helpful (for focal bleeding) Argon plasma coagulation Local hemostasis with hemostatic spray	Very helpful at reducing risk of bleeding: Argon plasma coagulation; EBL; Radiofrequency ablation; YAG laser therapy	[202-207]
TIPS	Significantly reduces severity and risk of bleeding by reducing portal hypertension. Option for very severe bleeding from PHG or for moderate PHG in patients with variceal bleeding	Not recommended. Does not affect severity of GAVE or risk of bleeding	[75,77]
Liver transplantation	Resolves. Ultimate therapy mostly reserved for patients with end-stage liver disease	Improves or resolves with liver transplantation	[75,200,208-210]
Other surgery	Usually resolves with shunt surgery that lowers portal pressure. Partial gastrectomy not recommended	Limited surgical resection (partial gastrectomy) recommended for refractory cases. Shunt surgery not recommended	[75,200,211-213]
Prognosis from bleeding	Bleeding rarely severe and very rarely fatal	Bleeding occasionally severe	[34,71,72]

YAG: Yttrium aluminum garnet; TIPS: Transjugular intrahepatic portosystemic shunt; PHG: Portal hypertensive gastropathy; GAVE: Gastric antral vascular ectasia; EBL: Endoscopic band ligation.

analysis of gastric biopsies is useful to differentiate PHG from GAVE<sup>[86,183,197,212]</sup>. Superficial mucosal biopsies are frequently falsely negative because the lesions of PHG are generally submucosal<sup>[214,215]</sup>. Endoscopists are reluctant to perform deep biopsies in patients with known portal hypertension or suspected PHG because of increased risks of bleeding because of a coagulopathy from underlying cirrhosis or a bleeding diathesis from underlying portal hypertension<sup>[137,183]</sup>. However, deep biopsies may be necessary for the histologic diagnosis of PHG.

Characteristic histologic findings of PHG include capillary and venule dilatation, and markedly congested and tortuous submucosal venules<sup>[137]</sup>. Stromal fibrosis and edema of lamina propria can occur<sup>[137]</sup>. Inflammatory cells and fibrin thrombi are generally absent<sup>[3,139]</sup>. Characteristic histologic features of GAVE include presence of fibrin thrombi in dilated capillaries and fibromuscular proliferation within the lamina propria<sup>[96,216]</sup>.

#### Differentiating GI bleeding from varices vs PHG:

PHG may occasionally resemble gastric varices at EGD. PHG can be prominent on gastric rugae in the gastric body and fundus. The intraluminal linear projections of gastric rugae might superficially resemble that of gastric varices. However, gastric varices tend to be more serpiginous than linear and tend to be grayish due to the presence of deoxygenated venous blood within varices, whereas the lesions of PHG on gastric rugae tend to be erythematous and surrounded by a prominent mosaic pattern. It is also important to distinguish between GI bleeding from esophageal varices vs PHG in patients having both lesions. Table 10 outlines differences in GI bleeding from PHG vs esophageal varices.

#### Clinical presentation

**Acute GI bleeding:** GI bleeding is the only known clinically relevant complication of PHG. PHG is responsible for < 1% of upper GI bleeding in the general population, and for about 8% of non-variceal upper GI bleeding in patients with liver disease<sup>[217]</sup>. The reported frequency of acute upper GI bleeding in patients with

**Table 10** Differences in gastrointestinal bleeding from portal hypertensive gastropathy *vs* esophageal varices

Parameter	Portal hypertensive gastropathy	Esophageal varices
Etiology	Portal hypertension: Cirrhotic or non-cirrhotic	Portal hypertension: Cirrhotic or non-cirrhotic
Concurrence	Frequently occur simultaneously with esophageal varices because the two diseases share common risk factors	Frequently occurs simultaneously with PHG because the two diseases have common risk factors
Location	Stomach: Predominantly fundus and body	Distal esophagus: Also can have gastric varices or ectopic varices in other gastrointestinal regions, particularly duodenum
Diagnosis	Esophagogastroduodenoscopy	Esophagogastroduodenoscopy
Endoscopic appearance	Erythematous small polygonal areas of mucosa surrounded by a fine, whitish, reticular or mosaic/snakeskin mucosa with red or brown spots	Serpiginous mucosal greyish luminal projections in distal esophagus
Clinical presentation	Mild acute or chronic bleeding	Acute gastrointestinal bleeding-typically massive
Severity of bleeding	Typically mild and not life-threatening	Typically severe and life-threatening
Histology		Not biopsied at endoscopy
Endoscopic therapy	Limited role	Variceal ligation recommended as initial therapy. Sclerotherapy an alternative therapy
Medical therapy	Octreotide Propranolol Vasopressin or vasopressin analogues-infrequently recommended any more	Octreotide Propranolol Vasopressin or vasopressin analogues-infrequently recommended any more
Blakemore tube	Not recommended	Sometimes used for refractory bleeding especially as a temporizing measure before performing more definitive therapy
Angiographic therapy	TIPS used as a last resort	TIPS recommended if endoscopic therapy fails
Transfusion of packed erythrocytes	Transfuse only to hematocrit of about 28. Over-transfusion may increase portal pressure and induce greater bleeding	Transfuse only to hematocrit of about 28. Over-transfusion may increase portal pressure and induce greater bleeding
Liver transplantation	Improves or resolves with liver transplantation	Improves or resolves with liver transplantation
Prognosis	Rarely fatal	Frequently fatal

TIPS: Transjugular intrahepatic portosystemic shunt; PHG: Portal hypertensive gastropathy.

PHG ranges in incidence from 2%-20% (Table 11<sup>[3,8,25,34,37,103,217,218]</sup>). Primignani *et al.*<sup>[34]</sup> reported acute GI bleeding in 2.7% of patients with PHG, whereas Stewart *et al.*<sup>[179]</sup> reported a 20% incidence of acute bleeding in patients with PHG. McCormack *et al.*<sup>[3]</sup> reported that 29 (44.6%) of 65 patients with PHG bled from this lesion. In this study, PHG was the second most common cause of GI bleeding, after esophageal varices<sup>[3]</sup>. The reported variability is partly due to inaccuracies in the endoscopic diagnosis of PHG and in the endoscopic diagnosis of PHG as the cause of bleeding<sup>[71]</sup>. Diagnosis of PHG as the cause of bleeding can be challenging if a bleeding point is not visualized at EGD<sup>[71]</sup>.

Major risk factors for bleeding from PHG are increasing PHG duration, extent, and severity<sup>[72,179]</sup>. For example, > 90% of acute bleeding occurs with severe PHG<sup>[10,35,71,72]</sup>, and < 10% of acute bleeding occurs with mild PHG<sup>[112]</sup>. Other risk factors for bleeding from PHG include advanced cirrhosis, and prior endoscopic eradication of esophageal varices<sup>[3,5,10,81,179,180,219]</sup>. Unlike bleeding from GAVE, acute bleeding from PHG is rarely severe, very rarely fatal, and typically requires transfusion of only one-to-two units of packed erythrocytes or less<sup>[34,71,72,139]</sup>.

**Chronic bleeding:** The frequency of chronic bleeding ranges from 3%-26%<sup>[25,34,37]</sup>. Stewart *et al.*<sup>[179]</sup> reported a 6% incidence of chronic bleeding from PHG, whereas Primignani *et al.*<sup>[34]</sup> reported chronic bleeding in 11% of patients with PHG (Table 11<sup>[3,8,25,34,37,103,217,218]</sup>).

The incidence of chronic gastrointestinal bleeding from PHG is difficult to determine precisely because of variable definitions of chronic GI bleeding<sup>[67,68]</sup>. Common definitions include: (1) > 2 g/dL decrease in hemoglobin level during > 6 mo in patients without acute GI bleeding and not receiving NSAID therapy; (2) presence of anemia in patients with cirrhosis; and (3) positive fecal occult blood (Baveno II)<sup>[181]</sup>. Moreover, chronic GI bleeding can be overestimated if hemoglobin decline is solely used for the diagnosis. Patients with chronic liver disease frequently have anemia without GI bleeding, from causes including alcoholism, chronic kidney disease, hypersplenism, or bone marrow suppression. No studies have objectively quantified chronic blood loss from PHG.

Chronic bleeding from PHG is usually mild to moderate but occasionally severe<sup>[37,139]</sup>. Patients after endoscopic variceal obliteration have a higher incidence of chronic GI bleeding from PHG<sup>[10,25,72]</sup>. Chronic GI bleeding from PHG can cause iron deficiency anemia<sup>[220,221]</sup>.

### Pharmacotherapy for PHG

Current pharmacologic therapies aim to reduce portal pressure to decrease bleeding from PHG<sup>[191,214]</sup>.

**$\beta$ -adrenergic receptor antagonists:** Nonselective  $\beta$ -adrenergic receptor antagonists reduce portal pressure and gastric mucosal blood flow, and thereby reduce bleeding from PHG<sup>[103,104,132,191,222-224]</sup>. Several studies evaluated the efficacy of propranolol, a nonselective  $\beta$ -adrenergic receptor antagonist in primary and secon-

**Table 11 Rates of gastrointestinal bleeding from portal hypertensive gastropathy**

Ref.	Year published	Population	Bleeding from PHG	Transfusions required
McCormack <i>et al</i> <sup>[3]</sup>	1985	127 patients with portal hypertension of various etiologies	29 patients out of 65 with PHG, representing 25% of the total number of bleeds from all sources; 9 episodes presenting with bleeding; 71 episodes of subsequent bleeding	2-15 units required for 60 bleeds
D'Amico <i>et al</i> <sup>[25]</sup>	1990	212 patients with cirrhosis; 75 being treated with sclerotherapy		
Sarin <i>et al</i> <sup>[8]</sup>	1992	107 patients with portal hypertension presenting with variceal bleeding, undergoing sclerotherapy	No bleeding before sclerotherapy from PHG (4/107 had PHG); 2/13 post-sclerotherapy patients who developed PHG	Average of 4 units per patient with range of 2-8 units
Pérez-Ayuso <i>et al</i> <sup>[103]</sup>	1991	54 cirrhotic patients with PHG, in a RCT to look for rebleeding; propranolol 26 <i>vs</i> control 28	First hemorrhage: Acute/chronic bleeding in propranolol group 12/14; in control 12/16, rebleeding: Acute/chronic; in propranolol 6/6; in control 10/12	
Gostout <i>et al</i> <sup>[217]</sup>	1993	Patients admitted for GI bleeding (1496)	12 patients (0.8%), representing 8% of nonvariceal bleeding in patients with liver disease	
Primignani <i>et al</i> <sup>[34]</sup>	2000	373 patients with cirrhosis; PHG in 299 patients (80.1%)	8 PHG patients with acute bleeding; chronic bleeding in 34 patients	
Merli <i>et al</i> <sup>[37]</sup>	2004	222 cirrhotic patients with portal hypertension; 48 patients with PHG on enrollment	During follow up for 47 ± 28 (SD) mo, acute bleeding 9, chronic bleeding 7 from PHG	
Kimura <i>et al</i> <sup>[218]</sup>	2014	297 patients with living donor liver transplantation; retrospective analysis	2 patients bled from PHG within 3 mo after transplantation	

PHG: Portal hypertensive gastropathy; RCT: Randomized controlled trial; GI: Gastrointestinal.

dary prevention of bleeding from PHG<sup>[104,225]</sup>. Pérez-Ayuso *et al*<sup>[103]</sup> reported in a multi-center, randomized, controlled trial of 57 patients with acute or chronic bleeding from severe PHG with cirrhosis that the 26 patients administered propranolol at 20-160 mg twice daily rebled significantly less frequently than the 31 controls receiving only iron therapy as needed at 12 mo (38% *vs* 65%;  $P < 0.05$ ), and at 30 mo follow-up (7% *vs* 52%,  $P < 0.05$ ). Patients receiving propranolol were transfused less units of packed erythrocytes than the controls, but this difference was not statistically significant [ $0.10 \pm 0.06$  (SD) units/mo *vs*  $0.60 \pm 0.20$  (SD) units/mo,  $P = 0.08$ ].

Propranolol also reduced the risk of developing PHG after esophageal variceal eradication<sup>[81]</sup>. Lo *et al*<sup>[81]</sup> reported in a randomized, controlled trial that 40 patients receiving placebo had a significant increase in PHG severity after variceal ligation ( $P < 0.01$ , ANOVA), but the 37 patients receiving propranolol [mean dose =  $96 \pm 20$  (SD) mg/d] had no significant increase in PHG severity. The frequency of PHG 6 mo after variceal ligation was significantly less in patients receiving propranolol than in the controls (48% *vs* 85%,  $P = 0.002$ ). This difference gradually decreased over time and became not significant at 12 mo. Also, the mean PHG severity score was lower in patients receiving propranolol than in the controls at 6 mo after variceal ligation ( $P < 0.05$ ).

Propranolol at 240-480 mg/d has been used to arrest acute bleeding from PHG. Bleeding stopped within 3 d in 13 (93%) of 14 patients with portal hypertension administered propranolol in one study<sup>[101]</sup>. None of these patients rebled while receiving propranolol during a median of 23 mo of follow-up, but 4 out of 7 patients rebled after electively discontinuing propranolol therapy<sup>[104]</sup>. Nonresponse to  $\beta$ -adrenergic receptor antagonists, defined as continued bleeding despite

this therapy and transfusion-dependency despite iron replacement therapy, should prompt consideration of interventional therapies<sup>[214]</sup>.

Nonspecific  $\beta$ -adrenergic receptor antagonists are a first line therapy for secondary prophylaxis of PHG bleeding<sup>[191,208]</sup>. Nadolol alone was as effective as nadolol with isosorbide mononitrate in preventing the first episode of PHG bleeding<sup>[226]</sup>. No studies have analyzed the efficacy of carvedilol, another nonspecific  $\beta$ -adrenergic receptor antagonist, in controlling bleeding from PHG<sup>[227]</sup>.

**Somatostatin and octreotide:** Somatostatin and octreotide, a synthetic somatostatin analogue, cause splanchnic vasoconstriction, reduce portal pressure, reduce portal blood flow, and decrease gastric perfusion in animal models and in patients with PHG<sup>[105,106,160,228-231]</sup>. For example, Chan *et al*<sup>[228]</sup> found octreotide infusion, compared to placebo, significantly increased systemic vascular resistance [ $3.4 \pm 0.2$  (SD) mmHg/mL per minute per 100 g *vs*  $2.7 \pm 0.2$  (SD) mmHg/mL per minute per 100 g,  $P < 0.05$ ], and significantly decreased portal pressure [ $9.9 \pm 0.5$  (SD) mmHg *vs*  $12.5 \pm 1.2$  (SD) mmHg,  $P < 0.05$ ] in cirrhotic rats. Another study found that somatostatin only modestly reduced portal pressure in PHG<sup>[232]</sup>. Octreotide treatment also significantly reduced mean cross-sectional area of gastric mucosal vessels compared to placebo [ $1810 \pm 101$  (SD) microns *vs*  $2290 \pm 145$  (SD) microns,  $P < 0.05$ ], and significantly inhibited release of several vasoactive gastrointestinal polypeptides, gastric acid, and pepsinogen<sup>[106,233]</sup>. In the stomach, somatostatin activates  $K^+$ -ATP channels (adenosine triphosphate-dependent potassium channels) which normally protect against gastric mucosal injury in the presence of portal hypertension, and antagonizes

the portal hypertensive and injury-promoting effects of glucagon<sup>[160]</sup>.

Octreotide is a first-line treatment for acute bleeding from PHG. In a randomized controlled trial, octreotide, at 100 mcg bolus followed by infusion of 25 mcg/min for the first 24 h and then 20 mcg/min for the second 24 h, controlled bleeding from PHG in 20 (83%) of 24 patients at 24 h and in 24 (100%) of 24 patients at 48 h<sup>[106]</sup>. Octreotide significantly more frequently controlled the bleeding than vasopressin (64%,  $P < 0.005$ ), or omeprazole (59%,  $P < 0.005$ ), and tended to be more effective than both vasopressin and omeprazole (88%, NS)<sup>[106]</sup>. Octreotide also controlled the bleeding significantly faster and required significantly less transfusions of packed erythrocytes than vasopressin or omeprazole<sup>[106]</sup>. Octreotide even successfully stopped bleeding within 48 h in the patients with bleeding refractory to vasopressin and omeprazole therapy.

Kouroumalis *et al.*<sup>[105]</sup> reported that somatostatin or octreotide infusion for 3 d stopped severe bleeding from PHG in all 26 study patients. Only 3 patients experienced recurrent bleeding which stopped after retreatment with somatostatin, and only one patient required gastrectomy for refractory bleeding.

Somatostatin and octreotide only temporarily reduce portal pressure. Escorsell *et al.*<sup>[232]</sup> reported rapid desensitization to the effects of octreotide with prolonged administration in cirrhotic patients with portal hypertension. Therefore somatostatin and octreotide are useful for acute bleeding but not for preventing chronic bleeding from PHG. Octreotide did not significantly change the severity of PHG at endoscopy.

**Vasopressin and terlipressin:** Vasopressin, a systemic vasoconstrictor, reduces splanchnic blood flow, lowers portal pressure, and decreases gastric mucosal blood flow<sup>[106]</sup>. In a randomized, controlled trial, vasopressin, administered intravenously (IV) at a rate of 1 unit/min for the first 10 min, followed by continuous infusion at 0.1 unit/min for 48 h, arrested bleeding from PHG in 14 (64%) of 22 patients<sup>[106]</sup>. However, as aforementioned, this result was inferior to that achieved by octreotide, possibly because vasopressin does not inhibit release of peptides, including glucagon and vasoactive intestinal polypeptide, and does not inhibit gastric acid secretion<sup>[106]</sup>. Concomitant omeprazole therapy may modestly increase vasopressin efficacy<sup>[106]</sup>. Vasopressin is considered an alternative therapy to octreotide.

Vasopressin causes significantly more frequent side effects (41%) than octreotide, especially abdominal pain<sup>[106]</sup>. Vasopressin reduces oxygen saturation of gastric mucosa, but this reduction can be partly reversed by administering supplemental oxygen<sup>[234,235]</sup>. Two analogues of vasopressin have been studied. Glypressin showed similar reduction in gastric mucosal perfusion as vasopressin by laser-Doppler flowmetry, but less impairment in gastric mucosal oxygenation<sup>[235]</sup>. Terlipressin may be useful in controlling acute bleeding from PHG,

especially when used at a dose of 1 mg IV every 4 h for 5 d<sup>[103,107,192]</sup>.

**Antioxidants:** Antioxidants help in free radical scavenging and in reversing impairment of oxidative stress-induced ERK2 activation. They may decrease susceptibility of PHG gastric mucosa to alcoholic injury, as demonstrated by administration of vitamin E, an antioxidant<sup>[144]</sup>. Vitamin E reduced oxidative state, normalized MKP-1 expression, and reversed impairment of oxidative stress-induced ERK2 activation<sup>[144]</sup>. Vitamin E helped reduce gastric injury from alcohol exposure in rats with PHG<sup>[71]</sup>.

Vitamin E administration decreased mucosal lipid peroxidation, decreased lysosomal enzymes, and increased levels of antioxidants. Kaur *et al.*<sup>[143]</sup> administered vitamin E 240 mg subcutaneously to rats with common bile duct ligation vs sham surgery. Seven days after ligation or sham surgery, the level of thiobarbituric acid reactive substances in gastric mucosa was significantly higher in ligated rats not receiving vitamin E [ $0.78 \pm 0.22$  (SD) nmol of malondialdehyde formed/mg protein] as compared to sham surgery rats administered vitamin E [ $0.56 \pm 0.07$  (SD) nmol of malondialdehyde formed/mg protein,  $P < 0.01$ ]. These data suggest that vitamin E decreased mucosal lipid peroxidation. In the ligation group vitamin E administered preoperatively significantly reduced the levels of  $\beta$ -glucuronidase as compared to untreated or post-operatively-treated groups ( $P < 0.01$ ). Preoperative vitamin E therapy significantly lowered levels of acid phosphatase as compared to untreated or postoperatively treated groups ( $P < 0.01$ ). Preoperative administration of vitamin E in the ligation group led to significantly increased levels of the three major antioxidant enzymes, including superoxide dismutase ( $P < 0.005$ ), glutathione peroxidase ( $P < 0.01$ ), and catalase ( $P < 0.05$ ) when compared to the levels of these antioxidant enzymes in untreated groups or in groups treated postoperatively with vitamin E. These data provide a theoretical basis that vitamin E administration may potentially improve PHG.

Kawanaka *et al.*<sup>[144]</sup> administered vitamin E or saline for 13 d in rats with PHG vs sham-operated rats used as a control. Rats with PHG had a 2.3-fold increased area of gastric mucosal necrosis after gastric exposure to ethanol than sham-operated rats ( $P < 0.05$ ), but vitamin E treatment in rats with PHG almost completely reversed this increased necrosis compared to controls ( $P < 0.05$ ). Vitamin E treatment did not significantly change portal pressure or gastric mucosal blood flow in PHG gastric mucosa.

**Rebamipide:** Rebamipide, an antiulcer medication, protects against oxygen-derived production of free radicals by scavenging free radicals. Intragastric administration ameliorates oxidative stress, reduces nitration of tyrosine residues of ERK, and reverses delayed mucosal healing occurring in PHG. It reversed the increased susceptibility to ethanol-induced injury and

reversed the delayed healing after gastric injury in rats with PHG<sup>[145]</sup>. Kinjo *et al.*<sup>[145]</sup> reported that administration of rebamipide in rats with PHG, significantly decreased lipid peroxide and nitrotyrosine and nitration of ERK by peroxynitrite in PHG mucosa, therefore normalizing ERK activation and restoring normal gastric mucosal healing after ethanol injury. Rebamipide requires further study as a therapy for PHG<sup>[119]</sup>.

**Estrogen and progesterone:** Estrogen and progesterone therapy reduced gastric mucosal blood flow, portal pressure, and porto-collateral resistance in rats with surgically-induced portal hypertension<sup>[236]</sup>. Panés *et al.*<sup>[236]</sup> reported that treatment with estradiol, dihydroxyprogesterone, or low dose combination estradiol-dihydroxyprogesterone significantly decreased gastric mucosal blood flow in rats that underwent portal vein ligation as compared to placebo [ $56 \pm 3.5$  (SD) mL/min per 100 g for placebo;  $43 \pm 3.4$  (SD) mL/min per 100 g for estrogen;  $32 \pm 2.6$  mL/min per 100 g for dihydroxyprogesterone, and  $42 \pm 6.1$  (SD) mL/min per 100 g for low dose estrogen/dihydroxyprogesterone,  $P < 0.05$ ]. Estrogen and progesterone have not been studied in patients with PHG.

**Thalidomide:** Thalidomide blunts development of a hyperdynamic circulation and decreases portal pressure by reducing NO production<sup>[114]</sup>. Thalidomide, at a low dose of 100 mg daily, was successful as a last resort therapy in one case report of bleeding from PHG caused by neoplastic invasion of the portal vein<sup>[237]</sup>. Before thalidomide therapy, the patient had required transfusion of 30 units of packed erythrocytes during 35 d while treated with propranolol and terlipressin.

**Corticosteroids:** There is one case report of cessation of PHG bleeding with corticosteroid therapy, using prednisolone 20 mg/d, after being admitted for five times during 5 mo with severe iron deficiency anemia from chronic GI bleeding from PHG that was refractory to propranolol therapy. At 2 mo follow-up the hemoglobin was rising and at 4 mo follow-up repeat EGD showed an improved endoscopic appearance of PHG<sup>[238]</sup>. The patient was stable during 3-years of follow-up using 15 mg prednisolone every other day, with no recurrence of the anemia.

**Losartan:** Hepatic stellate cells help modulate sinusoidal resistance and the sinusoidal microcirculation. These cells are influenced by vasoconstrictors such as endothelin and angiotensin II. The angiotensin II receptor antagonist, losartan, lowers portal pressure by inhibiting stellate cell contraction and by reducing sinusoidal resistance<sup>[239]</sup>. Administration of losartan at 25 or 50 mg/d resulted in improvement of PHG in 9 (56.3%) of 16 patients during 4 wk of follow-up. The higher dose had greater efficacy. There was also evidence of decreased portal pressure. Further studies are needed to evaluate the effect of losartan on PHG<sup>[239]</sup>.

### Sucralfate and acid-suppressing medications:

Proton pump inhibitors, sucralfate<sup>[74]</sup>, and histamine-2 receptor antagonists are not very effective at reducing bleeding from PHG because most patients with PHG already have hypochlorhydria<sup>[79,106,240-242]</sup>. However, proton pump inhibitors may indirectly stop bleeding from the stomach by raising intraluminal gastric pH and thereby stabilizing blood clots<sup>[243,244]</sup>. Zhou *et al.*<sup>[106]</sup> reported that omeprazole at 40 mg IV bolus every 12 h for 48 h successfully stopped bleeding in 59% of patients with PHG bleeding. Additionally, patients whose bleeding was refractory to vasopressin, benefited from omeprazole co-administration and vice versa.

**Teprenone:** In a controlled clinical trial, teprenone (geranylgeranyl acetone) administered to 15 patients with PHG decreased VEGF and hexosamine content in the gastric antrum, and thereby significantly decreased the severity of PHG<sup>[136]</sup>. Among these 15 treated patients, one patient decreased from severe to moderate PHG and another patient decreased from moderate to mild PHG<sup>[180]</sup>. Contrariwise, all 15 patients receiving placebo experienced no change in PHG severity.

**Endoscopic therapies:** Endoscopic therapies play a minor role in PHG bleeding because the bleeding is typically diffuse and obscure. Little data exist on efficacy of endoscopic therapy for PHG bleeding<sup>[71,245]</sup>. No single predominant site of bleeding is identified that can be locally treated at endoscopy. The role of endoscopic therapy is limited to the rare circumstances in which a single active bleeding site identified that is amenable to point therapy such as cauterization or sclerotherapy.

Argon plasma coagulation (APC) or hemospray, a rapid hemostatic agent, are experimental endoscopic therapies for PHG. These therapies can treat a larger bleeding surface area than cauterization or sclerotherapy. Nine (81%) of 11 patients undergoing APC for PHG bleeding achieved hemostasis, with a significant rise in hematocrit from baseline values after a mean of  $2.2 \pm 2.0$  (SD) endoscopic therapy sessions. The other two treated patients required fewer blood transfusions after APC therapy<sup>[202]</sup>.

Hemospray has recently shown promise in halting active PHG bleeding while long-term therapy is being initiated<sup>[203,246]</sup>. Ibrahim *et al.*<sup>[246]</sup> reported complete cessation of diffuse bleeding from severe PHG after spraying hemospray TC-325 (a nanopowder hemostatic agent<sup>[247]</sup>) in a 41-year-old woman who presented with a hemoglobin of 8.8 g/dL. No active bleeding was seen on follow-up endoscopy performed 24 h later. In another study, however, one of four patients treated with hemospray for bleeding from PHG expired from GI perforation<sup>[203]</sup>.

Endoscopic cryotherapy has been used for PHG bleeding after all other modalities failed. In one patient salvage cryotherapy was successful after failed TIPS and APC, with normal hemoglobin levels maintained during 4 wk of follow-up<sup>[248]</sup>.

**TIPS:** TIPS increases gastric mucosal blood flow while decreasing total gastric blood flow due to decreasing portal hypertension<sup>[76]</sup>. TIPS reduces the frequency and severity of PHG because it lowers portal pressure<sup>[76]</sup>. PHG can sometimes resolve completely after TIPS<sup>[75-77,249-253]</sup>. Urata *et al.*<sup>[77]</sup> reported in a prospective study of 12 Japanese patients undergoing TIPS for portal hypertension that portal pressure declined from  $25.1 \pm 8.8$  (SD) mmHg before TIPS to  $17.1 \pm 6.2$  (SD) mmHg after TIPS ( $P < 0.005$ ). This decline in portal pressure was correlated with a significant decrease in PHG severity after TIPS ( $P < 0.01$ ), and a significant decrease in number of patients with PHG (10 before vs 4 after TIPS,  $P < 0.01$ ). In particular, PHG disappeared in 2 of 5 patients who had severe PHG before TIPS. Mezawa *et al.*<sup>[76]</sup>, likewise, reported that mean portal pressure declined from 23.4 to 14.0 mmHg in 16 cirrhotic patients after TIPS ( $P < 0.01$ ). All four patients with severe PHG before TIPS, had significant improvement in PHG severity after lowering portal pressure with TIPS, and five of 12 patients with mild PHG had resolution of PHG after TIPS. In contrast, GAVE does not resolve after lowering portal pressure with TIPS, and GAVE is, therefore, likely related to hepatic dysfunction rather than portal hypertension<sup>[78]</sup>.

TIPS also decreased the risk of PHG bleeding<sup>[75-77,100,249-253]</sup>. For example, Kamath *et al.*<sup>[75]</sup> reported TIPS led to improvement or resolution of PHG findings and decreased transfusion requirements from  $2.9 \pm 2.0$  (SD) units/mo of packed erythrocytes before TIPS to  $0.6 \pm 0.8$  units/mo after TIPS performed for severe PHG ( $P = 0.04$ ). Ashraf *et al.*<sup>[98]</sup> reported one patient with chronic liver disease from hepatitis C who presented with chronic bleeding from PHG that required transfusions of 28 units of packed erythrocytes during the prior 6 mo. The bleeding ceased after TIPS with marked improvement in the severity of PHG. Contrariwise, GAVE does not respond to TIPS or other measures that lower portal pressure.

**Shunt surgery:** Shunt surgery decreases portal hypertension, decreases PHG severity, decreases risk of PHG bleeding, and may sometimes completely resolve the endoscopic features of PHG<sup>[100]</sup>. Shunt surgery is rarely used today to control bleeding because TIPS is preferred because of less invasiveness<sup>[100,101,238,254]</sup>.

TIPS and shunt surgery are therapies of last resort for patients who fail other therapies for PHG because they entail more morbidity and mortality than pharmacologic therapy<sup>[71]</sup>. TIPS, however, is very useful for refractory bleeding from esophageal varices from portal hypertension<sup>[255]</sup>, and is a reasonable option in patients having recurrent severe bleeding from PHG despite administration of  $\beta$ -adrenergic receptor antagonists<sup>[102]</sup>.

**Other invasive therapies:** Liver transplantation is the ultimate therapy for PHG<sup>[118]</sup>. In a study of 29 patients undergoing living donor liver transplantation for end stage liver disease, PHG resolved in all 19 patients who

had PHG before transplantation<sup>[44]</sup>.

Kimura *et al.*<sup>[218]</sup> retrospectively examined the 19 patients experiencing gross GI bleeding, defined as gross melena or hematemesis, within 3 mo after liver transplantation among 297 patients undergoing living donor liver transplantation. The etiologies included PHG in 2 patients, varices in 1, anastomotic ulcer in 13, and other in 3.

Splenic embolization, by transcatheter splenic arterial embolization, significantly improves PHG in patients with hypersplenism as compared to controls<sup>[99,255]</sup>. Ohmagari *et al.*<sup>[99]</sup> evaluated 30 patients with hypersplenism who underwent transcatheter splenic arterial embolization in 17 vs no interventional therapy in 13 patients. Splenic embolization significantly reduced the frequency of PHG (reduction of 71% vs 8%,  $P < 0.05$ ). Partial splenic embolization also successfully controlled PHG bleeding in one case report<sup>[256]</sup>.

Laparoscopic splenectomy, for various indications, was reported to decrease PHG severity<sup>[55]</sup>. Anegawa *et al.*<sup>[55]</sup> prospectively analyzed the effect of laparoscopic splenectomy on preexistent PHG in 70 patients with liver cirrhosis from various etiologies. All patients underwent EGD before and 1 mo after splenectomy. Splenectomy was performed for indications of bleeding diathesis, interferon induction, hepatocellular cancer treatment, and sclerotherapy-resistant varices. Before splenectomy, 49 of 70 patients had PHG, including mild PHG in 32 and severe PHG in 17 patients. After splenectomy, PHG resolved completely in 7 patients with prior severe PHG, resolved completely in 12 patients with mild PHG, and was reduced from severe to mild PHG in 9 patients ( $P < 0.0001$ ).

### Summary of clinical treatment

**Acute bleeding:** Variceal bleeding must be excluded by performing EGD before initiating treatment for PHG<sup>[257,258]</sup>. General measures for patients presenting with acute bleeding from PHG include volume resuscitation and cautious transfusion of packed erythrocytes, as necessary, to maintain the hemoglobin level at 8 g/dL<sup>[192,259,260]</sup>. Over-transfusion to a higher hemoglobin level could promote bleeding from PHG by raising portal pressure, as reported for bleeding from esophageal varices<sup>[261,262]</sup>. However, patients with cardiopulmonary disease or severe other comorbidities may require a hemoglobin level of 9-10 g/dL<sup>[263]</sup>. Antibiotic prophylaxis is generally recommended for bleeding from PHG<sup>[214]</sup>, just as it is recommended for esophageal variceal bleeding in cirrhotic patients<sup>[189,264-266]</sup> because of an increased risk of systemic infections, particularly spontaneous bacterial peritonitis, in cirrhotic patients with GI bleeding<sup>[267]</sup>.

Bleeding from PHG may be exacerbated by a coagulopathy with an elevated international normalized ratio from advanced liver disease. This coagulopathy may require transfusion of fresh frozen plasma. Severe thrombocytopenia may occur from bone marrow suppression in alcoholic cirrhosis and from hypersplenism with portal hypertension in any cirrhotic patient.

**Table 12 Treatment of acute or chronic gastrointestinal bleeding from portal hypertensive gastropathy**

Acute bleeding
Patient stabilization
Treat severe coagulopathy with highly elevated INR associated with cirrhosis with fresh frozen plasma
Treat severe thrombocytopenia associated with hypersplenism and bone marrow suppression from alcoholism with platelet transfusions
Transfuse packed erythrocytes to main hemoglobin level at about 8 g/dL
Consider antibiotic prophylaxis in patient with cirrhosis
Endoscopic therapy from bleeding-rarely used
Consider argon plasma coagulation
Hemospray - an experimental therapy
Pharmacotherapy
Octreotide - first line therapy
Vasopressin or terlipressin - second line therapy
Proton pump inhibitor therapy - adjunct therapy
Propranolol - can be instituted after bleeding controlled and patient stabilized
Interventional therapy
TIPS - for uncontrolled hemorrhage or for bleeding from PHG associated with variceal bleeding
Liver transplantation - for advanced end stage liver disease
Chronic bleeding
Treatment of anemia
Transfusions of packed erythrocytes as necessary
Iron replacement therapy
Pharmacotherapy
Consider propranolol

TIPS: Transjugular intrahepatic portosystemic shunt; PHG: Portal hypertensive gastropathy; INR: International normalized ratio.

Platelet transfusion may be necessary for severe thrombocytopenia in the setting of active bleeding from PHG.

Somatostatin or octreotide are first line therapies. Vasopressin or terlipressin are second-line therapies for acute bleeding<sup>[106]</sup>. Once the acute bleeding is controlled and the patient is hemodynamically stable, a nonselective  $\beta$ -adrenergic receptor antagonist is instituted for secondary prevention of PHG bleeding<sup>[103,258,268]</sup>. Propranolol is the recommended drug in this class because it has been the most studied. Propranolol should be started at a dose of 20 mg twice daily and gradually escalated to 160 mg twice daily or the maximum tolerated dose, maintaining it as long as the portal hypertension is present<sup>[214]</sup>. The dose is titrated to slow the pulse to 60 beats/min. This class of drugs is not used in the acute setting because it can blunt the physiologic tachycardia to restore end-organ perfusion in response to hypovolemia and requires gradual dose titration to achieve an adequate response<sup>[214]</sup>. This class of drugs also prevents bleeding from concomitant esophageal varices.

**Treatment of chronic bleeding:** Scant data exist regarding management of chronic bleeding from PHG<sup>[72]</sup>. In patients with suspected chronic bleeding from PHG, after excluding other etiologies, iron replacement therapy should be initiated to avoid depleting iron reserves<sup>[260]</sup>. Propranolol is the primary therapy to reduce portal pressure and prevent chronic bleeding<sup>[72,214,260]</sup>. However, propranolol was not superior to placebo in one study, as determined by percentage of patients free from chronic GI bleeding during long term follow-up<sup>[103]</sup>.

Liver transplantation is an option in patients with decompensated cirrhosis and PHG bleeding. Table 12 summarizes the recommendations for the treatment of

acute and chronic bleeding from PHG.

### Prevention

The risk of bleeding from mild PHG is low. Primary prophylaxis is, therefore, not recommended for patients with mild PHG<sup>[72,191,269]</sup>. Propranolol can be used for primary prophylaxis for severe PHG, and can significantly reduce the risk of bleeding. However, scant evidence exists that this reduction will affect the risk of a primary bleeding episode in PHG patients<sup>[72,103,104,269,270]</sup>. Propranolol is recommended regardless of the severity or presence of PHG in patients with esophageal varices because it treats both entities by reducing portal pressure<sup>[105-107,198,271,272]</sup>.

Prophylaxis of bleeding from PHG is not recommended<sup>[260]</sup>. Current guidelines do not recommend endoscopic surveillance in patients with cirrhosis who have asymptomatic PHG, without evident esophageal varices, other than the standard surveillance for development of esophageal varices in these patients<sup>[189]</sup>.

**Mortality:** Limited data exist on mortality from bleeding from PHG, but this bleeding is rarely fatal<sup>[72]</sup>. It contributes little to overall morbidity and mortality from portal hypertension, especially in comparison to variceal bleeding<sup>[118]</sup>. It represents a minor cause (< 1%) of mortality in cirrhotic patients because the bleeding is typically mild<sup>[25,34,37,71]</sup>. Only one patient expired from PHG in one series of 38 deaths among 373 study patients with cirrhosis<sup>[34]</sup>. Bleeding-related mortality was much lower for PHG [1 of 8 patients (12.5%)] than that for esophageal varices [9 of 20 patients (45%)]<sup>[34]</sup>.

**Lesions resembling PHG in other gastrointestinal regions:** PHG-like lesions can occur in other parts of

the GI tract and are named according to the involved segment as portal hypertensive duodenopathy<sup>[40]</sup>, portal hypertensive biliopathy, small intestinal vasculopathy<sup>[139]</sup>, and portal hypertensive colopathy<sup>[96,139]</sup>. These uncommon extragastric lesions occur particularly in patients with extrahepatic portal hypertension<sup>[71]</sup>. Portal hypertensive duodenopathy has been defined as the endoscopic appearance of patchy or diffuse congestion of duodenal mucosa associated with portal hypertension<sup>[40]</sup>, but a consensus definition is not established<sup>[273]</sup>. Histologically, vascular changes predominate, including capillary angiogenesis, dilatation and congestion, as well as fibrous proliferation and apoptosis<sup>[46]</sup>. This duodenopathy is significantly more severe in patients having severe than mild PHG (56.8% vs 23.5%,  $P < 0.05$ )<sup>[46]</sup>. Portal congestive jejunosopathy is defined histologically by the presence of ectatic capillaries and venules in the villi, with an increase in the number of vessels to  $> 6/\text{villus}$ <sup>[274]</sup>. Portal hypertensive ileopathy<sup>[275]</sup>, and portal hypertensive colopathy<sup>[38,276]</sup> are also associated with portal hypertension. The colopathy histologically appears as dilatation of mucosal blood vessels and is classified into four different types by Ito *et al.*<sup>[38]</sup>, including solitary vascular ectasias, diffuse vascular ectasias, erythema, and blue vein.

## DISCUSSION

The pathophysiology of PHG is not well understood. Portal hypertension plays a central role in the pathogenesis, and liver disease a subsidiary role in the disease, but a hyperdynamic circulation likely also plays an important role. However, the precise nature and pathophysiology of the hyperdynamic circulation must be further elucidated. The pathophysiology of more severe gastric mucosal injury and blunted reparative response after exposure to toxic substances in PHG must be clarified in terms of molecular mediators and histopathology. In particular, the pathophysiologic basis of decreased superficial mucosal perfusion in PHG must be better characterized in terms of its molecular mechanisms.

The current pharmacotherapy for bleeding from PHG focuses on decreasing portal pressure because portal hypertension is a prerequisite for developing PHG. Understanding the molecular mechanisms of this disease may permit development of better targeted and more effective pharmacotherapies.

## COMMENTS

### Background

Portal hypertensive gastropathy (PHG) is characterized at endoscopy by characteristic lesions present in the proximal stomach; characterized pathophysiologically by a hyperdynamic circulation induced by portal hypertension by inadequately understood mechanisms; and characterized clinically by mild-to-moderate acute or chronic gastrointestinal bleeding from the endoscopically identified lesions. However, much about the pathophysiology and clinical therapy of PHG is inadequately understood. This work systematically reviews the literature on the pathophysiology, natural history and

therapy of PHG to report what is known and what is not known or controversial about PHG.

### Research frontiers

This work systematically reviews gaps or controversies in the current understanding of PHG. First, this work exposes gaps in the current understanding of the pathophysiology. Portal hypertension is necessary but insufficient to develop PHG because many patients have portal hypertension without PHG. The pathogenesis is related to a hyperdynamic circulation, induced by portal hypertension, characterized by increased intrahepatic resistance to flow, increased splanchnic flow, increased total gastric flow, and most likely decreased gastric mucosal flow. However, this review shows that the cellular and molecular mechanisms for this hyperdynamic circulation are inadequately characterized. Nitrous oxide, free radicals, tumor necrosis factor- $\alpha$ , and glucagon may be important mediators of PHG. Second, this work reports the inadequacies of the current recommended therapies for PHG and for bleeding from PHG based on the currently inadequate understanding of the pathophysiology. This work should be useful to clinicians, clinical researchers, and basic researchers by describing what is known, controversial, or unknown about the pathophysiology, natural history, and therapy of PHG. It is hoped that this work stimulates further research in this field by exposing gaps in the current understanding of PHG.

### Innovations and breakthroughs

This systematic review extensively reviews what is known and what is not known or controversial about PHG. This work is particularly helpful to clinicians in reporting the current recommended therapy for PHG, the clinical trials supporting the current recommendations, and the limitations of the current therapies. This is also helpful to clinical and basic researchers in systematically reviewing the current state of knowledge about its pathophysiology, including gaps, uncertainties, and controversies in the current understanding of the pathophysiology.

### Applications

This systematic review extensively reviews what is known and what is not known or controversial about PHG. First, this work exposes gaps in the understanding of the pathophysiology. Portal hypertension is necessary but insufficient to develop PHG because many patients have portal hypertension without PHG. The pathogenesis is related to a hyperdynamic circulation, induced by portal hypertension, characterized by increased intrahepatic resistance to flow, increased splanchnic flow, increased total gastric flow, and most likely decreased gastric mucosal flow. However, this review shows that the cellular and molecular mechanisms for this hyperdynamic circulation are inadequately characterized. Nitrous oxide, free radicals, tumor necrosis factor- $\alpha$ , and glucagon may be important mediators of PHG development. Second, this work describes the natural history of PHG. PHG increases in frequency with more severe portal hypertension, advanced liver disease, longer liver disease duration, presence of esophageal varices, and endoscopic variceal obliteration. Acute and chronic gastrointestinal bleeding are the only clinical complications. Bleeding is typically mild-to-moderate. Third, this work reports the current therapies for PHG and for bleeding from PHG and characterizes their inadequacies based on the currently inadequate understanding of the pathophysiology. In particular, this work reviews clinical trials of the therapeutic efficacy of octreotide; proton pump inhibitors; nonselective  $\beta$ -adrenergic receptor antagonists, particularly propranolol; and vasopressin or terlipressin. This work should be useful to clinicians, clinical researchers, and basic researchers by describing what is known, controversial, and uncertain about the pathophysiology, natural history, and therapy of PHG.

### Terminology

This work systematically reviews portal hypertensive gastropathy, characterized at endoscopy by characteristic lesions present in the proximal stomach; characterized pathophysiologically by a hyperdynamic circulation induced by portal hypertension by inadequately understood mechanisms, and characterized clinically by mild-to-moderate acute or chronic gastrointestinal bleeding from the endoscopically identified lesions.

### Peer-review

This review by Mihajlo Gjeorgjievski on portal hypertensive gastropathy is well

written and helpful to understand its pathophysiology, clinical presentation, natural history and therapy. This review is informative and helpful to readers who are interested in the topic or subtopics.

*terology*, we have read the article by Li *et al* with great interest. We would like to thank the authors for their comprehensive contribution. However, it is our wish to make minor criticism over the present study from the perspective of methodology.

**Key words:** Cirrhosis; Intercostal approach; Subcostal approach; Acoustic radiation force impulse; Liver fibrosis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Hepatitis B virus infection is still one of the leading causes of cirrhosis and hepatocellular carcinoma. Liver biopsy is the gold standard method to assess the severity of liver fibrosis. However, there are several limitations of liver biopsy, including its invasive nature, small tissue sample size, and subjective grading system. Nowadays, noninvasive parameters have been utilized to evaluate liver histology. Additionally, ultrasound-based techniques, such as acoustic radiation force impulse have gained popularity in assessing liver fibrosis. Herein, we aimed to make a minor criticism regarding this study.

Karagoz E, Ozturker C, Sivrioglu AK. Non-invasive evaluation of liver fibrosis by acoustic radiation force impulse and aminotransferase:platelet ratio index in chronic hepatitis C. *World J Hepatol* 2016; 8(4): 263-264 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i4/263.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i4.263>

### TO THE EDITOR

In a previous issue of the *World Journal of Gastroenterology*, we have read the article by Li *et al*<sup>[1]</sup> with great interest. We would like to thank the authors for their

### Abstract

In a previous issue of the *World Journal of Gastroen-*

comprehensive contribution. However, it is our wish to make minor criticism over the present study from the perspective of methodology.

First, the measurements of Acoustic Radiation Force Impulse Imaging were performed in the right liver lobe through the intercostal space in present study<sup>[1]</sup>. Uslu *et al*<sup>[2]</sup> demonstrated that subcostal approach to the liver parenchyma was significantly superior to intercostal approach for the evaluation of liver stiffness in their study. As the pressure was transmitted better to liver parenchyma and the anterior abdominal wall, we are of the opinion that subcostal approach would give better results than intercostal approach in terms of determining the elasticity of the liver.

Second, it would have been better, if the authors had stated the length of the biopsy material and the number of the pieces of the portal tracts. Fibrosis is heterogeneously distributed throughout the liver, whereas a biopsy evaluates only 1/50000 of the total volume of the liver<sup>[3]</sup>. Additionally, if the biopsy material is not long enough, appropriate evaluation cannot be done. A length of at least 25 mm is required to assess

the fibrosis score accurately<sup>[3]</sup>. It would have been better, if the authors had mentioned these conditions as limitations.

Further studies are needed to indicate the role of acoustic radiation force impulse imaging method in the management of liver fibrosis and cirrhosis in patients with chronic hepatitis C.

Editorial Board Member of *World Journal of Hepatology*, Daniel J Felmlee, Research Lecturer, Hepatology Research Group, Plymouth University Peninsula School of Medicine and Dentistry, 67000 Strasbourg, France

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/  
ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Primary sclerosing cholangitis (PSC) remains a rare but significant disease, which affects mainly young males in association with inflammatory bowel disease. There have been few advances in the understanding of the

pathogenesis of the condition and no therapeutics with proven mortality benefit aside from liver transplantation. There remain areas of controversy in the management of PSC which include the differentiation from other cholangiopathies, in particular immunoglobulin G4 related sclerosing cholangitis, the management of dominant biliary strictures, and the role of ursodeoxycholic acid. In addition, the timing of liver transplantation in PSC remains difficult to predict with standard liver severity scores. In this review, we address these controversies and highlight the latest evidence base in the management of PSC.

**Key words:** Immunoglobulin G4 related sclerosing cholangitis; Cholangiocarcinoma; Primary sclerosing cholangitis; Liver transplantation; Dominant strictures

### INTRODUCTION

Primary sclerosing cholangitis (PSC) is a chronic cho-

**Table 1 Differential diagnosis for primary sclerosing cholangitis**

Vascular	Hepatic artery thrombosis
	Portal hypertension bilopathy
	Portal cavernoma associated cholangiopathy
	Intra-arterial chemotherapy
Trauma	Sickle cell disease related cholangiopathy
	Trauma post cholecystectomy
	Abdominal trauma
Infections	AIDS related cholangiopathy
	Recurrent pyogenic cholangitis
Benign	Intraductal stone disease
Malignancy	Cholangiocarcinoma
Autoimmune	Autoimmune sclerosing cholangitis
	IgG4 related sclerosing cholangitis
	Systemic vasculitis
Other	Recurrent pancreatitis
	Sclerosing cholangitis in critically ill patient
	TPN related cholangiopathy
	Histocytosis X

IgG4: Immunoglobulin G4; TPN: Total parenteral nutrition; AIDS: Acquired immune deficiency syndrome.

lestatic disorder characterised by inflammation and fibrosis of intrahepatic and extrahepatic bile ducts, resulting in multifocal biliary strictures<sup>[1]</sup>. The pathogenesis of PSC remains unclear but hypotheses include genetic factors<sup>[2]</sup>, lymphocyte recruitment and activation<sup>[3]</sup>, portal bacteraemia<sup>[4]</sup> and bile salt toxicity<sup>[5]</sup>.

PSC commonly affects males<sup>[6]</sup> with a median age at diagnosis of 35 years<sup>[6,7]</sup>. In addition, there is a significant association with inflammatory bowel disease (IBD)<sup>[8]</sup>, hepatobiliary malignancies<sup>[9]</sup> and colorectal cancer<sup>[10]</sup>. A key aspect in the management of PSC is surveillance for the development of these conditions. Patients commonly present with cholestatic liver enzymes and a normal bilirubin<sup>[8]</sup>. The demonstration of a cholangiopathy is essential for the diagnosis of PSC<sup>[11]</sup>. Characteristic ERCP findings include diffuse multifocal strictures and irregularities, with normal or minimally dilated segments in between giving rise to the characteristic beaded pattern<sup>[12]</sup>. The use of MRCP has been increasing, partially driven by the complication rate of 11% following ERCP<sup>[13]</sup>, and a comparable sensitivity and specificity to ERCP<sup>[14]</sup>.

PSC is strongly associated with IBD, with prevalence of 63%-81%<sup>[8,15]</sup>, most commonly ulcerative colitis (UC), in 86%-88%<sup>[15,16]</sup>. The temporal relationship of the 2 conditions can be variable, although IBD usually precedes the diagnosis of PSC. Patients with colitis typically have mild symptoms and are sometimes asymptomatic<sup>[17]</sup>. Endoscopic findings are very different between PSC and non-PSC groups, with more pancolitis, backwash ileitis, and rectal sparing in those with PSC<sup>[16]</sup>. Colonoscopy with biopsies is recommended as part of the diagnostic work-up in any new diagnosis of PSC<sup>[18]</sup>. In addition, patients with PSC and IBD have a significantly higher risk of colorectal cancer than those with IBD alone<sup>[10]</sup> (OR = 4.79, 95%CI: 3.58-6.41).

To date, certain aspects remain controversial in the management of PSC. They include the differentiation

of PSC and from other causes of sclerosing cholangitis in particular immunoglobulin G4 related sclerosing cholangitis (IgG4-SC), the optimal management of dominant biliary strictures at endoscopy, the role of ursodeoxycholic acid (UDCA), its optimal dose and likely benefit, and the timing of liver transplantation. In this review article we will address these controversies.

## SEARCH STRATEGY

We searched PubMed using the following terms: "primary sclerosing cholangitis", "secondary sclerosing cholangitis", "cholangiocarcinoma", "IgG4 related disease" and "liver transplantation". We included data from full-text articles, published in English. Further relevant articles were identified from the reference lists of review articles and guidelines from liver societies.

## THE DIFFERENTIAL DIAGNOSIS OF PSC

Secondary sclerosing cholangitis (SSC), includes a heterogeneous group of conditions where different insults (*i.e.*, infections, thrombosis, iatrogenic, trauma) can give rise similar clinical characteristics to PSC<sup>[19]</sup> (Table 1). A single-centre series of 31 patients with SSC, identified a shorter transplant free survival (median 72 mo) when compared to controls with PSC, and with no complicating cases of cholangiocarcinoma (CCA)<sup>[20]</sup>. A more recently described entity is sclerosing cholangitis in critically ill patients. This may be related to hepatic hypoperfusion and biliary cast formation<sup>[21]</sup>, and has a particularly aggressive clinical manifestation with a reported transplant free survival of approximately 1 year<sup>[22]</sup>.

IgG4 disease was first described in 1995 in patients with pancreatitis, raised serum IgG levels and a response to corticosteroids<sup>[23]</sup>, which was termed autoimmune pancreatitis (AIP). Extra-pancreatic biliary changes that were found on ERCP, in addition to lymphoplasmocytic infiltration and fibrosis on liver biopsy, suggested an extra-pancreatic biliary component to the disease<sup>[24]</sup>. This has now been termed IgG4-SC, and is the commonest extra-pancreatic manifestation of AIP<sup>[25]</sup>.

IgG4-SC is an important differential diagnosis for PSC, with a different natural history and treatment profile. There are some subtle differences and similarities between PSC and IgG4-SC (Table 2). Similar to PSC, IgG4-SC has a male preponderance, however it usually presents in older patients<sup>[26]</sup>. The clinical presentation in patients with IgG4-SC is more commonly acute onset of obstructive jaundice, than is seen in classical PSC<sup>[25]</sup>, and was evident in 75% in one series<sup>[27]</sup>. IgG4-SC can also be diagnosed in asymptomatic patients with AIP, either at initial diagnosis or during follow up. The data on rates of co-existent IBD are limited to small case series from Japan<sup>[27]</sup> and United Kingdom<sup>[28]</sup>, which show much lower detection of IBD when compared to patients with PSC. Serum IgG4 is elevated in 76% of patients with AIP, and total IgG is elevated in 42%<sup>[29]</sup>. An elevated

**Table 2 Primary sclerosing cholangitis compared to immunoglobulin G4 related sclerosing cholangitis (adapted from Joshi 2014)**

	PSC	IAC
Gender (M:F)	1.5:1	7:1
Age of onset	Young (< 40 yr)	Older (> 50 yr)
Presentation	Cholestatic liver enzymes	Obstructive jaundice
Cholangiogram	Beading, band-like strictures, peripheral pruning	Long smooth strictures, low CBD strictures
Cholangioscopy	Dilated and tortuous vessels	Scarring, pseudo diverticula
Raised serum IgG4 levels	< 20%	> 70%
Pancreatic involvement	< 5%	> 80%
Cholangiocarcinoma	9%	Rare
Association with IBD	80%	< 10%
Response to steroids	Rare (IgG4 + ve PSC)	97%

M: Male; F: Female; PSC: Primary sclerosing cholangitis; IgG4: Immunoglobulin G4; IBD: Inflammatory bowel disease.

serum IgG4 level however is not sufficient to diagnose IgG4-SC, especially as the optimal cut-off value has not been defined and may differ for subgroups of IgG4-SC<sup>[30]</sup>.

There are 4 cholangiographic patterns of disease which vary in the level of stricture location<sup>[31]</sup>. These are usually long smooth strictures as opposed to beading and band-like strictures in PSC. Depending on the pattern of disease, hepatobiliary malignancy may form part of the differential diagnosis, hence the role for ERCP to obtain samples from dominant strictures<sup>[26]</sup>. Brush cytology during ERCP is beneficial in detecting malignancy, however intra-ductal or ampullary biopsies are required to confirm the diagnosis of IgG4-SC. Histological features of IgG4 related disease are infiltration of plasma cells and IgG4 positive plasma cells, storiform fibrosis, and obliterative phlebitis<sup>[32,33]</sup>. Cholangioscopy in IgG4-SC patients has demonstrated dilated and tortuous vessels in 69%, a feature that was not observed in patients with PSC<sup>[34]</sup>. In addition, less scarring and pseudo diverticula were noted in IgG4-SC patients compared to the PSC patients. When a second procedure was carried out after steroids (32 to 93 d), a significant improvement in stenosis, dilated and tortuous vessels, and mass lesions were identified<sup>[34]</sup>.

The cholangiopathy of IgG4-SC is very responsive to corticosteroids and an improvement in bilirubin can be detected within 8 wk of therapy<sup>[28]</sup>. We recommend 30-40 mg prednisolone o.d. for 4 wk followed by a slow wean, blood test monitoring and imaging at 6 wk<sup>[26]</sup>. Regular clinical assessment in this period is required due to the potential risk of cholangitis and sepsis. A follow up study of IgG4 related disease patients, which included 84 with IgG4-SC, demonstrated a response to steroids in 97% but also a high relapse rate of 50%, which was not predicted by initial or on treatment serum IgG4 levels<sup>[35]</sup>. Five percent were diagnosed with cirrhosis (histological and clinical) and one patient required liver transplantation. It has been hypothesised that unlike PSC, which presents as a more indolent disease with established fibrosclerotic changes, the biliary strictures found in IgG4-SC are at an earlier more inflammatory stage of the disease process which is more responsive

to steroids<sup>[36]</sup>. IgG4-SC patients have not been identified to develop CCA<sup>[37]</sup>, which is in contrast to PSC which confers a significant risk of CCA<sup>[38]</sup>.

## MANAGEMENT OF DOMINANT BILIARY STRICTURE

A dominant stricture is defined as a narrow biliary stricture which impedes normal bile flow, with a diameter < 15 mm in the CBD/CHD or < 10 mm in the hepatic duct<sup>[39]</sup>. In a follow up study of 9.8 years, a new dominant stricture was found in 63% of patients<sup>[40]</sup>. Where liver biopsies were available, those with more advanced liver disease histologically were more likely to have dominant strictures<sup>[39,40]</sup>. The mean survival of patients with dominant strictures was significantly poorer than those without<sup>[40]</sup> (14 years vs 23 years,  $P = 0.01$ ). Data from long-term follow up studies (7.1 and 9.8 years), demonstrates that patients who developed CCA, almost all had pre-existing dominant strictures<sup>[40,41]</sup>.

The most concerning differential diagnosis of a dominant stricture is CCA. When a new dominant stricture is identified, a malignant aetiology needs to be excluded using the combination of axial imaging, biliary cytology and/or histology. Therapy for dominant strictures should be offered to all symptomatic patients, and current guidelines recommend endoscopic dilatation with or without stenting<sup>[40]</sup>. A prospective study of 52 patients with dominant strictures who underwent biliary intervention (stent or dilatation) identified a significantly better survival free of transplantation at 3, 5 and 7 years, when compared to that predicted by the Mayo Risk Score<sup>[39]</sup>.

Despite an improvement in prognosis with biliary intervention, the evidence for the ideal therapeutic strategy is not clear and guidelines suggest endoscopic dilatation, but do not give definitive guidance regarding stenting<sup>[40]</sup>. This decision is a balance between the likelihood of biochemical improvement and the risk of intervention. A large retrospective review of all biliary interventions performed for dominant strictures revealed a similar clinical and biochemical course independent

of modality of intervention, although a lower procedure related complication rate was evident in the balloon dilatation group compared to those who underwent stenting<sup>[42]</sup>. A trial of short term temporary biliary stents (mean 11 d) demonstrated an improvement in symptoms, with only 20% requiring further intervention in 1 year and 40% in 3 years<sup>[43]</sup>. However, within the same study a procedure related complication rate of 15% was reported<sup>[43]</sup>.

A prospective multicentre study of patients with compensated PSC without recent biliary intervention, comparing balloon dilatation to short-term plastic stenting (1-2 wk) is underway (www.clinicaltrials.gov, NCT01398917). The main endpoints of the study include re-intervention free survival time at 2 years, change in cholestatic symptoms and biochemistry at 3 mo, and adverse incidents. Data from this study may guide us towards the optimal management strategy for this group of patients.

Cholangioscopy allows for direct optical visualisation and guided biopsies of the biliary epithelium and biliary lesions. It is another diagnostic tool in the management of dominant strictures. In a multi-centre retrospective study of 52 patients with sclerosing cholangitis (48 PSC, 4 IgG4-SC) who underwent 54 procedures for suspicious biliary strictures, the sensitivity and specificity (50% and 100%, respectively) for diagnosing malignancy was comparable to a control group of patients investigated for a single biliary stricture<sup>[44]</sup>. Failure of cannulation rate was higher in the sclerosing cholangitis group (15%), and was related to difficulty cannulating the narrowed bile duct. The adverse events rate was 17%, with 11% developing cholangitis post procedure despite prophylactic antibiotics.

A further single centre prospective study of patients with PSC referred for cholangioscopy, reported their findings in 41 consecutive patients<sup>[45]</sup>. Cholangioscopy identified ductal stones in 56% of patients (of which 30% were not previously identified on cholangiography), and achieved complete or partial clearance in approximately three quarters of patients. One patient was diagnosed with CCA. Two of the 8 patients who proceeded to transplant were diagnosed with CCA on their explants, both of whom had undergone cholangioscopy directed biopsies which were negative. It appears that the diagnostic accuracy may be related to difficulties in deciding which parts of a stricture to biopsy, especially as it may contain both inflammation and cancer<sup>[44]</sup>. The addition of narrow-band imaging increases the biopsy rate but does not improve the dysplasia detection rate<sup>[46]</sup>.

The use of fluorescence *in situ* hybridisation (FISH) on ERCP brushing samples has been studied in patients with PSC and suspicion of CCA. A recent meta-analysis involving 828 patients from 8 studies, identified a pooled sensitivity and specificity of 68% and 70%, respectively, and 51% and 93% respectively for the 6 studies characterising FISH polysomy<sup>[47]</sup>. In a patient with PSC, a dominant stricture and FISH polysomy, there was a 88% specificity for CCA<sup>[48]</sup>, and where

there was serial FISH polysomy detected with no overt evidence of malignancy, 69% were diagnosed with CCA upto 2.5 years post initial test<sup>[49]</sup>. FISH may play a role in patients with high pre-test probability of CCA, or where CCA is suspected with no clear radiological or histological evidence. However it needs to be used with caution due to the low sensitivity, and importantly the risks of repeated invasive tests and the implications of delaying or excluding patients from liver transplantation.

## THE ROLE OF UDCA

UDCA is a hydrophilic bile acid which was studied in patients with PSC following the discovery of its efficacy in chronic cholestatic conditions, in particular primary biliary cirrhosis<sup>[50]</sup>.

Small prospective studies using UDCA at different doses in patients with PSC showed improvement in symptoms and liver biochemistry (8-16 mg/kg<sup>[51]</sup>, 10 mg/kg<sup>[52]</sup>), as well as histology (13-15 mg/kg<sup>[53]</sup>). Further studies at standard (13-15 mg/kg)<sup>[54]</sup> and higher doses (17-23 mg/kg)<sup>[55]</sup> did not demonstrate any survival advantage or prevention of CCA, although none were powered sufficiently to answer this hypothesis. A more recent randomised placebo controlled study at high dose (28-30 mg/kg) was terminated early due to an interim analysis demonstrating significantly higher rate of serious adverse events in the high dose UDCA group<sup>[56]</sup>. A subsequent meta-analysis on the use of UDCA in PSC concluded that there is no significant difference in mortality, histology or risk of CCA, at both standard and higher dose<sup>[57]</sup>, and guidelines advise against its use in PSC<sup>[18]</sup> (Table 3).

Patients with PSC and IBD have an increased risk of developing colorectal dysplasia compared to patients with IBD alone<sup>[10]</sup>. Although the true mechanisms for this increased risk remains unclear, one proposed hypothesis is the increased exposure of the colon to toxic bile acids<sup>[58]</sup>. Attention has therefore turned to UDCA with some data suggesting a possible chemo-preventative role for UDCA in reducing the incidence of colorectal cancer in PSC and UC patients<sup>[59]</sup>. A meta-analysis also suggested a benefit of using low-dose UDCA (8-13 mL/kg per day) but there was significant heterogeneity of the studies<sup>[60]</sup>. A double-blind, placebo controlled multicentre trial of 56 patients with PSC and UC given high dose UDCA (28-30 mg/kg) identified a significantly increased risk of colorectal cancer and dysplasia on both univariate, HR = 4.44 (1.30-20.1), and multivariate analysis, HR = 5.97 (1.39-41.44), in those receiving UDCA<sup>[61]</sup>. At present based on published guidelines, the use of UDCA for chemo-prevention for colorectal dysplasia is not recommended<sup>[18]</sup>.

## THE ROLE AND TIMING OF LIVER TRANSPLANTATION

Liver transplantation is an effective treatment for PSC,

**Table 3** Important studies involving ursodeoxycholic acid

Ref.	Dose and study design	Number UDCA (number placebo)	Follow up	Parameter	Outcome
Chazouillères <i>et al</i> <sup>[51]</sup>	8-16 mg/kg UDCA alone	15	6 mo	Liver enzymes	Improved
O'Brien <i>et al</i> <sup>[52]</sup>	10 mg/kg UDCA alone	12	37 mo	Liver enzymes	Improved
Beuers <i>et al</i> <sup>[53]</sup>	13-15 mg/kg UDCA <i>vs</i> placebo	6 (8)	12 mo	Liver enzymes Histology	Improved Improved

with survival post-transplant 93.7% at 1 year, 86.4% at 5 years, 69.8% at 10 years<sup>[62]</sup>. The indications for liver transplantation are similar to other aetiologies of chronic liver disease, but also include intractable pruritus and recurrent cholangitis. Organ allocation varies according to national policy. Recurrence of PSC following liver transplantation occurs in up to 20% of patients at 5 years<sup>[63,64]</sup>. The diagnosis of PSC recurrence post-transplant can be challenging due to the variety of causes of biliary strictures and cholangiopathy in the post-transplant setting. After exclusion of these, in combination with a concordant liver biopsy, a diagnosis of PSC recurrence can be made<sup>[65]</sup>. In patients who develop PSC recurrence, re-transplant free survival is 85% at 1 year and 45% at 5 years<sup>[66]</sup>.

Identifying which patients will benefit from liver transplantation, and the optimal timing for this is a challenge in the management of PSC, and many predictive models have been developed to optimise this. The Mayo Risk Score was initially devised following a single centre analysis of 174 patients with PSC<sup>[67]</sup>. Using multivariate analysis, age, log bilirubin, log haemoglobin, presence of IBD and liver biopsy stage, were identified as key parameters in predicting transplant-free survival. These parameters were incorporated into a statistical survival model which stratified patients into "low", "intermediate", and "high" risk<sup>[67]</sup>. The Mayo Risk Score for PSC has had numerous iterations over the last 20 years<sup>[68,69]</sup>. The latest version of the Mayo Risk Score incorporates age,

log bilirubin, log aspartate aminotransferase, variceal bleeding and albumin<sup>[69]</sup> (Table 4). This model predicts survival over 4 years and classifies patients as "low", "medium" and "high" risk.

Cholangiograms of 129 patients with PSC identified that high-grade and diffuse strictures of the intrahepatic ducts were markers of poor prognosis<sup>[70]</sup>. A retrospective review of 181 cholangiograms from 4 centres<sup>[71]</sup>, utilised the Amsterdam Cholangiographic Classification System for PSC<sup>[72]</sup>. The intrahepatic and extrahepatic ducts are scored based on severity of cholangiographic changes, and combined to calculate a prognostic index, where a higher score is associated with a poorer prognosis. If a patient however has a normal cholangiogram, a score of 0 is attributed and a score cannot be calculated, thereby making this model invalid for patients with small-duct PSC. Using this classification, a validation study was able to construct a model which could predict medium and long term prognosis in individual patients with PSC<sup>[73]</sup>.

The enhanced liver fibrosis (ELF) test has recently been assessed to predict clinical outcomes in a cohort of patients with large-duct PSC<sup>[74]</sup>. Median transplant-free survival differed significantly in the tertiles based on ELF score and a cut-off value was calculated to stratify patients into "low-score" and "high-score" groups, with a sensitivity of 67% and specificity of 83%. Patients with higher ELF score had a shorter survival, which was confirmed in a validation group of 138 patients<sup>[74]</sup>. In a multivariate Cox regression analysis, the ELF score was associated with transplant-free survival independent of the Mayo Risk Score.

CCA remains a contraindication to liver transplantation in the majority of liver transplant centres. A protocol was developed at the Mayo Clinic (inclusion criteria: < 3 cm lesion, no metastases, no prior abdominal radiation therapy, no transperitoneal biopsy of the tumour, no prior attempt at resection with violation of the bile ducts), which included pre-transplant neo-adjuvant chemo-irradiation, and a modified post-transplant immunosuppression regimen<sup>[75]</sup>. Using this protocol reported outcomes were comparable to other

indications for liver transplantation<sup>[76]</sup>. Of 215 patients who received neo-adjuvant chemotherapy, 136 patients proceeded to liver transplantation (87 with PSC), with 92% 1 year and 74% 5 year survival. Twenty one percent of those who underwent operative staging were excluded from transplantation due to metastatic disease, and there was a 21% tumour recurrence post transplantation<sup>[77]</sup>. Unfortunately these promising results have not been reproduced at other centres<sup>[78]</sup>. There are currently several studies in progress in order to further understand the role for liver transplantation for CCA, and this data is eagerly awaited<sup>[79]</sup>.

## CONCLUSION

The management of patients with PSC continues to pose a challenge to clinicians worldwide. Although guidelines are available, there are few proven therapeutic options, and there remain clinical scenarios which lack a robust evidence base with which to guide management. Many of the commonly used diagnostic tests, particularly for the detection of hepatobiliary malignancy, lack an appropriate sensitivity and specificity. Until further advances in the field take place, the mainstay of management should involve optimal biliary drainage, timely referral for liver transplantation and a low threshold for investigation for hepatobiliary or colorectal malignancy.

### Abstract

Approximately 3 million healthcare workers per year receive an injury with an occupational instrument, with around 2000000 exposures to hepatitis B virus (HBV) and 1000000 to hepatitis C virus (HCV). Although an effective HBV vaccine has been available since the early eighties, and despite the worldwide application of universal vaccination programs started in the early nineties, HBV still remains a prominent agent of morbidity and mortality. There is no vaccine to limit the diffusion of HCV infection, which progresses to chronicity in the majority of cases and is a major cause of morbidity and mortality worldwide due to a chronic liver disease. Healthcare workers are frequently exposed by a mucosal-cutaneous or percutaneous route to accidental contact with human blood and other potentially infectious biological materials while carrying out their occupational duties. Mucosal-cutaneous exposure occurs when the biological material of a potentially infected patient accidentally comes in contact with the mucous membranes of the eyes or mouth or with the skin of a healthcare worker. Percutaneous exposure occurs when an operator accidentally injures himself with a sharp contaminated object, like a needle, blade or other sharp medical instrument. About 75% of the total occupational exposure is percutaneous and 25% mucosal-cutaneous, the risk of infecting a healthcare worker being higher in percutaneous than in mucosal-cutaneous exposure. All healthcare workers should be considered for HBV vaccination and should meticulously apply the universal prophylactic measures to prevent exposure to HBV and HCV.

**Key words:** Hepatitis B virus infection; Hepatitis C virus infection; Needle-stick injury; Healthcare workers

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Preventing the transmission of hepatitis B virus

(HBV) or hepatitis C virus infection from source patients to healthcare workers is of vital importance in all healthcare settings worldwide, since these workers are exposed daily to these infections over a period of almost four decades. Needle pricks with contaminated needles, cuts from sharp instruments and blood splashes to the conjunctiva are the most frequent causes of exposure, injuries largely preventable by taking the standard universal precautions. HBV vaccination of anti-HBs-negative healthcare workers is recommended in all countries, but numerous healthcare workers remain exposed to infection because they have eluded HBV vaccination.

Hepatitis B virus and hepatitis C virus infection in healthcare workers. *World J Hepatol* 2016; 8(5): 273-281 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i5/273.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i5.273>

## INTRODUCTION

Hepatitis B virus (HBV) and hepatitis C virus (HCV) are responsible for the two most widespread forms of chronic hepatitis worldwide<sup>[1-3]</sup>. Healthcare workers are exposed to the risk of acquiring HBV and HCV infection through mucosal-cutaneous exposure (eyes or mouth mucosa or skin) to potentially infectious blood or blood products or through percutaneous exposure to contaminated sharp objects (needles, blades, *etc.*). Twenty-five percent of the total occupational exposure is mucosal-cutaneous and 75% percutaneous<sup>[4]</sup>. The risk of HBV or HCV infecting a healthcare worker is higher in percutaneous than in mucosal-cutaneous exposure. According to the data provided by the World Health Organization (WHO), there are approximately 36 million healthcare workers worldwide, of whom around 3 million per year receive an injury with a sharp instrument, thus resulting in 2000000 subjects contaminated with HBV and 1000000 with HCV<sup>[4]</sup>. Other studies estimated that the incidence of injuries to healthcare workers caused by sharp objects ranges from 1.4 to 9.5 per 100 healthcare workers per year, resulting in 0.42 HBV infections per 100 sharp-object injuries per year<sup>[5]</sup>.

This review article will focus on the risks of healthcare workers acquiring HBV and HCV chronic infections while carrying out their occupational duties.

## HBV INFECTION

HBV infection is a global health problem since 240 to 350 million<sup>[6-9]</sup> people worldwide are estimated to be chronically infected, of whom 312000 die annually of advanced cirrhosis and 341000 of liver cancer<sup>[7]</sup>.

Ten genotypes of HBV have been identified to date, from A to J, based on a genetic diversity of at least 8% in the viral genome<sup>[10,11]</sup>. HBV genotypes show a peculiar

geographical distribution<sup>[12]</sup>. Genotype A predominates in Northern Europe and North America, genotypes B and C in central Asia, genotype D in Mediterranean countries, genotype E in sub-Saharan Africa and in Madagascar, genotype F in South and Central America, genotypes G and H in Mexico and some countries in Central America<sup>[13,14]</sup> and genotypes I and J in Eastern Asia<sup>[15]</sup>.

The age at the time of infection modulates the progression to chronicity of HBV infection, which occurs in around 90% of babies born to hepatitis B e antigen (HBeAg)-positive mothers, a rate that progressively decreases with the increase in age up to 2%-5% in the adult population<sup>[16]</sup>.

The endemicity of HBV infection in a geographical area is classified according to the prevalence of subjects with hepatitis B surface antigen (HBsAg) positivity in the general population as, high (> 8%), intermediate (2.0%-7.9%) and low (< 2%)<sup>[11]</sup>. These categories reflect the predominant patterns of transmission and outcomes of HBV infection. In geographical areas with a high HBV endemicity, such as some countries in Eastern Asia or in sub-Saharan Africa, the majority of HBsAg-positive individuals acquired HBV infection at birth or in early childhood, when the risk of progression to chronicity is very high<sup>[7,15]</sup>. In geographical areas with an intermediate HBV endemicity, such as countries in Northern Africa, the Middle East and Southern Asia, and Eastern Europe, the majority of HBsAg-positive subjects acquired HBV infection in childhood or early adulthood, and family transmission plays an important role in the spread of HBV infection. Finally, in most countries in Western Europe, North, Central and South America and Australia the prevalence of HBsAg-positive individuals is below 2%<sup>[6,7,14]</sup>, the impact of vertical and horizontal transmission in childhood is low, and most HBsAg-positive individuals acquired HBV infection through sexual contact, intravenous drug use (IVDU) or other parenteral exposure to infected blood<sup>[17,18]</sup>.

## HCV INFECTION

HCV infection progresses to chronicity in 70% of cases, a condition that may lead to liver cirrhosis and hepatocellular carcinoma<sup>[19,20]</sup>. According to a WHO report<sup>[21]</sup>, 130-150 million people are chronically infected with HCV. HCV epidemiology shows considerable regional differences. In some geographical areas the endemicity is high, with more than 3.5% of the population having an HCV chronic infection, such as some countries in the Middle East and Central and Eastern Asia and Northern Africa. Several countries in Southern Asia, sub-Saharan Africa, the Andean territories, Central and South America, the Caribbean area, Oceania, Australasia and central and Eastern Europe have a moderate endemicity, with 1.5%-3.5% of subjects carrying HCV infection. The areas considered at low endemicity (< 1.5% of HCV chronic carriers) include countries in the Asian Pacific regions, tropical Latin America, North America and Western Europe<sup>[22]</sup>.

HCV strains have been classified to date into seven genotypes, namely from 1 to 7, on the basis of phylogenetic and sequence analyses of the whole viral genome<sup>[23]</sup>. The global geographical distribution of HCV genotypes is complex. HCV genotype 1 is the most prevalent worldwide, comprising 83.4 million cases (46.2% of all HCV chronic carriers), of whom approximately one-third live in Eastern Asia. HCV genotype 3 is the second most prevalent, and genotypes 2, 4 and 6 are responsible for the majority of the remaining cases worldwide. Eastern Asia has the largest number of carriers with genotype 2 and genotype 6, while Northern Africa and the Middle East have the largest number of carriers with genotype 4. HCV genotype 5 is responsible for around 1.4 million chronic infections (< 1% of all HCV cases worldwide), of which the vast majority in Southern and Eastern sub-Saharan Africa<sup>[22-26]</sup>. Worthy of note, HCV genotypes 1 and 3 generally predominate irrespective of the economic status, while the largest proportions of chronic carriers of HCV genotypes 4 and 5 live in low-income countries.

## RISK FACTORS FOR THE ACQUISITION OF HBV AND HCV INFECTION

HBV circulates in peripheral blood of infected subjects and any parenteral or mucosal exposure to potentially infected blood or blood contaminated material can be considered a risk for HBV transmission to non-immune/non-infected subjects<sup>[18,27]</sup>. In addition, the virus is present at infectious concentrations in semen and cervical secretions, and, consequently, HBV is frequently transmitted also by sexual and vertical routes<sup>[8,16]</sup>. The impact of the various routes of transmission varies significantly from one country to another<sup>[8,16]</sup>. In countries with a high endemicity level, HBV infection is prevalently acquired at birth from an HBeAg-positive mother, in which case it becomes chronic in around 90% of cases, or by horizontal transmission in early childhood through household contact, with a progression to chronicity from 10% to 40% of cases. Promiscuous unprotected sexual activity and IVDU are the major risk factors for acquiring HBV infection in areas with a low-prevalence, such as the United States<sup>[28]</sup>.

Worthy of note, the screening of blood donors for markers of HBV infection has dramatically reduced the risk of HBV transmission through the transfusions of blood and blood products. At present, this risk is estimated as 1-4 cases per million blood components transfused in low-prevalence areas<sup>[29]</sup> and around 1 case per 20000 blood transfusions in high-prevalence regions<sup>[30]</sup>.

The transfusion of infected blood and blood products was the most prominent route of transmission of HCV infection until 1989<sup>[1,31]</sup>. Routine mandatory screening of blood donors for circulating antibodies to HCV that started in the early 1990s has drastically reduced the risk of HCV transmission due to the transfusion of blood and

blood products, currently estimated between 1/500000 and 1/1000000 blood units<sup>[32]</sup>. Some concern for HCV transmission through blood transfusion remains only for some geographical areas with limited resources<sup>[33]</sup>. In developed countries, the sharing of injection equipment among IVDUs is one of the major risk factors for the acquisition of HCV infection, as demonstrated by the high anti-HCV seroprevalence found (70% or more in some studies) in this subset of subjects<sup>[34]</sup>. Conversely, in low-income countries, HCV transmission is frequently due to re-using equipment for injection and other inadequately sterilized therapeutic instruments<sup>[35]</sup>. HCV is rarely acquired through sexual intercourse<sup>[36]</sup>, but some outbreaks of acute HCV infections occurring in men having sex with men in the last decade have attracted the interest of the scientific community on this route of transmission, particularly in human immuno-deficiency virus (HIV)-infected individuals<sup>[37]</sup>. Perinatal transmission of HCV infection from HCV-monoinfected mothers occurs infrequently (around 3% of the cases), whereas it reaches 20% among HIV-coinfected mothers<sup>[38]</sup>. Other risk factors for the acquisition of HCV infection have been described, including acupuncture, tattooing, body piercing, some cosmetic procedures, sharing of shaving razors, nail scissors and other personal effects, and needle-stick injury for healthcare workers<sup>[28]</sup>.

## MODES OF EXPOSURE AND FACTORS ASSOCIATED WITH HBV AND HCV TRANSMISSION IN HEALTHCARE WORKERS

Healthcare workers are exposed to human blood and other potentially infectious biological material more frequently than the general population. Among the 60 or more agents responsible for blood-borne transmissible infectious diseases, HCV and HBV are those most frequently transmitted to healthcare workers. Contact with potentially infectious material occurs in most cases through mucosal-cutaneous or percutaneous exposure. In mucosal-cutaneous exposure, a patient's blood, blood derivative or other potentially infected biological material accidentally enters into contact with the mucous membranes of the eyes or mouth or with the skin, healthy or non-intact, of a healthcare worker<sup>[39]</sup>. Percutaneous exposure occurs when an operator receives an injury with a sharp contaminated object, such as a needle, blade or piece of glass. Around 75% of the total occupational exposure is percutaneous and the remaining 25% mucosal-cutaneous. The risk of HBV or HCV infecting a healthcare worker is higher in percutaneous than in mucosal-cutaneous exposure. The rate of transmission of HCV infection can be five times higher in percutaneous than in mucosal-cutaneous exposure, but the risk of acquiring these infections through conjunctival exposure is also high.

A prominent role in the transmission of an infection

is also played by the degree of infectiveness of the contaminated biological material to which the healthcare worker has been exposed<sup>[40-42]</sup>. The highest rates of transmission of HBV or HCV infection follow exposure to blood or its products, but transmission can also occur, generally at a lower rate, after exposure to ascites, cerebrospinal fluid or solutions from cell cultures. HBV and HCV transmissions have never been observed following exposure to feces, urine, sweat, vomitor tears.

Other main factors significantly affecting the likelihood of transmission of infecting agents are the extent and depth of the cutaneous or mucosal wound and the volume of blood transferred<sup>[40-43]</sup>. All punctures from contaminated needles and sharp objects may be responsible for the transmission of infections. However, the medical devices used to access the blood vessels directly cause most of the conversions to positivity of HCV and HBV serum markers worldwide. Such conversions are less frequent after the intramuscular or subcutaneous use of hollow needles or the use of lancets for capillary blood collection, due to the lesser amount of organic material present on their surface. Nurses generally perform these clinical practices and are the occupational group with the highest risk of needle-stick injuries<sup>[40-43]</sup>.

The risk of exposure is also related to the medical procedure performed. For example, of the 99 percutaneous injuries observed by Tokars *et al.*<sup>[44]</sup> during 1382 surgical operations in five different wards (general, orthopedic, gynecologic, traumatic and cardiac surgery), most (73%) were related with the suturing. Risk factors for percutaneous injuries included the performing an emergency procedure, a patient blood loss greater than 250 mL, and a duration of surgery procedure greater than 1 h<sup>[45]</sup>.

The HBV load in the source patient may influence the risk of transmission of HBV infection to non-immune healthcare workers. In these cases, the risk of HBV transmission is estimated at 19%-30%, if the source patient is HBeAg-positive or shows an HBV load > 10<sup>6</sup> IU/mL and at 5% if the source patient is HBeAg-negative or has a lower HBV load. The anti HBV vaccination of healthcare workers was introduced in the 1980s in most countries, but a substantial number of healthcare workers worldwide have eluded vaccination and, despite the excellent immunogenicity of the vaccine, about 20% of vaccinated subjects show anti-HBs titers lower than 10 IU/mL. It is common opinion, however, that HBV-vaccinated subjects with an anti-HBs titer below 10 IU/mL and those who have become anti-HBs-negative can be considered protected against HBV infection, since the immunological memory for HBsAg may persist even in these cases and ensure a rapid rise in protective antibodies in the case of an HBV assault<sup>[46-48]</sup>. Nevertheless, a highly infectious HBV inoculum might overpower a low antibody titers against HBsAg (anti-HBs) titer during the long professional life of a healthcare worker. In these cases, the administration of a booster dose of HBV vaccine could be considered<sup>[49]</sup>.

The transmission of HCV infection occurs in nearly 10% of the healthcare workers after parenteral exposure to the blood of an HCV-RNA-positive source patient, a rate that may vary according to the HCV load of the source patient<sup>[39,42]</sup>.

## PRE-EXPOSURE MANAGEMENT

The prevention of exposure remains the primary strategy for reducing occupational infections by blood-borne pathogens. The healthcare organizations should make available for their personnel a system that includes written protocols for prompt reporting, evaluation, counseling, treatment, and follow-up of occupational exposures<sup>[39]</sup>. Healthcare workers should be trained to adopt effective measures to prevent infections from occupational exposure to blood, *i.e.*, eliminating unnecessary injections, implementing universal precautions, eliminating needle recapping and disposing of the sharp into a sharps container immediately after use, use of safer devices such as needles that sheath or retract after use<sup>[50]</sup>.

Furthermore, healthcare workers should be aware that any person at risk of contact with blood, blood-contaminated body fluids, other body fluids, or sharps should be vaccinated against HBV<sup>[51]</sup>. The vaccination should happen early after the start of their career to avoid infection and development of carrier status. The healthcare workers should be vaccinated with a standard vaccination schedule and the serum anti-HBs should be assessed 1-2 mo after completion of a 3-dose vaccination series<sup>[52]</sup>. The HBV vaccination is, therefore, an essential part of prevention and control of HBV infection for healthcare workers and its use was one of the causes of drastic reduction of its prevalence in healthcare workers.

## POST-EXPOSURE MANAGEMENT

Although the primary prevention constitutes the first line of defense against the risk of occupational infections by blood-borne viruses, the adequate management of exposures with the post-exposure prophylaxis constitutes a key element in managing and limiting the transmission of these infections to staff exposed.

Regarding HBV infection, the risk of infection and the post-exposure management depends on the HBV status of the source and of the healthcare worker.

The risk of developing clinical hepatitis or serological evidence of HBV infection is high (22%-31% and 37%-62%, respectively) if the source is HBsAg and HBeAg positive, and low (1%-6% and 23%-37%, respectively) if it is HBsAg positive and HBeAg negative<sup>[28]</sup>. Moreover, it needs to evaluate the serological status of the healthcare worker: If HBsAg, anti-HBs (or titer less than 10 IU/mL) and HBV core antigen (anti-HBc) are negative, the healthcare worker is at risk to HBV infection. Precisely, in this case it should be taken in account the post exposure prophylaxis with a first dose of HBV vaccine and anti-HBV-specific immunoglobulin

(HBIG), that should be initiated as soon as possible, preferably within 24 h of exposure and not more than 7 d. If the healthcare worker is vaccinated with protective antibody response ( $\geq 10$  IU/mL) or is anti-HBc positive, no treatment is needed.

Currently, there is no prophylaxis for HCV infection: In fact, immunoglobulin and antivirals are not recommended and only the observation is indicated. However, recently the available of the second and third wave direct antiviral agents enhanced the efficacy and tolerability of anti-HCV treatment<sup>[53]</sup>; consequently, the traditional management of HCV infection after exposure in healthcare workers probably should be revised.

## STUDIES ON HBV INFECTION IN HEALTHCARE WORKERS

The rates of HBsAg and anti-HBc positivity in healthcare workers reported in several studies published in the last three decades<sup>[54-70]</sup> range from 0.1% to 8.1% and from 6.2% to 73.4%, respectively, depending on the age of the subjects investigated, the spread of HBV infection in their country of origin and on the prevention strategies used by the healthcare workers (Table 1).

Of 5813 healthcare workers tested in Italy in 1985, 21.5% were found to be anti-HBc-positive and 1.8% HBsAg-positive<sup>[65]</sup>. A logistic regression analysis showed that the exposure to HBV infection was associated with male sex, an older age, history of blood transfusion, dental treatment, needle-stick injury and working in a healthcare setting (surgeons and nurses vs others). A similar rate of HBsAg positivity (1.5%) was observed in a study on 960 healthcare workers tested in Denmark in 1998<sup>[59]</sup>. A much higher HBsAg prevalence (8.1%) was detected in 480 healthcare workers investigated by Kondili *et al*<sup>[62]</sup> in 2004 in Albania, in accordance

with the widespread of HBV infection in this country. In this study, the highest rates of HBsAg positivity were found in the youngest age group (11.4% in the aged 20-30) and in the auxiliaries (12.6%), but a high HBsAg prevalence (7.2%-7.5%) was also found in the healthcare workers aged over 30. The anti-HBc seroprevalence was also extremely high (70%) in this study and was associated with an age over 40 (OR = 2.9; 95%CI: 1.9-4.6).

In a study performed in Libya in 2008 on 601 healthcare workers, the rate of HBsAg positivity was 1.8%, higher in nurses (2.3%) and lower in physicians (0.7%) and laboratory staff (0.8%)<sup>[54]</sup>. Of 237 healthcare workers tested in Cameroon, 6.3% were HBsAg-positive and 73.4% anti-HBc-positive, in accordance with the wide spread of HBV infection in this geographical area<sup>[60]</sup>. Seroprevalence studies conducted in Asia showed varying results. Aziz *et al*<sup>[57]</sup>, Rehman *et al*<sup>[66]</sup> and Sarwar *et al*<sup>[68]</sup>, in three different studies conducted in Pakistan, reported that 2.4%, 5% and 2.4% of the healthcare workers, respectively, were HBsAg-positive.

Low rates of HBsAg positivity were found in two seroprevalence studies conducted on healthcare workers in the United States (0.1%) and Brazil (0.8%)<sup>[63,70]</sup>.

Some case-control studies allowing a comparison of the HBsAg prevalence in the healthcare workers with that of the general population provided contrasting results. Rehman *et al*<sup>[66]</sup>, in a small case-control study performed in Pakistan, enrolled 95 healthcare workers and 91 volunteer blood donors as controls and observed higher rates of HBsAg (14% vs 5%) and anti-HBc (36% vs 28%) positivity in the control group. Instead, in a case-control study conducted in Turkey<sup>[64]</sup>, the rate of HBsAg positivity was similar in 702 healthcare workers and 5670 blood donors (3% vs 2.1%), and in the Philippines, Arguillas *et al*<sup>[56]</sup> found 6.5% of 123 healthcare workers and 2.2% of 382 blood donors to be

**Table 2** Prevalence of hepatitis C virus infection in healthcare workers

NR: Not reported; HCV: Hepatitis C virus.

HBsAg-positive. Finally, in the United States, Thomas *et al*<sup>[70]</sup> observed the same HBsAg-positivity rate (0.1%) in 943 healthcare workers and 104239 blood donors, whereas they found a higher rate of anti-HBc positivity in the healthcare workers, 6.2% vs 1.8%, indicating a greater exposure to HBV in these subjects, but exposure was not followed by a chronic infection, most probably because it occurred in adulthood.

## STUDIES ON HCV INFECTION IN HEALTHCARE WORKERS

The prevalence of anti-HCV positivity in healthcare workers<sup>[54-74]</sup> ranges from 0% to 9.7% in different studies worldwide: 9.7% in the Philippines, 8% in Egypt, 3.2%-5.6% in three studies in Pakistan, 5% in Georgia, 0.14% in Denmark, 0.8% in Poland, 0.7% in the United States, 0.6% in Albania and 0.3% in Turkey (Table 2).

The majority of 1386 healthcare workers investigated in Georgia in 2006<sup>[58]</sup> stated an episode of occupational exposure to HCV infection, including accidental needle-stick injuries in 45% of cases, cuts with contaminated instruments in 38% and blood splashes in 46%. For the healthcare workers who received a cut, this unfavorable event occurred during the reassembling of tools or when receiving tools from a colleague in the majority of the cases, and the highest proportion of needle-stick injuries occurred when recapping used needles, more frequently in nurses (39%) than in physicians (22%).

In a cross-sectional study performed on 1770 healthcare workers in Egypt in 2008<sup>[74]</sup>, the anti-HCV seroprevalence was 8.0%, the estimated incidence of HCV infection 7.3 per 1000 persons-year and the risk factors independently associated with HCV seropositivity were an older age, performing a manual job, having a history

of blood transfusion or a history of parenteral treatment for schistosomiasis.

Only five case-control studies compared the prevalence of HCV infection in healthcare workers and in the general population of the same country<sup>[56,64,66,70,72]</sup>. Four of these 5 studies showed similar prevalences of anti-HCV positivity in the two groups of subjects: 0.3% vs 0.4%, respectively, in a study from Turkey on 702 healthcare workers<sup>[64]</sup> and 5670 blood donors, 1.6% in 123 healthcare workers and 2.2% in 382 blood donors investigated in the Philippines<sup>[56]</sup>, 1.2% in 407 healthcare workers and 0.8% in pregnant women studied in Italy<sup>[72]</sup> and 0.7% in 943 healthcare workers and 0.4% in 104239 blood donors in the United States<sup>[70]</sup>. Unexpectedly, but similarly to what was observed for HBsAg by Rehman *et al*<sup>[66]</sup> in a study in Pakistan (see above), they observed that the 95 healthcare workers less frequently than the 91 blood donors were anti-HCV positive (4% vs 14%). The results of this study are of difficult interpretation.

## CONCLUSION

Mucosal-cutaneous and percutaneous exposure to human blood or bloodstained medical instruments occurs more frequently in healthcare workers than the general population. A major role in the transmission of HBV or HCV infection is played by the virus concentration on the infecting materials, high in blood and blood products, much lower in ascites and in cerebrospinal fluid and at non-infectious concentrations in feces, urine, sweat, vomit and tears.

The characteristics of the wound received by a healthcare worker and the volume of blood transferred are other main factors influencing a possible transmission of HBV or HCV infection. In fact, the devices

used to access the blood vessels directly, more frequently than cable needles used for intramuscular or subcutaneous treatments, are responsible for HBV and HCV transmission because of the higher amount of organic material carried on their surface.

The transmission of HBV infection from a source patient to a healthcare worker is also influenced by the natural or vaccine-induced immunological protection against HBV in the healthcare worker. Although HBV vaccination of anti-HBs-negative healthcare workers is highly recommended in all countries, some healthcare workers have eluded vaccination and some were low- or non-responders to the vaccine, indicating that a highly infectious HBV inoculum might overpower low immunological protection.

Since no anti-HCV vaccine is at present available to counteract HCV transmission, healthcare workers should protect themselves by meticulously applying all the universal prophylactic measures whenever potentially exposed.

## Abstract

**AIM:** To address the effect of heat-shock protein 90 (HSP90) inhibitors on the release of the hepatitis C virus (HCV), a cell culture-derived HCV (JFH1/HCVcc) from Huh-7 cells was examined.

**METHODS:** We quantified both the intracellular and extracellular (culture medium) levels of the components (RNA and core) of JFH-1/HCVcc. The intracellular HCV RNA and core levels were determined after the JFH1/HCVcc-infected Huh-7 cells were treated with radicicol for 36 h. The extracellular HCV RNA and core protein levels were determined from the medium of the last 24 h of radicicol treatment. To determine the possible role of the HSP90 inhibitor in HCV release, we examined the effect of a combined application of low doses of the HSP90 inhibitor radicicol and the RNA replication inhibitors cyclosporin A (CsA) or interferon. Finally, we statistically examined the combined effect of radicicol

and CsA using the combination index (CI) and graphical representation proposed by Chou and Talalay.

**RESULTS:** We found that the HSP90 inhibitors had greater inhibitory effects on the HCV RNA and core protein levels measured in the medium than inside the cells. This inhibitory effect was observed in the presence of a low level of a known RNA replication inhibitor (CsA or interferon- $\alpha$ ). Treating the cells with a combination of radicicol and cyclosporin A for 24 h resulted in significant synergy (CI < 1) that affected the release of both the viral RNA and the core protein.

**CONCLUSION:** In addition to having an inhibitory effect on RNA replication, HSP90 inhibitors may interfere with an HCV replication step that occurs after the synthesis of viral RNA, such as assembly and release.

**Key words:** Hepatitis C virus; Inhibition of hepatitis C virus release; Cell culture-derived hepatitis C virus; Heat-shock protein 90 inhibitors; Hepatitis C virus RNA replication

**Core tip:** Hepatitis C virus (HCV) is a major causative agent of hepatocellular carcinoma. Several non-structural proteins of HCV physically and functionally interact with heat-shock protein 90 (HSP90). Although HSP90 inhibitors, which inhibit the chaperone function of HSP90, have been shown to inhibit HCV replication by several groups, a recent report using a reporter system for HCV RNA replication (replicon) suggests that the effect is nonspecific. Thus, the inhibitory mechanism of HSP90 inhibitors remains controversial. Here, we address the effect of HSP90 inhibitors on the release of JFH1/cell culture-derived HCV from Huh-7 cells, and suggested that, HSP90 inhibitors may also interfere with an HCV replication step that occurs after the synthesis of viral RNA, such as assembly and release.

Hepatitis C virus inhibitor synergism suggests multistep interactions between heat-shock protein 90 and hepatitis C virus replication. *World J Hepatol* 2016; 8(5): 282-290 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i5/282.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i5.282>

## INTRODUCTION

Chronic infection with hepatitis C virus (HCV) frequently causes liver cirrhosis and hepatocellular carcinoma<sup>[1]</sup>. Approximately 170 million individuals have been infected by HCV<sup>[2]</sup> and are at risk for developing liver disease<sup>[3]</sup>. HCV has a positive-sense single-stranded RNA genome that encodes a 3000 amino acid polyprotein and also

contains an internal entry site for translation and a non-coding region for genome replication at the 5'- and 3'- flanking region. Translation of the polyprotein is followed by cleavage by the host and viral proteases, which yields three structural proteins (core, E1 and E2) and seven nonstructural (NS) proteins (p7, NS2, NS3, NS4A, NS4B, NS5A and NS5B)<sup>[4]</sup>. Establishment of the cell culture-derived HCV (HCVcc) system (*i.e.*, human hepatoma Huh-7 cells propagating the highly infectious clone of HCV genotype 2a, JFH-1<sup>[5]</sup>) provides a native infection-cycle system, which is suitable for determination of the precise function of HCV proteins and thus the mechanism for replication and secretion of viral particles. Accumulating evidence has indicated that NS3, NS4B and NS5A are required for not only genome RNA replication but also virus assembly<sup>[6]</sup>, whereas P7 and NS2 are dispensable for RNA replication but are required for virus production<sup>[7]</sup>.

Heat-shock protein 90 (HSP90) functions as a molecular chaperone for various client proteins and interacts with a cohort of co-chaperones that modulate the HSP90 ATPase cycle. The ATPase activity of HSP90 is inhibited by HSP90 inhibitors, which compete with ATP for binding and thereby eliminate HSP90 chaperone activity<sup>[8]</sup>. HSP90 clients include not only host proteins but also some virus proteins. Thus, some of the replication steps are required for HSP90 activity<sup>[9]</sup>. In fact, activities of multiple HCV proteins are affected by inhibition of HSP90 by specific inhibitors of HSP90, such as radicicol and geldanamycin and its derivatives. HSP90 inhibitors restrict the activity of NS2/3 protease<sup>[10]</sup>, the stability of NS3<sup>[11]</sup>, and the RNA replication of HCV in cells harboring the HCV replicon by inhibiting a complex consisting of HSP90, NS5A and a human FK506-binding protein (FKBP8)<sup>[12]</sup>. The host factors that are required for HCV replication are also affected by inhibition of HSP90<sup>[13,14]</sup>. Apart from these positive results, Beran *et al.*<sup>[15]</sup> have shown that an HSP90 inhibitor elicits effects similar to those of known cytostatic compounds, abrogating propagation of the mini-genome (subgenomic) replicon of HCV indirectly, through slowing cell growth. HCV subgenomic replicons are generally composed of a selection marker gene, such as G418 resistance, a reporter gene such as luciferase, and a whole HCV genome, except for the regions encoding the structural proteins and NS2 protease, which are deleted<sup>[16]</sup>. The replicons propagating in Huh-7 cells are widely used for studying RNA replication as well as for screening for anti-HCV drugs. However, it is possible that the replicon system does not fully represent the native function of HCV proteins, because mutations that accumulate in NS3 and NS5A in the replicon during enhancement of the RNA replication interfere with virus assembly when the mutation is introduced in the HCVcc construct<sup>[17]</sup>. Hence, the HCVcc system may be more suitable than the subgenomic replicon system to evaluate the anti-viral effect of HSP90 inhibitors. In addition, HSP90 is required for NS3 stability<sup>[11]</sup> and for formation of the complex composing NS4A<sup>[12]</sup>. Because NS3 and NS4A can act on both RNA

replication and HCV assembly, it is possible that HSP90 activity may contribute to post-RNA replication steps, such as virus assembly and release, which is represented by HCVcc but not the replicon system.

In this study, we used JFH1/HCVcc to demonstrate the effect of HSP90 inhibition on HCVcc release from infected Huh-7 cells. Our results showed that the HSP90 inhibitor radicicol preferentially reduced the levels of the core and the HCV RNA released from cells in the medium compared with those in the cells. The HSP90 inhibitor had a more potent effect on viral release in the medium than that of the inhibitor for RNA replication.

## MATERIALS AND METHODS

### Reagents

Radicicol (Sigma-Aldrich, St. Louis, MO, United States) was dissolved in methanol (1 mg/mL). Cyclosporin A [cyclosporin A (CsA); Wako Pure Chemical, Osaka, Japan], 17-AAG [17-(allylamino)-17-demethoxygeldanamycin, Sigma-Aldrich] and 17-DMAG [17-(dimethylaminoethylamino)-17-demethoxygeldanamycin; BIOMOL, Plymouth Meeting, PA, United States] were dissolved in ethanol (1 mg/mL). Interferon- $\alpha$  (IFN- $\alpha$ ; PeproTec EC, London, United Kingdom) was dissolved in water (0.1 mg/mL).

### Culture of human hepatoma Huh-7 cells and preparation of JFH1/HCVcc

Human hepatoma Huh-7 cells (purchased from Human Science Resources Bank, Osaka, Japan) were cultured in DMEM (Nissui Pharmaceuticals, Tokyo, Japan) supplemented with 10% fetal calf serum, 0.06% glutamine, 0.35% glucose and 1% penicillin-streptomycin (Life Technologies, Carlsbad, CA, United States). The cells were maintained at 37 °C in an atmosphere of 5% CO<sub>2</sub>. We synthesized the HCV genomic RNA of genotype 2a (JFH1) *in vitro* using a MEGAscript™ T7 kit (Ambion, Austin, TX, United States) and introduced the RNA into Huh-7 cells by electroporating the cells with the GenePulser II electroporation system (Bio-Rad, Hercules, CA, United States) as previously described<sup>[5]</sup>. The cytotoxic effects of the reagents were examined with Alamar Blue cell viability reagent (Serotec, Raleigh, NC, United States), which allows an estimation of the oxidation levels in the cellular electron-transport pathways with a fluorescent indicator. Alamar Blue was used as described by the manufacturer.

### Quantification of the HCV core protein and genomic RNA

We washed the JFH1/HCVcc cells with PBS and lysed them in lysis buffer (20 mmol/L Tris-Cl, pH 7.5, 0.1% SDS, 1% Triton X-100, 1% deoxycholate, 0.1 mmol/L EDTA, 0.1 mmol/L phenylmethanesulfonyl fluoride, 50  $\mu$ mol/L N-*p*-tosyl-L-phenylalanine chloromethyl ketone, 5  $\mu$ mol/L N- $\alpha$ -tosyl-L-lysine chloromethyl ketone hydrochloride, 5  $\mu$ g/mL aprotinin and 5  $\mu$ g/mL leupeptin). We quantified the level of core protein present in

the lysates and spent culture medium using the Ortho HCV antigen ELISA test (Ortho Clinical Diagnostics, Rochester, NY, United States). We used a QIAamp™ Viral RNA Mini kit (Qiagen, Hilden, Germany) to isolate the HCV genomic RNA from the medium. We used an RNeasy™ mini kit (Qiagen) to isolate total RNA from the HCV-infected cells. We quantified the HCV genomic RNA using TaqMan™ EZ RT-PCR Core Reagents (Applied Biosystems, Foster City, CA, United States) and the iCycler™ iQ real-time detection system (Bio-Rad) as previously described<sup>[18]</sup>.

### Effects of radicicol and CsA

The JFH1/HCVcc cells ( $5 \times 10^4$  cells in one well of a 24-well culture dish) were treated with radicicol, CsA and/or IFN- $\alpha$  for 12 h, at which point the medium was replaced by fresh medium that contained the same level(s) of drug(s). After culturing for another 24 h, the core and the HCV RNA in each cell lysate and culture medium were quantified as described above. The synergism between CsA and radicicol was evaluated by the combination index (CI) equation and the Chou and Talalay method<sup>[19,20]</sup> using CalcuSyn software (BIOSOFT, Cambridge, United Kingdom). The CI equation is based on the multiple drug-effect equation of Chou *et al.*<sup>[20]</sup>, which is derived from enzyme-kinetic models. Assuming that CsA and radicicol were mutually non-exclusive drugs that have totally independent modes of action, we used the following equation:

Equation 1 dictates that the combination of drug 1 (D)<sub>1</sub> and drug 2 (D)<sub>2</sub> inhibits a reaction (or phenomenon) by x% in an actual experiment. (D<sub>x</sub>)<sub>1</sub> and (D<sub>x</sub>)<sub>2</sub> are the doses of drug 1 and drug 2 alone that inhibit the same reaction by x%.

$$CI = [(D)_1 / (D_x)_1] + [(D)_2 / (D_x)_2] + \frac{[(D)_1 (D)_2 / (D_x)_1 (D_x)_2]}{[(D)_1 (D)_2 / (D_x)_1 (D_x)_2]} \quad (1)$$

### Statistical analysis

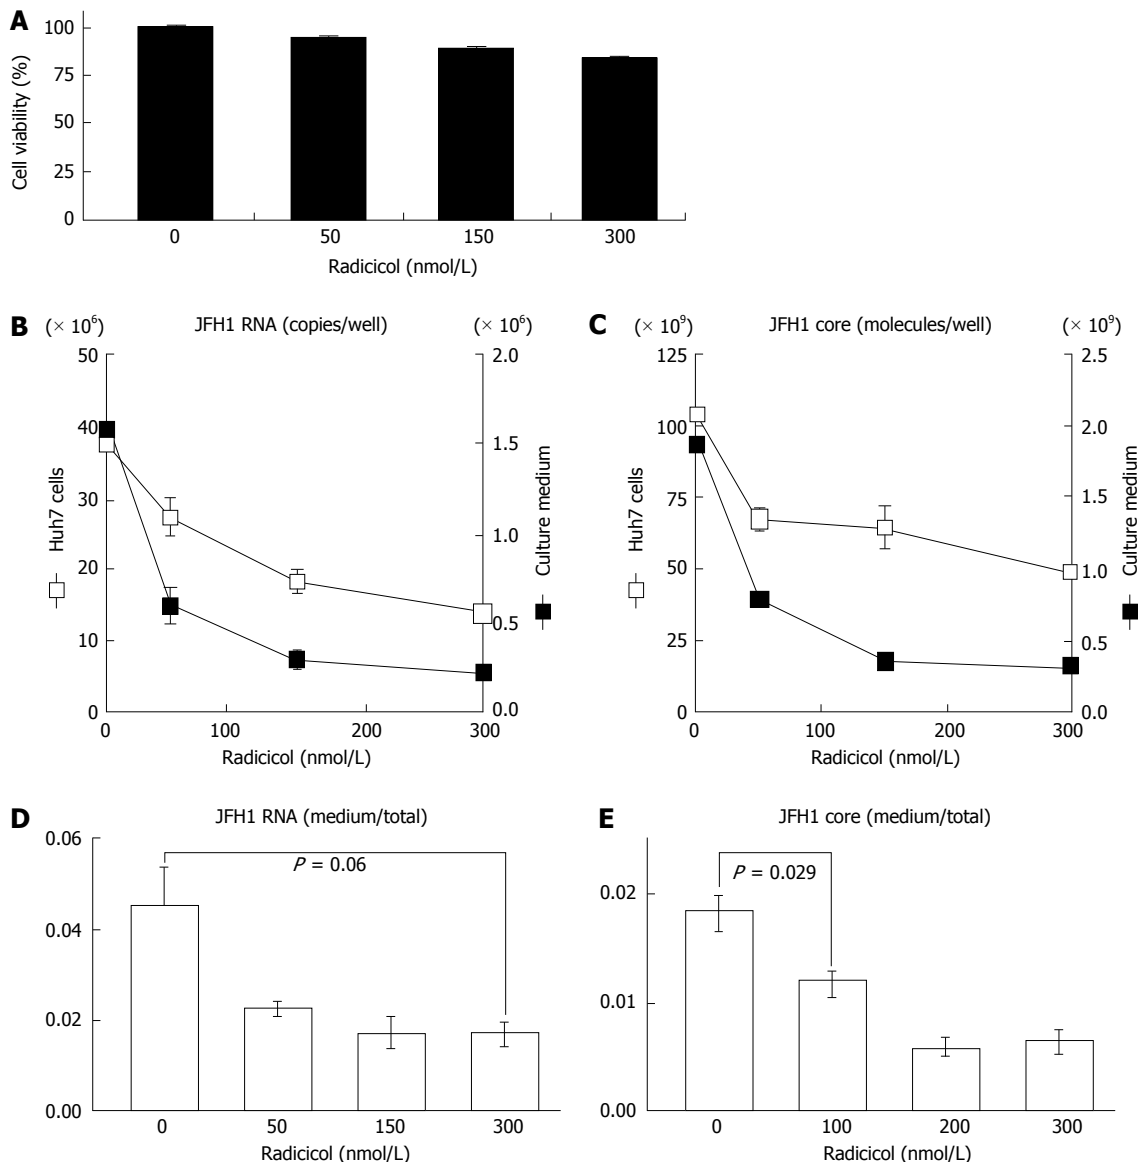

We used Student's *t*-test to examine statistical significance ( $P < 0.05$ ). All of the experiments were performed with multiple independent replicates, and all of the data are presented as the mean results of three independent experiments with the standard error of the mean. The statistical methods of this study were reviewed by professor Kotaro Tanahashi from Mathematics, Tohoku Pharmaceutical University.

## RESULTS

### HCV released into the medium is preferentially reduced by HSP90 inhibitors

To examine the effects of HSP90 inhibitor on the release of HCV, we quantified both the intracellular and extracellular (culture medium) levels of the components (RNA and core) of JFH-1/HCVcc. The intracellular HCV RNA and core levels were determined after the cells were treated with radicicol for 36 h. The extracellular HCV RNA and the core were determined from the medium of the

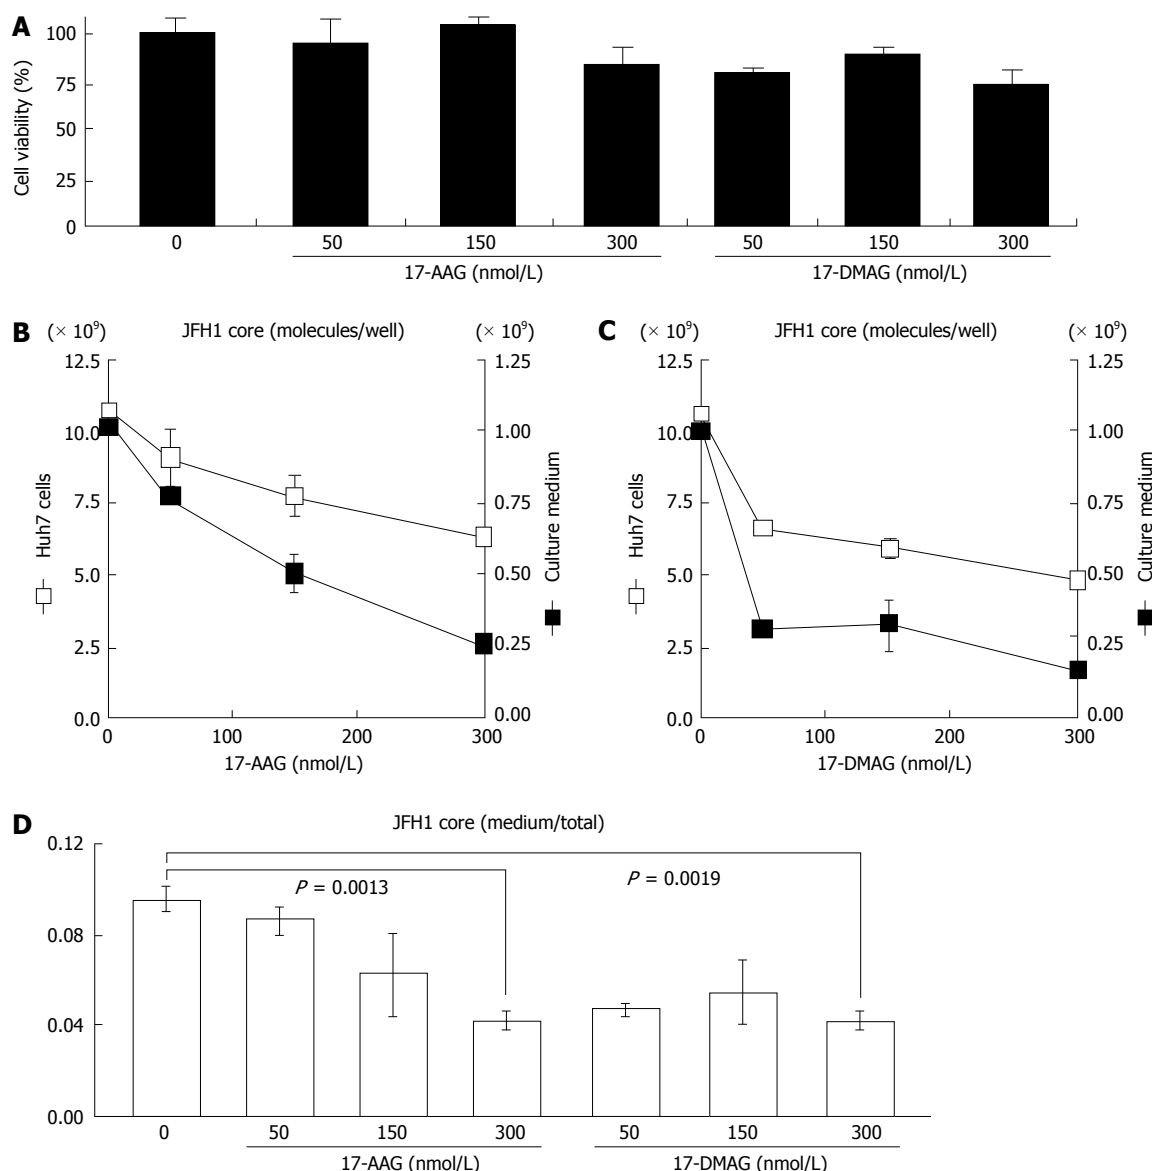

**Figure 1** Radicicol affects the relative level of hepatitis C virus (core and hepatitis C virus RNA) produced from the JFH1/cell culture-derived hepatitis C virus system of Huh-7 cells. A: After the cells were treated with radicicol (at final concentration of 0, 50, 150 and 300 nmol/L) for 12 h, the culture medium was replaced with fresh medium containing the same radicicol levels, and the HCV RNA and core levels released into the medium for the next 24 h and produced within cells were determined as described in the text. The cytotoxic effects of the treatment of radicicol on HCVcc Huh-7 cells were examined as described in the text; B and C: The levels of HCV RNA (B) and core (C) in the HCVcc Huh-7 cells (open squares) and the culture medium (filled squares) were quantified. The scales on the left sides (B and C) indicate the scales for the HCV RNA and the core in the Huh-7 cells. The scales on the right sides (B and C) indicate the scales for the HCV RNA and the core in the culture medium; D: The ratios of HCV RNA in the medium to the total HCV RNA (the sum of HCV RNA in the medium and in the cells) are shown; E: The ratios of the core in the medium to the total core (the sum of the core in the medium and in the cells) are shown. The data represent the mean values ( $\pm$  SEM) of the results from three independent experiments. HCV: Hepatitis C virus; HCVcc: Cell culture-derived HCV.

last 24 h of radicicol treatment. The radicicol treatment (50–300 nmol/L) exhibited no apparent cytotoxic effect (Figure 1A), reduced both the intracellular and extra-cellular (medium) levels of the HCV RNA (Figure 1B) and the core (Figure 1C) in a dose-dependent manner. Interestingly, the RNA level in the culture medium relative to the total RNA level was apparently reduced by radicicol even at a low concentration (50 nmol/L) (Figure 1D). Similarly, the core level in the medium relative to the total core level was also significantly decreased ( $P = 0.029$ ) in the presence of 50 nmol/L radicicol (Figure 1E). Furthermore, two derivatives of the geldanamycin HSP90 inhibitor, 17-AAG and 17-DMAG, also inhibited the

release of the HCV RNA and core more effectively than they decreased the intracellular HCV RNA and core levels (Figure 2).

We next examined whether the integrity of HCV was affected by the radicicol treatment during production of HCV from JFH1/HCVcc. The infectivity of the HCV that had been released into the medium in the presence of radicicol was compared to the infectivity of HCV released in the absence of radicicol. As shown in Figure 3, there was no significant difference ( $P > 0.3$ ) in the infectivity between the HCV produced in the presence and that produced in the absence of radicicol. These results suggested that even though radicicol preferentially reduced

**Figure 2** Effects of the geldanamycin derivatives 17-allylamino-17-demethoxygeldanamycin and 17-dimethylaminoethylamino-17-demethoxygeldanamycin on the release of JFH1. A: The cytotoxic effects of 17-AAG and 17-DMAG on Huh-7 cells carrying JFH1/HCVcc were examined as described in the text; B and C: JFH1-infected Huh-7 cells were treated with 17-AAG (B) or 17-DMAG (C) for 24 h and then the protein samples were isolated and quantified. The levels of the HCV core present in the JFH1-infected Huh-7 cells (open squares) and the culture medium (filled squares) were examined as described in the text. The scales on the left (B and C) and right sides (B and C) indicate the scales for the HCV core in the Huh-7 cells and in the culture medium, respectively; D: The ratios of the core in the medium to the total core are shown. The concentrations of 17-AAG and 17-DMAG (0-300 nmol/L) are shown under the histograms. The data represent the mean values ( $\pm$  SEM) of the results from three independent experiments. HCV release, radicicol did not affect its infectivity.

#### **Radicicol preferentially suppressed the HCV RNA release in the presence of CsA or interferon**

NS3 and NS5A, which are known targets of HSP90<sup>[11,12]</sup>, are required for both RNA replication and virus assembly<sup>[6,21]</sup>. Thus, it is difficult to distinguish whether the inhibitory step of the HSP90 inhibitor affects the RNA replication or the assembly. If the HSP90 inhibitor were to preferentially inhibit the post-RNA replication steps, the HSP90 inhibitor might enhance the RNA-replication inhibitor-dependent inhibitory effect on HCV release. CsA an immunosuppressant, inhibits interaction between a

CsA's target cyclophilin A and NS5A and the interaction of the cyclophilin A with the NS5B polymerase/RNA complex, thereby inhibiting RNA replication<sup>[22]</sup>. This inhibitory effect is distinct from CsA's immunosuppressive activity<sup>[23]</sup>. To determine the possible role of the HSP90 inhibitor on HCV release, we examined the effect of a combined application of low doses of radicicol and CsA. By studying the dose-dependent inhibition of HCV RNA production in Huh-7 cells (data not shown), we determined the doses showing the partial effect of CsA (250 nmol/L) and radicicol (50 nmol/L) on the viral RNA production in cells after 36 h of treatment (Figure 4A, column 1, 2 and 3, open bars). CsA alone, radicicol

**Figure 3 Infectivity of hepatitis C virus produced from Huh-7 cells that were treated with radicicol.** A: Experimental design. To examine whether the infectivity of the JFH1/HCVcc released from the Huh-7 cells in the presence of radicicol was altered, we infected fresh Huh-7 cells with JFH1/HCVcc prepared in the presence of radicicol. To prepare a viral stock, the JFH1/HCVcc infected Huh-7 cells with 50 nmol/L radicicol were maintained for an additional 36 h. HCVcc released in the medium during the last 24 h was collected and used as the viral stock. We diluted the viral stock 59.7 times (None) and 28.6 times (Radicicol) to reduce the effects of radicicol carryover and to adjust the HCV levels (core protein level: 200 fmols). The final radicicol concentration was 1.75 nmol/L which did not affect HCV propagation. The HCV samples were added to fresh Huh-7 cells and cultured for 24, 48 and 72 h. The HCV RNA in the infected Huh-7 cells was quantified as described in the text. The multiplicities of infection for HCV were 0.2 copies/cell and 0.16 copies/cell for the HCV infection without and with radicicol, respectively; B: The copies of HCV RNA in the Huh-7 cells of each well after infection (24, 48 and 72 h) were determined as described in the text. The value of the RNA copy number in the Huh-7 cells [which were infected with the viral stock from radicicol-treated cells (values of the closed bars)] was adjusted by multiplying by a factor of 1.25. The data represent the mean values ( $\pm$  SE) of the results from three independent experiments. HCV: Hepatitis C virus; HCVcc: Cell culture-derived HCV.

**Figure 4 Radicicol and cyclosporin A have a synergistic effect on hepatitis C virus release into the medium.** A: JFH1/HCVcc-infected Huh-7 cells were treated with 250 nmol/L CsA alone, 50 nmol/L radicicol alone, or both for 36 h. The total RNA was prepared from the Huh-7 cells, and the HCV RNA was quantified by reverse transcription-polymerase chain reaction (open columns, the scale on the left of the panel indicates the copies/well). The medium was replaced by the fresh medium containing the same levels of the drugs after 12 h, and total RNA was prepared from the medium 24 h later. The copy numbers of the HCV RNA in the medium are indicated by the filled columns (scale on the right of the panel); B: The cytotoxic effects of the drugs used in (A) on the Huh-7 cells carrying JFH1/HCVcc; C: The ratios of the RNA in the medium to the total RNA (as described above) are shown. HCV: Hepatitis C virus; HCVcc: Cell culture-derived HCV; CsA: Cyclosporin A.

alone and simultaneous treatment with both drugs did not affect the cytotoxicity in JFH1-infected Huh-7 cells (Figure 4B). When the HCV-infected cells were treated

with the low concentration of both drugs simultaneously, the level of HCV RNA released in the medium after 24 h fell significantly (Figure 4A, comparison of the closed

**Figure 5 Radicicol and interferon- $\alpha$  have a synergistic effect on hepatitis C virus release into the medium.** A: JFH1/HCVcc-infected Huh-7 cells were treated with 12.5 U INF- $\alpha$  alone, 50 nmol/L radicicol alone, or both for 36 h. The total RNA was prepared from the Huh-7 cells, and the HCV RNA was quantified by reverse transcription-polymerase chain reaction (open columns, the scale on the left of the panel indicates the copies/well). The medium was replaced by fresh medium after 12 h, and the total RNA was prepared from the medium 24 h later. The copy numbers of the HCV RNA in the medium are indicated by the filled columns (scale on the right of the panel); B: The cytotoxic effects of the drugs used in (A) on the Huh-7 cells carrying JFH1/HCVcc; C: The ratios of RNA in the medium to RNA in the total RNA (as described above) are shown. HCV: Hepatitis C virus; HCVcc: Cell culture-derived HCV; INF- $\alpha$ : Interferon- $\alpha$ .

bars in columns 3 and 4,  $P = 0.0015$ ), whereas the level of HCV RNA in the cells was the same as that in the cells treated with CsA alone (Figure 4A, comparison of the open bars in columns 3 and 4). Intriguingly, the RNA level in the culture medium relative to the RNA levels in the infected cells fell in the presence of radicicol (Figure 4C, comparison of columns 1 and 2). However, this medium-to-total ratio was not affected by simultaneous treatment of CsA with radicicol (Figure 4C, column 2 and 4). Thus, radicicol could have more of an inhibitory effect on viral release from infected cells than CsA.

Previous results have indicated that the combined effect of IFN and CsA on RNA replication is mostly additive<sup>[23]</sup> and have suggested that both CsA and IFN target a similar point in HCV replication. However, Robida *et al.*<sup>[24]</sup> have indicated that CsA resistant mutants maintain their sensitivity to IFN- $\alpha$ . Thus, although both IFN- $\alpha$  and CsA inhibit RNA replication, the inhibitory effects of IFN- $\alpha$  and CsA seems to be different. As shown in Figure 5A, we observed that radicicol efficiently reduced the level of HCV in the medium even in the presence of IFN- $\alpha$ . Although the combined treatment of radicicol and IFN- $\alpha$  and the treatment of IFN- $\alpha$  alone exhibited a similar level of HCV RNA in cells (columns 3 and 4, open bars), HCV RNA in the medium was significantly reduced (columns 3 and 4, closed bars). Again, HCV RNA in the medium was significantly suppressed in the presence of radicicol (Figure 5C). All of these results suggested that HSP90 might be responsible for a post-replication step such as viral release. It should be noted that a similar synergism has been previously reported: A combined administration of an HSP90 inhibitor and polyethylene glycol-conjugated interferon (PEG-IFN) in HCV-infected chimeric mice with humanized livers was more effective at reducing the HCV genomic RNA levels in mouse serum than a single PEG-IFN treatment<sup>[25]</sup>.

#### Analysis of the synergistic effect between radicicol and CsA

Our results suggested that radicicol has a greater inhibitory effect on the release of HCVcc into the medium and that the point of inhibition of HCV production by the HSP90 inhibitor may be different from that of CsA. Thus, we statistically examined the combined effect of radicicol and CsA using the CI and the graphical representation proposed by Chou *et al.*<sup>[19,20]</sup>. We examined the effects of various CsA (125, 250, 750 and 1500 nmol/L) and radicicol (25, 50, 150 and 300 nmol/L) concentrations on the release of the core into the medium after 24 h (data not shown). Next, we examined the effects of a fixed molar ratio of these drugs (5:1 CsA to radicicol). The results (Figure 6A) indicated that CsA and radicicol had a synergistic effect ( $CI < 1$ ) above a fractional effect of 0.5 and close to a strong synergism ( $CI \leq 0.3$ ) at a fractional effect of 1. The combined effect was additive near a fractional effect of 0.5 and antagonistic at a fractional effect less than 0.4. Figure 6B shows the conservation isobologram ( $CI = 1$ ) for the different effective doses of the combination treatment that yielded 50% ( $ED_{50}$ ), 75% ( $ED_{75}$ ) and 90% ( $ED_{90}$ ) inhibition of the core release (constructed using actual experimental data). The combined effect at  $ED_{50}$  ( $CI = 1.05$ ) was additive, whereas the combined effects at  $ED_{75}$  ( $CI = 0.75$ ) and  $ED_{90}$  ( $CI = 0.57$ ) were synergistic (Figure 6). The combined use of 408 nmol/L CsA and 82 nmol/L radicicol yielded  $ED_{90}$  (Figure 6B; if a  $CI = 1$  was expected, an estimated 605 nmol/L CsA and 121 nmol/L radicicol would be required to yield  $ED_{90}$ ). We obtained similar results for the 3:1 and 10:1 molar ratios of CsA

**Figure 6 Analysis of the synergistic effect of cyclosporin A and radicicol.** A: The graphs were constructed using the Chou and Talalay method. The CI and the fractional effect were derived from the release of the HCV core protein into the culture medium of JFH1-infected Huh-7 cells that were treated with a combination of CsA and radicicol (5:1 molar ratio). The open circles indicate actual experimental data. The CI vs fractional effect plots were generated with CalcSyn software. The dotted line and solid lines represent the mean values and standard deviation (1.96), respectively, of three independent experiments. The CI < 1, CI = 1, and CI > 1 indicate synergy, an additive effect and antagonism, respectively; B: The conservation isobologram (CI = 1) depicting different effective doses that yielded 50% (ED<sub>50</sub>), 75% (ED<sub>75</sub>) and 90% (ED<sub>90</sub>) inhibition of viral release by the combination treatment was graphed with actual experimental data (ED<sub>50</sub>, open triangles; ED<sub>75</sub>, open squares; ED<sub>90</sub>, open circles). The data represent the mean values of the results from three independent experiments; C: The CI values of each ED<sub>50</sub>, ED<sub>75</sub> and ED<sub>90</sub> by the combined CsA and radicicol treatment at molar ratios of 3:1, 5:1 and 10:1, respectively; D: The combined effect of CsA and radicicol at a molar ratio of 10:1. The HCV core levels in the medium are shown. The mean values and standard deviation ( $\pm$  SD) of the amounts of the HCV core released into the medium during three independent experiments are shown. The concentrations used in each set of experiments are shown under the histogram. ND: Not detected; CsA: Cyclosporin A; HCV: Hepatitis C virus; CI: Combination index.

to radicicol (Figure 6C). One example, shown in Figure 6D, indicated that treating the cells with both 1000 nmol/L CsA and 100 nmol/L radicicol for 36 h caused the HCV core to be undetectable in the medium for the last 24 h of the combined treatment.

## DISCUSSION

Collectively, our results suggest that HSP90 inhibitors might affect both the RNA replication and the post-RNA replication stage of viral propagation. Previous reports have indicated that HSP90 is required for NS3 stability<sup>[11]</sup> and for the formation of a complex consisting of NS5A and FKBP8<sup>[12]</sup>. Thus, it is possible that HSP90 may affect the post RNA-replication step, such as assembly, through affecting the activity of NS3 and NS5A. Elucidating the precise mechanism for the HSP90 on HCV assembly may provide an alternative drug target for HCV clearance.

## COMMENTS

### Background

Although heat-shock protein 90 (HSP90) inhibitors, which inhibit the chaperone function of HSP90, have been shown to inhibit hepatitis C virus (HCV) repli-

cation by several groups, a recent report using a reporter system for HCV RNA replication (replicon) suggests that the effect is nonspecific. Thus, the inhibitory mechanism of HSP90 inhibitors remains controversial.

### Research frontiers

The authors found that the HSP90 inhibitors had greater inhibitory effects on the HCV RNA and core protein levels measured in the medium than inside the cells. This inhibitory effect was observed in the presence of a low level of a known RNA replication inhibitor [cyclosporin A (CsA) or interferon- $\alpha$ ].

### Innovations and breakthroughs

The authors' results suggested that, HSP90 inhibitors may also interfere with an HCV replication step that occurs after the synthesis of viral RNA, such as assembly and release.

### Applications

This study would benefit the effort to explore new targets for the treatment of HCV infection.

### Terminology

HSP90 inhibitors inhibit the chaperone function of HSP90. HSP90 clients include not only host proteins but also multiple HCV proteins including NS2/3 protease, NS3 and the RNA replication complex consisting of NS5A.

### Peer-review

The authors suggested that HSP90 inhibitors may interfere with an HCV replication step that occurs after the synthesis of viral RNA such as assembly

and release. The results of this study were quite interesting. The data were appropriately presented and interpreted. This manuscript also was well prepared.

### Abstract

**AIM:** To determine the significance of cholesteryl ester transfer protein (CETP) in lipoprotein abnormalities in chronic hepatitis C virus (HCV) infection.

**METHODS:** We evaluated the significance of the serum concentration of CETP in 110 Japanese patients with chronic HCV infection. Fifty-five patients had active HCV infection, and HCV eradication had been achieved in 55. The role of CETP in serum lipoprotein abnormalities, specifically, in triglyceride (TG) concentrations in the four major classes of lipoproteins, was investigated using Pearson correlations in conjunction with multiple regression analysis and compared them between those with active HCV infection and those in whom eradication had been achieved.

**RESULTS:** The serum CETP levels of patients with active HCV infection were significantly higher than those of patients in whom HCV eradication was achieved (mean  $\pm$  SD,  $2.84 \pm 0.69$   $\mu$ g/mL vs  $2.40 \pm 1.00$   $\mu$ g/mL,  $P = 0.008$ ). In multiple regression analysis, HCV infection status (active or eradicated) was an independent factor significantly associated with the serum CETP level. TG concentrations in low-density lipoprotein (mean  $\pm$  SD,  $36.25 \pm 15.28$   $\mu$ g/mL vs  $28.14 \pm 9.94$   $\mu$ g/mL,  $P = 0.001$ ) and high-density lipoprotein (HDL) (mean  $\pm$  SD,  $25.9 \pm 7.34$   $\mu$ g/mL vs  $17.17 \pm 4.82$   $\mu$ g/mL,  $P < 0.001$ ) were significantly higher in patients

with active HCV infection than in those in whom HCV eradication was achieved. The CETP level was strongly correlated with HDL-TG in patients with active HCV infection ( $R = 0.557$ ,  $P < 0.001$ ), whereas CETP was not correlated with HDL-TG in patients in whom HCV eradication was achieved ( $R = -0.079$ ,  $P = 0.56$ ).

**CONCLUSION:** Our results indicate that CETP plays a role in abnormalities of lipoprotein metabolism in patients with chronic HCV infection.

**Key words:** Hepatitis C virus; Cholesteryl ester transfer protein; High-density lipoprotein triglyceride; Case control study; Lipoprotein metabolism

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Cholesteryl ester transfer protein (CETP) mediates the transfer of neutral lipids between lipoproteins. Although lipoprotein metabolism abnormalities have been extensively studied, the role of CETP in abnormal lipoprotein profiles in patients with hepatitis C virus (HCV) infection is unknown. Accordingly, we investigated, for the first time, high serum CETP level in patients with active HCV infection. HCV infection was a determinant of the serum CETP level in multiple regression analysis. A high CETP concentration in HCV infection was strongly correlated with excessive triglyceride accumulation in high-density lipoprotein. Thus, CETP may contribute to abnormal lipoprotein metabolism in HCV infection.

High level of serum cholesteryl ester transfer protein in active hepatitis C virus infection. *World J Hepatol* 2016; 8(5): 291-300 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i5/291.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i5.291>

## INTRODUCTION

Chronic hepatitis C virus (HCV) infection is one of the most important etiologies of chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma worldwide<sup>[1-3]</sup>. HCV is a unique virus; its use of host lipid metabolism results in a persistent infection. Therefore, it is very important to understand how HCV uses host lipid metabolism and how host lipid metabolism is affected by HCV infection, because HCV infection represents a unique model in which the virus causes chronic infection while coexisting with the host, simultaneously taking over the host's metabolism<sup>[4]</sup>.

Infectious HCV forms a lipoviral particle that can enter into hepatocytes in the blood<sup>[5]</sup>. The characteristics of HCV lipoviral particles are similar to those of very-low-density lipoproteins (VLDLs)<sup>[6]</sup>. This suggests a close association between HCV infection and VLDL. Both VLDL and HCV lipoviral particles are synthesized,

assembled, and secreted from hepatocytes *via* similar metabolic pathways<sup>[7]</sup>. Consequently, dysregulated lipid metabolism in chronic HCV infection may primarily be caused by VLDL abnormalities. According to some *in vitro* studies, HCV core protein suppressed VLDL production and secretion from the liver by inhibiting microsomal triglyceride (TG) transfer protein<sup>[8,9]</sup>.

In clinical situations, chronic HCV infection alters serum lipid profiles by decreasing the low-density lipoprotein cholesterol (LDL-C) level<sup>[10]</sup> and the VLDL-TG/non-VLDL-TG ratio<sup>[11]</sup>. However, the abnormalities of lipoproteins as a whole in patients with chronic HCV infection have not been clarified. In particular, the abnormal distribution of TGs among lipoprotein subclasses has not been extensively studied, because TG content in each lipoprotein subclass cannot be measured easily by routine laboratory tests.

Cholesterol ester transfer protein (CETP) is a plasma glycoprotein that facilitates the transfer of cholesteryl ester (CE) from high-density lipoprotein (HDL) to other subclasses of lipoprotein [chylomicrons (CM), VLDL, and LDL]<sup>[12]</sup>. The principal effect of CETP on lipoproteins is considered to be the reduction of HDL-C levels and facilitation of reverse cholesterol transport to the liver<sup>[13]</sup>. Accordingly, CETP adjusts the distribution of TG among the different lipoprotein subclasses. Therefore, we speculated that CETP may play an important role in the abnormalities of lipoprotein metabolism in patients with active HCV infection.

In this study, we determined the serum concentration of CETP in patients with HCV infection and in those in whom HCV was eradicated, to determine the significance of CETP in HCV infection. Furthermore, we investigated the influence of CETP on lipoprotein abnormalities in HCV infection, with particular attention to TG concentrations.

## MATERIALS AND METHODS

The protocol of this case control study was in accordance with the 2004 standards of the Declaration of Helsinki and current ethical guidelines, and was approved by the human ethics review committee of the Jikei University School of Medicine. Written informed consent was obtained from all patients who enrolled in this study.

### Patient population

Japanese patients with active chronic HCV infection (active HCV group) or successfully eradicated chronic HCV infection [negative serum HCV-RNA 6 mo after the end of interferon (IFN)-based therapy] (eradication group) who had been followed up at Jikei University Katsushika Medical Center between September 2013 and October 2014 were randomly considered for enrollment. Patients receiving treatment for diabetes (DM) or hyperlipidemia or hormone replacement therapy and those with hepatitis B virus or human immunodeficiency virus infection were excluded. Additionally, patients who had received IFN within 6 mo or who

**Figure 1** Comparison of the serum cholesteryl ester transfer protein level between the active hepatitis C virus infection group and the hepatitis C virus eradication group. The serum CETP level was significantly higher in patients with active HCV infection than those in whom HCV eradication was achieved ( $2.84 \pm 1.00$  µg/mL vs  $2.40 \pm 0.70$  µg/mL,  $P = 0.008$ ). CETP: Cholesterol ester transfer protein; HCV: Hepatitis C virus.

had been diagnosed with hepatocellular carcinoma or decompensated cirrhosis were excluded.

#### Laboratory tests and demographic data

Demographic data, including age, sex, and body mass index (BMI), and basic laboratory data were obtained from the medical records. The collected basic laboratory data included aspartate 2-oxoglutarate aminotransferase (AST), alanine 2-oxoglutarate aminotransferase (ALT), gamma-glutamyl transpeptidase ( $\gamma$ -GTP), albumin, total bilirubin, fasting blood glucose (FBG), and hemoglobin A1c (HbA1c) levels, hemoglobin (Hb) levels and the platelet count. In addition, basic serum lipid data, including total cholesterol, TG, HDL-cholesterol (HDL-C), and LDL-C were collected. HDL-C had been directly measured by a commercial kit (Kyowa Medex, Tokyo, Japan), and the LDL-C level had been calculated by the Friedewald equation.

#### CETP measurement

The CETP concentration was measured in sera collected after at least a 10-h overnight fast. The CETP mass concentration was measured using a sandwich enzyme-linked immunosorbent assay with two monoclonal antibodies specific to human CETP, JHC1, and JHC2, as previously described<sup>[14]</sup>. The assay was performed in duplicate, and the mean was adopted as the measured value<sup>[15]</sup>.

#### Measurement of cholesterol and TG concentration in the major classes of serum lipoproteins

To examine the distribution of cholesterol and TG in lipoprotein fractions, fresh sera from the collected patient samples were fractionated by high-performance liquid chromatography, and the cholesterol and TG

concentration in the major four lipoprotein classes was measured using the online detection system (Skylight Biotech, Inc., Akita, Japan)<sup>[16,17]</sup>. Serum lipoproteins were classified into four classes according to particle size: CM ( $> 80$  nm), VLDL (30–80 nm), LDL (16–30 nm), and HDL ( $< 16$  nm).

#### Biostatistics

A statistical review of the study was performed by a biomedical statistician.

#### Statistical analysis

Continuous data are expressed as mean  $\pm$  SD. Categorical data are expressed as numbers (%). We used Welch's *t* test or the  $\chi^2$  test for comparisons between the two groups. Correlations between two parameters were evaluated by the Pearson product-moment correlation coefficient. To determine the significance of HCV infection on the serum CETP level, multiple regression analysis was performed, with demographic and basic laboratory data including the HCV infection status (active infection or HCV eradication) as independent variables. The most suitable regression model for explanation of the serum CETP level was constructed by backward elimination of candidate variables.

We performed statistical analyses using STATISTICA software, version 6 (StatSoft Japan Inc. Tokyo, Japan), and two-tailed *P* values of  $\leq 0.05$  were considered significant; *P* values  $> 0.05$  but  $\leq 0.1$  were considered to indicate marginal significance. *P* values less than 0.001 are expressed as  $P < 0.001$ . We determined the multicollinearity of the multiple regression analysis to verify the reliability; the variance inflation factor was  $< 5$ , indicating that our models were reliable.

## RESULTS

#### Study population

In total, 110 patients were included in the study. Fifty-five had active HCV infection, and HCV eradication with IFN-based anti-viral therapy had been achieved in the remaining 55 patients. In the active HCV group, 48 (87%) had HCV genotype (G) 1b infection and 7 (13%) had HCV G2 infection. In the eradication group, 34 (62%) were previously infected with HCV G1b and 21 (38%) were previously infected with HCV G2.

#### Increase in the CETP level in active chronic HCV infection

The serum CETP level was significantly higher in the active HCV group than in the eradication group ( $2.84 \pm 1.00$  µg/mL vs  $2.40 \pm 0.70$  µg/mL,  $P = 0.008$ , Figure 1).

#### Characteristics of the active HCV group and the eradication group

The clinical features of patients in the active HCV group and those in the HCV eradication group are summarized in Table 1. There were significant differences in the proportion of patients with HCV G1b infection. There

**Table 1 Clinical features of patients with active hepatitis C virus infection (active hepatitis C virus group) and of those in whom hepatitis C virus infection was eradicated (eradication group) *n* (%)**

Discrete traits	Active HCV group ( <i>n</i> = 55)	Eradication group ( <i>n</i> = 55)	<i>P</i> value
Sex			0.254
Male	22 (40)	28 (51)	
Female	33 (60)	27 (49)	
HCV genotype			0.003
1b	48 (87)	36 (65)	
2	7 (13)	19 (35)	
Quantitative traits	Mean ± SD	Mean ± SD	
Age (yr)	66.9 ± 11.2	64.3 ± 12.1	0.200
BMI (kg/m <sup>2</sup> )	22.5 ± 3.2	22.8 ± 3.4	0.631
AST (IU/L)	53.1 ± 27.5	24.0 ± 7.2	< 0.001
ALT (IU/L)	49.9 ± 37.1	20.0 ± 11.7	< 0.001
Total bilirubin (mg/dL)	0.8 ± 0.3	0.7 ± 0.3	0.242
γ-GTP (IU/L)	50.4 ± 64	27.1 ± 20	0.011
Albumin (g/dL)	3.9 ± 0.4	4.4 ± 0.3	< 0.001
Hb (g/dL)	13.4 ± 1.7	14.2 ± 1.5	0.010
Platelet (10 <sup>4</sup> /μL)	15.0 ± 6.3	20.0 ± 17.8	0.050
FBG (mg/dL)	108 ± 32	107 ± 16	0.740
HbA1c (%)	5.4 ± 0.6	6.1 ± 0.5	0.030
Lipid profiles			
Total cholesterol (mg/dL)	173.6 ± 31	200.5 ± 37.8	< 0.001
Triglyceride (mg/dL)	107.5 ± 52.0	103 ± 53.1	0.712
LDL cholesterol (mg/dL)	92.1 ± 25.7	117 ± 29.9	< 0.001
HDL cholesterol (mg/dL)	59.9 ± 17.4	64.9 ± 19.0	0.159
CETP level (μg/mL)	2.84 ± 1.00	2.40 ± 0.69	0.008

There were significant differences in the proportion of patients with HCV G1b infection. There were no significant differences in BMI, FBG levels, and HbA1c levels, whereas AST, ALT, and albumin levels differed significantly. TC and LDL-C levels were significantly lower in the active infection group than in the eradication group, whereas TG and HDL-C levels were similar in the two groups. HCV: Hepatitis C virus; BMI: Body mass index; AST: Aspartate-2-oxoglutarate aminotransferase; ALT: Alanine-2-oxoglutarate aminotransferase; γ-GTP: Gamma-glutamyl transpeptidase; Hb: Hemoglobin; FBG: Fasting blood glucose; HbA1c: Glycosylated hemoglobin; LDL: Low-density lipoprotein; HDL: High-density lipoprotein; CETP: Cholesterol ester transfer protein; LDL-C: Low-density lipoprotein cholesterol.

**Table 2 Influence of the hepatitis C virus infection status on the serum cholesterol ester transfer protein level as analyzed by multiple regression analysis**

	B	SE	<i>P</i> value
Constant	0.770	0.541	0.157
HCV infection	0.415	0.158	0.010
Age	0.014	0.006	0.042
Female sex	0.391	0.182	0.034
HDL	0.008	0.004	0.099

HCV infection status was an independent factor that significantly influenced the serum cholesterol ester transfer protein level. HCV: Hepatitis C virus; HDL: High-density lipoprotein.

were no significant differences in BMI, FBG levels, and HbA1c levels, whereas AST, ALT, and albumin levels differed significantly. TC and LDL-C levels were significantly lower in patients with active infection than in patients whose infection was eradicated, whereas TG and HDL-C levels were similar between the two groups.

#### **HCV infection status (active infection or eradication) as an independent determinant that significantly contributed to the serum CETP level**

To construct a multiple regression model that can suitably

explain the serum CETP concentration, six variables were selected as candidate independent variables. Among categorical data, HCV infection status and sex were selected, because the serum CETP level was significantly higher in female than in male patients ( $2.90 \pm 0.91 \mu\text{g/mL}$  vs  $2.28 \pm 0.73 \mu\text{g/mL}$ ,  $P < 0.001$ ). However, difference in HCV genotype was not selected as a candidate variable because there was no difference in serum CETP level between HCV G1b and G2 patients ( $2.51 \pm 0.68$  vs  $2.66 \pm 0.94$ ,  $P = 0.472$ ). Furthermore, the serum CETP level was similar between HCV G1b patients and G2 patients in the active group ( $2.82 \pm 1.02$  vs  $2.99 \pm 0.76$ ,  $P = 0.685$ ) and the eradication group ( $2.42 \pm 0.75$  vs  $2.36 \pm 0.57$ ,  $P = 0.734$ ).

Among the continuous variables, age ( $R = 0.246$ ,  $P = 0.010$ ), albumin level ( $R = -0.194$ ,  $P = 0.046$ ), Hb level ( $R = 0.249$ ,  $P = 0.009$ ), and HDL-C level ( $R = 0.236$ ,  $P = 0.014$ ) were significantly correlated with the serum CETP level and were thus selected as candidates. Other factors including HbA1c ( $R = 0.084$ ,  $P = 0.538$ ) and FBS ( $R = 0.074$ ,  $P = 0.589$ ) were not selected as candidates, because significant correlation was not verified.

Of these six candidates, HCV infection status, age, sex, and HDL-C level were selected as independent

**Table 3** Comparison of the cholesterol and triglyceride concentrations in the four major lipoprotein fractions according to hepatitis C virus infection status

Major class	Active HCV group	Eradication group	P value	Active HCV group	Eradication group	P value
	Cholesterol (mg/dL)			Triglyceride (mg/dL)		
CM	0.19 ± 0.19	0.19 ± 0.18	0.86	1.21 ± 1.53	1.28 ± 1.31	0.774
VLDL	29.04 ± 12.31	26.12 ± 10.66	0.187	57.66 ± 42.06	65.97 ± 44.18	0.314
LDL	87.94 ± 24.11	117.31 ± 26.91	< 0.001	36.25 ± 15.28	28.14 ± 9.94	0.001
HDL	49.58 ± 15.19	55.19 ± 16.29	0.064	25.9 ± 7.34	17.17 ± 4.82	< 0.001

The cholesterol concentration in LDL-C was significantly lower and HDL-C was marginally lower in the active HCV group, whereas cholesterol concentrations in CM and VLDL were similar between groups. The TG concentrations in LDL-TG and HDL-TG were significantly higher in the active HCV group, whereas TG concentrations in CM and VLDL were similar between groups. HCV: Hepatitis C virus; CM: Chylomicron; VLDL: Very-low-density lipoprotein; LDL: Low-density lipoprotein; HDL: High-density lipoprotein; TG: Triglyceride.

variables for the most suitable multiple regression model to explain the serum CETP level. As shown in Table 2, HCV infection status was an independent factor that significantly influenced the serum CETP level. The R<sup>2</sup> value of this model was 0.221, and the adjusted value was 0.191. The R<sup>2</sup> value did not improve significantly by the addition of any other candidate factors. However, elimination of any of these four factors significantly decreased the R<sup>2</sup> values.

The most suitable regression equation was as follows: Serum CETP (μg/mL) = 0.770 + 0.0139 (age) + 0.391 (sex: male: 0, female: 1) + 0.00818 HDL-C (mg/dL) + 0.416 HCV infection status (eradication: 0, active infection: 1).

#### **Differences in the TG concentration in the four major classes of lipoproteins according to HCV infection status**

The cholesterol concentration in LDL-C was significantly lower and the HDL-C concentration was marginally lower in the active HCV group compared to those in the eradication group, whereas cholesterol concentrations in CM and VLDL were similar between the groups.

The TG concentrations in LDL-TG and HDL-TG were significantly higher in the active HCV group compared to the eradication group, whereas TG concentrations in CM and VLDL were similar between groups (Table 3).

#### **Correlation between the serum CETP concentration and TG concentration in the four major lipoprotein classes**

The CETP level had a weak, inverse correlation with CM-C (R = -0.290, P = 0.031) in the eradication group; it had a positive correlation with HDL-C in the active HCV group (R = 0.324, P = 0.015), but this correlation was marginal in the eradication group (R = 0.250, P = 0.064). Significant correlations were not found between groups for the other lipoprotein fractions (Figure 2A).

According to the TG concentration, the CETP level was inversely correlated with chylomicron-TG (R = -0.348, P = 0.009) and VLDL-TG (R = -0.415, P = 0.002) and marginally correlated with LDL-TG (R = -0.247, P = 0.069), but was not correlated with HDL-TG (R = -0.079, P = 0.566) in the eradication group. In contrast, the CETP level was strongly correlated with HDL-TG in

the active HCV group (R = 0.557, P < 0.001). However, significant correlations with TG for other lipoprotein classes were not detected in the active HCV group (Figure 2B).

## **DISCUSSION**

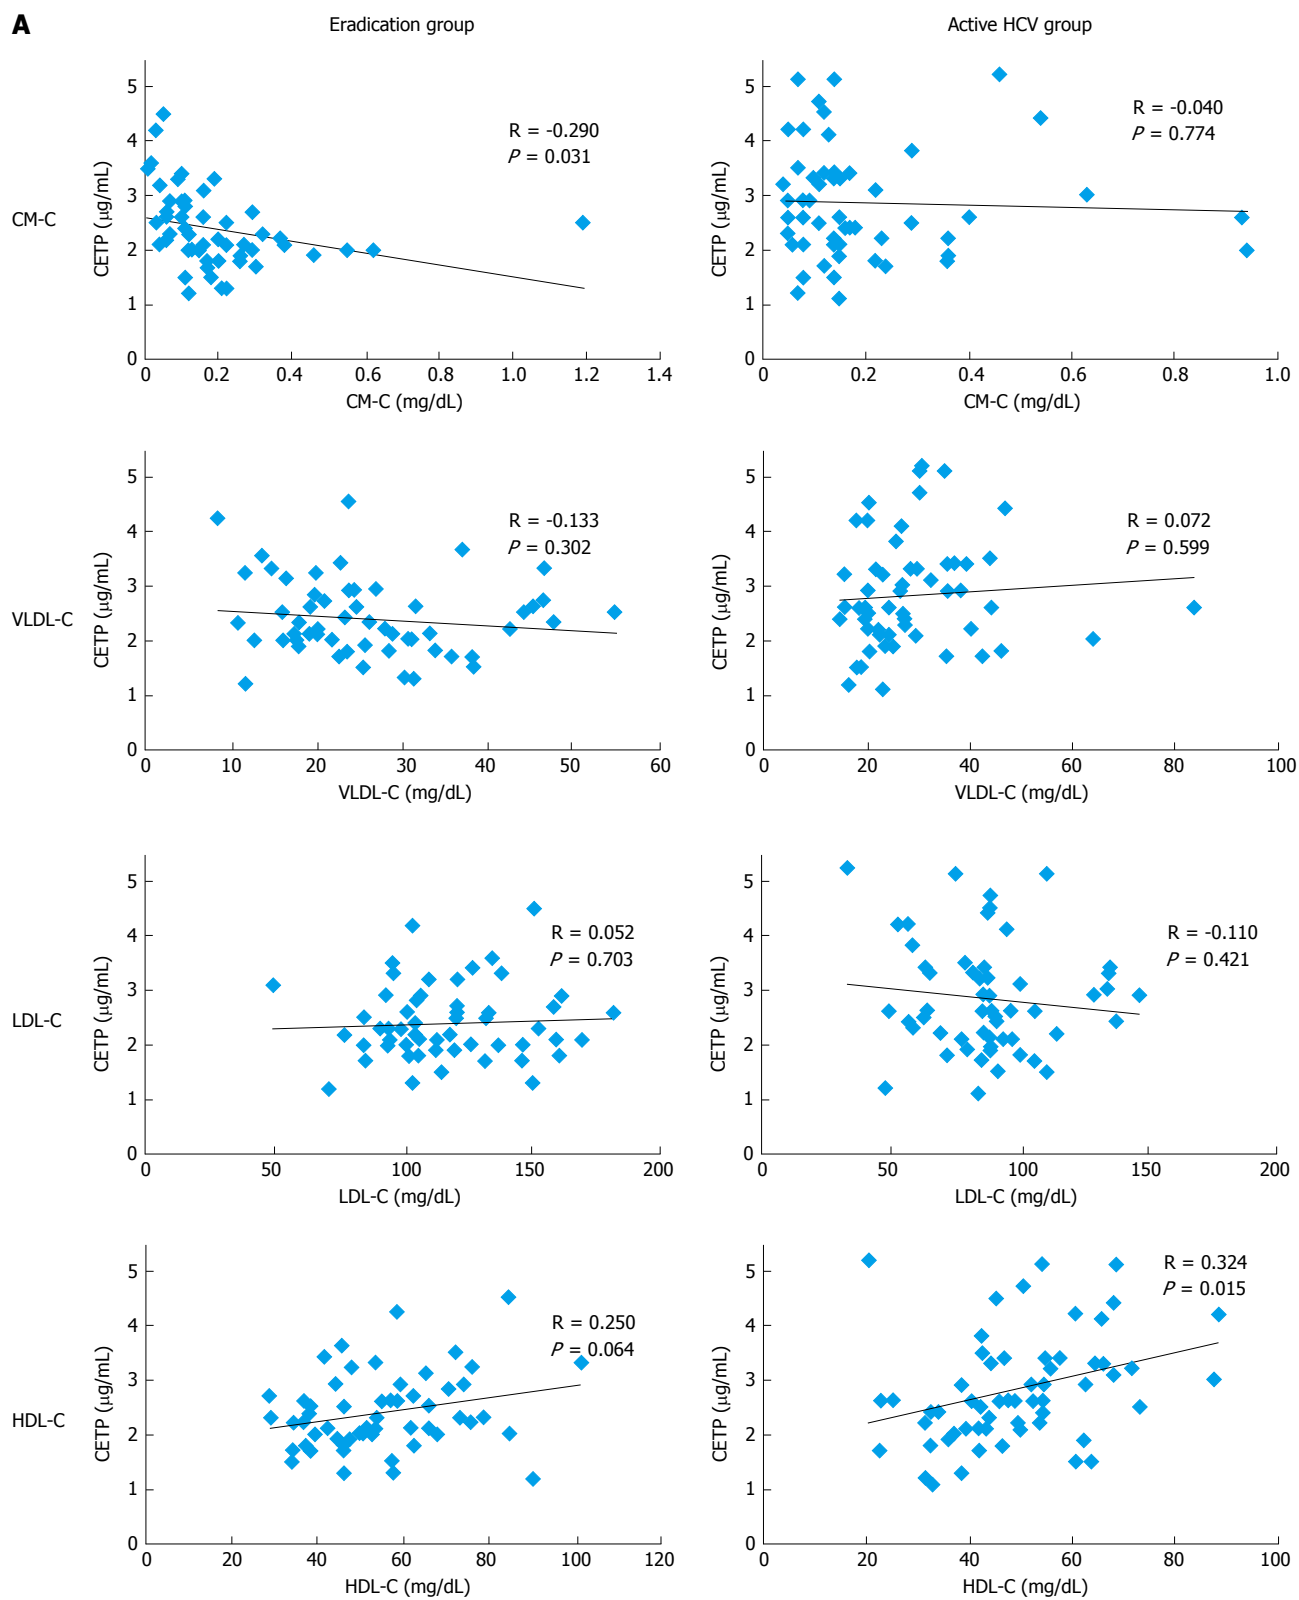

CETP is a glycoprotein that mediates the exchange of CE in HDL for TG in other lipoproteins. In the present study, we investigated the serum concentration of CETP and found that serum CETP levels were significantly higher in the active group than in the eradication group. Moreover, HCV infection was found to be an independent factor in determining the serum CETP level in multiple regression analysis. This suggests that HCV infection promotes the exchange of CE for TG in HDL by increasing the serum CETP concentration.

Although we did not evaluate the activity of CETP, it has generally been accepted that the serum CETP concentration reflects CETP activity<sup>[18]</sup>. Thus, an increase in the CETP level in patients with active HCV infection may indicate enhanced CETP activity.

CETP activity is regulated by the amount of dietary cholesterol<sup>[19,20]</sup> and hypertriglyceridemia<sup>[21]</sup>. In addition, CETP activity is dependent on genetic variations in the CETP gene<sup>[22-24]</sup>. However, the effect of HCV infection on the activity of CETP has not been investigated previously. Our results indicate that active HCV infection may promote CETP activity. This enhanced CETP activity may play a role in lipoprotein metabolism abnormalities in patients with active HCV infection<sup>[22-24]</sup>.

An unexpected finding in our study was a positive correlation between the serum CETP level and HDL-C, although the correlation was relatively weak and did not reach the level of significance in the eradication group. One of the major functions of CETP is the removal of CE from HDL. In fact, CETP inhibitors substantially increase HDL-C levels and moderately decrease LDL-C levels in humans<sup>[25]</sup>. There may be a weak negative correlation between CETP and HDL-C in patients with type 2 DM<sup>[26]</sup>. However, the correlation between serum level of HDL-C and CETP in a healthy population has not been observed<sup>[27]</sup>. Therefore, the HDL-C level is not simply determined by the function of CETP because the serum

**A**

**B**

**Figure 2** Correlation between the cholesteryl ester transfer protein level and triglyceride concentration in the four major lipoprotein classes in the hepatitis C virus eradication group and the active hepatitis C virus infection group. A: The CETP level had a weak correlation with HDL cholesterol in the active HCV infection group ( $R = 0.324$ ,  $P = 0.015$ ) and a weak, inverse correlation with chylomicron-cholesterol ( $R = -0.290$ ,  $P = 0.031$ ); B: The CETP level had a strong correlation with HDL-TG in the active HCV infection group ( $R = 0.557$ ,  $P < 0.001$ ). However, significant correlations with TG for other lipoprotein classes were not detected in the active HCV group. HCV: Hepatitis C virus; CM: Chylomicron; VLDL: Very-low-density lipoprotein; LDL: Low-density lipoprotein; HDL: High-density lipoprotein; TG: Triglyceride.

level of HDL-C may be dynamically controlled by the balance between HDL synthesis and catabolism, which is not mediated by CETP.

Although there is a consensus that a decrease in serum TC<sup>[28]</sup> and LDL-C<sup>[10]</sup> is a feature of HCV infection, little is known about TG abnormalities. A previous study reported that chronic hepatitis C patients had a lower serum VLDL-TG/non-VLDL-TG ratio<sup>[11]</sup>. Moreover, there was a reported increase in the TG concentration in HDL and LDL in patients with active HCV infection, although the total serum TG level was similar in the active HCV and eradication groups<sup>[29]</sup>.

In a correlation study between CETP and TG concentration in four lipoprotein classes, we found positive and strong correlations between CETP and HDL-TG in the active HCV group. However, this correlation was not found in the eradication group. Conversely, CETP was correlated with CM-TG and VLDL-TG in the eradication group, but was not significantly correlated with CM-TG or VLDL-TG in the active HCV group. These findings indicate that the significance of CETP in the regulation of TG concentration differs according to the HCV infection status. The most striking difference was found in HDL-TG.

The major source of serum TG is a TG-enriched VLDL that is secreted from the liver. TG in VLDL or LDL is transferred to HDL by the action of CETP. In active HCV infection, an increased serum CETP may enhance the transport of TG to HDL. Therefore, the increase in CETP and the strong positive correlation between CETP and HDL-TG in active HCV infection may indicate that HDL has abundant TG, promptly transferred from VLDL, but is not effectively catabolized and eliminated from the serum. Accordingly, as the major metabolic pathway that degrades and eliminates TG in HDL is mediated by hepatic lipase (HL)<sup>[30]</sup>, we speculate that HL activity in active HCV infection is impaired. Our hypothesis of reduced HL activity in active HCV infection is concordant with a previous result that the HL messenger RNA level is lower in the liver of patients with chronic hepatitis C than in the liver of patients with other etiologies and similar disease progression<sup>[31]</sup>. As a consequence of the abnormal retention of TG in HDL, the multifaceted functions of HDL on atherosclerosis<sup>[32]</sup> may be affected, and this could contribute to the progression of atherosclerosis in patients with active HCV infection<sup>[33]</sup>. Furthermore, dyslipidemia, which is caused by high serum CETP activity in active HCV infection, may contribute to intravascular lipoviral particle formation and thus for sustaining HCV infection<sup>[34,35]</sup>.

Our study had some limitations. It included a relatively small sample size, and the degree of atherosclerosis was not determined in the enrolled patients. In addition, we did not examine lipoviral particle and non-lipoviral particle viral load in the active HCV patients. To strengthen our hypothesis that an increase of TG in HDL contributes to atherosclerosis, further large-scale studies including the evaluation of the anti-inflammatory<sup>[36,37]</sup> and proinflammatory<sup>[38]</sup> functions of HDL and measurement

of the degree of atherosclerosis are warranted.

In summary, HCV infection was an independent factor contributing to the increase in serum CETP. The increase in CETP resulted in abnormal retention of TG in HDL. These findings suggest that CETP is one of the factors that contribute to abnormal lipoprotein metabolism in patients with active HCV infection.

## COMMENTS

### Background

Hepatitis C virus (HCV) is a unique virus; its use of host lipid metabolism results in a persistent infection. It is important to understand how HCV uses host lipid metabolism and how host lipid metabolism is affected by HCV infection, because HCV infection represents a unique model in which the virus causes chronic infection while coexisting with the host by taking over the host's metabolism.

### Research frontiers

The effect of HCV infection on the activity of cholesteryl ester transfer protein (CETP) has not been investigated previously. The authors have been the first to clarify that CETP may be increased with HCV.

### Innovations and breakthroughs

The authors confirmed that CETP plays a role in abnormal lipoprotein metabolism in patients with HCV infection.

### Applications

An increase of triglyceride (TG) in high-density lipoprotein (HDL) as a consequence of activated CETP may contribute to progression of atherosclerosis in HCV infection. Furthermore, disturbed lipoprotein metabolism induced by activated CETP may contribute to intravascular formation of HCV lipoviral particles.

### Terminology

CETP is a glycoprotein mediating the exchange of cholesteryl ester in HDL for TG in other lipoproteins.

### Peer-review

In this study, the authors found that HCV infection was an independent factor contributing to the increase in serum CETP, the increase in CETP resulted in abnormal retention of TG in HDL. These findings suggest that CETP is one of the factors that contribute to abnormal lipoprotein metabolism in patients with active HCV infection. This study has scientific basis and is interesting.

## Abstract

**AIM:** To determine if gene-specific DNA methylation in prospectively collected blood samples is associated with later development of hepatocellular carcinoma (HCC).

**METHODS:** Comparing genome-wide DNA methylation profiles using Illumina Human methylation 450K arrays, we previously identified a list of loci that were differentially methylated between tumor and adjacent nontumor tissues. To examine if dysregulation of DNA

methylation patterns observed in tumor tissues can be detected in white blood cell (WBC) DNA, we conducted a prospective case-control study nested within a community-based cancer screening cohort in Taiwan with 16 years of follow up. We measured methylation levels in ninety-six loci that were aberrant in DNA methylation in HCC tumor tissues compared to adjacent tissues. Baseline WBC DNA from 159 HCC cases and 312 matched controls were bisulfite treated and assayed by Illumina BeadArray. We used the  $\chi^2$  test for categorical variables and student's *t*-test for continuous variables to assess the difference in selected characteristics between cases and controls. To estimate associations with HCC risk, we used conditional logistic regression models stratified on the matching factors to calculate odds ratios (OR) and 95%CI.

**RESULTS:** We found that high methylation level in cg10272601 in *WNK2* was associated with increased risk of HCC, with an OR of 1.91 (95%CI: 1.27-2.86). High methylation levels in both cg12680131 in *TPO* and cg22511877 in *MYT1L*, however, were associated with decreased risk. The ORs (95%CI) were 0.59 (0.39-0.87) and 0.50 (0.33-0.77), respectively, for those with methylation levels of cg12680131 and cg22511877 above the median compared with those with levels below the median. These associations were still statistically significant in multivariable conditional logistic regression models after adjusting for hepatitis B virus infection and alcohol consumption.

**CONCLUSION:** These findings support the measurement of methylation markers in WBC DNA as biomarkers of HCC susceptibility but should be replicated in additional prospective studies.

**Key words:** DNA methylation; Epigenetics; Hepatitis B virus; Hepatocellular carcinoma; White blood cell DNA

**Core tip:** Hepatocellular carcinoma (HCC) is a highly fatal disease thus, the identification of biomarkers that could predict risk for development could enhance screening/early detection and prognosis. DNA methylation alterations are well established in HCC but whether changes in DNA methylation in white blood cells (WBC) are associated with increased risk of developing HCC is unknown. Taking advantage of a cancer screening program in Taiwan, we measured baseline WBC DNA methylation in prospectively collected blood samples at 96 CpG sites that were identified as differentially methylated in HCC tumors compared to adjacent tissues. Three were significantly associated with later development of HCC suggesting potential utility as a marker of risk.

*J Hepatol* 2016; 8(5): 301-306 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i5/301.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i5.301>

## INTRODUCTION

Hepatocellular carcinoma (HCC) is among the most common cancers around the world<sup>[1]</sup>. Hepatitis B and C virus infection are the most important risk factors of HCC<sup>[2-4]</sup>. More recent studies have also identified the importance of exposure to alcohol, dietary aflatoxins and cigarette smoke<sup>[5-7]</sup>.

The mechanisms of liver cancer induction are now known to include mutations in specific genes and epigenetic alterations such as changes in DNA methylation and microRNA expression. These changes lead to changes in expression of oncogenes and tumor suppressor genes<sup>[8-10]</sup>. DNA hypermethylation can silence tumor suppressor genes while hypomethylation can activate oncogenes<sup>[11,12]</sup>. Using Illumina HumanMethylation 27K and 450K BeadChips, we previously reported a distinct DNA methylation pattern between HCC tumor and paired adjacent nontumor tissues (NCBI's GEO database accession numbers GSE54503 and GSE37988)<sup>[13,14]</sup>. In one of the studies, we found 28017 CpG sites hypermethylated and 102495 hypomethylated in tumor tissues compared with paired adjacent tissues<sup>[14]</sup>, suggesting their role in HCC tumorigenesis.

Using data on baseline white blood cell (WBC) DNA banked up to 16 years before diagnosis, we recently reported that global hypomethylation of Sat2, a repetitive element, was associated with increased HCC risk<sup>[15]</sup> and was also associated with high AFB<sub>1</sub> exposure<sup>[16]</sup>. These results suggest that decreased overall DNA methylation in WBC DNA can be used as a biomarker for HCC risk.

The main aim of this study was to examine whether the dysregulation of DNA methylation markers observed in tumor tissues can be detected in WBC DNA. We measured methylation levels in ninety-six loci in WBC DNA from 159 HCCs who developed cancer after enrollment in a community-based cancer screening program in Taiwan<sup>[5,6,15]</sup> and compared them with 312 controls who remained cancer free in the same cohort.

## MATERIALS AND METHODS

### Study population

This study included individuals who participated in a Cancer Screening Program cohort in Taiwan. This study was approved by both the Institutional Review Board of Columbia University and the Research Ethics Committee of the College of Public Health at National Taiwan University. We obtained written informed consent from all study subjects in this study.

Detail information regarding the cohort description and screening procedure and follow-up was provided in previous publications<sup>[5,6,15,16]</sup>. Between July 1990 and June 1992, 12020 males and 11924 females aged from

30 to 65 years old and who lived in seven towns in Taiwan were enrolled in this study. Each participant filled out a structured questionnaire to collect information including demographic characteristics, history of alcohol intake and cigarette smoking, history of chronic disease and family history of cancers, including HCC. Each participant also donated a fasting blood sample during the time of recruitment.

In this study, we used blood collected from 159 participants who were diagnosed with HCC during the interval between their blood draw and June 2008. We also used blood from 312 controls who remained cancer free in the same cohort. Controls were selected by matching to each case by age (within 5 years), sex, residential area and time of recruitment (within 3 mo). Baseline WBCs were shipped to Columbia University on dry ice for DNA isolation and DNA methylation measurement.

#### DNA bisulfite conversion

We extracted genomic DNA from WBC using a salting out procedure. We bisulfite-treated an aliquot of DNA (500 ng) with EZ DNA methylation kits (Zymo Research, Orange, CA). The bisulfite DNA was resuspended in 20  $\mu$ L of distilled water and stored at -20 °C until use.

#### Loci selection and methylation measurement

We selected 96 CpG sites that previously had shown either hyper- or hypomethylation in HCC tumor compared to paired adjacent nontumor tissues in our 450k array data<sup>[14]</sup>. We selected our target CpG sites from among the top 250 most hyper or hypomethylated sites. Our selection of targets was based on the following criteria: (1) the largest methylation differences

between tumor and adjacent tissues; (2) half of the CpG sites showing hypomethylation and half hypermethylation; and (3) one site per gene. Due to the inability to design primers for some sites, we have 65 CpG sites with hypermethylation and 31 CpG sites with hypomethylation. DNA methylation analysis was measured using an Illumina GoldenGate assay with BeadArray technology. The arrays were customized to measure methylation covering the CpG sites identified in the 450k array. DNA methylation values were scored as  $\beta$ -values which ranges between 0 and 1.

#### Statistical analysis

We used the  $\chi^2$  test and/or student's *t*-test to assess the difference in selected variables between cases and controls. To estimate associations between methylation markers and HCC risk, we used a conditional logistic regression model using PROC PHREG procedure. Subjects were divided into different methylation groups: Those with methylation levels above the median value for all controls sample vs those below the median. In the multivariable model, we modeled the associations of methylation in cg10272601 in *WNK2*, cg12680131 in *TPO* and cg22511877 in *MYT1L* adjusting for, hepatitis B virus surface antigen (HBsAg) (Yes vs No), and history of alcohol intake (Ever vs Never) in the model. All analyses were performed with SAS software 9.2 (SAS Institute, Cary, NC).

## RESULTS

The distributions of subjects' characteristics at baseline for cases and matched controls is given in Table 1. The distributions of matching factors including age, sex were similar between cases and controls. There were 51.7% and 52.5% males in cases and controls, respectively. The distribution of smoking was also similar, while the percentage of ever alcohol consumption was slightly lower in controls (11.5%) than in cases (18.2%). The percents positive for HBsAg and anti-HCV were higher in cases than in matched controls [58.5% vs 23.1% for HBsAg (+) and 18.2% vs 4.8% for anti-HCV (+)].

Table 2 presents the distributions of the 96 methylation markers by HCC status. The mean values of methylation vary by methylation markers. Fifty DNA methylation markers had mean methylation values below 10% in cases and controls. Nineteen DNA methylation markers had mean methylation values above 90%. About 27 DNA methylation markers had mean methylation levels between 10% and 90%. The mean levels of three DNA methylation markers were statistically significantly different between cases and controls, including cg10272601, cg12680131, and cg22511877. The mean methylation beta values for cg1027261 were  $0.30 \pm 0.07$  for cases and  $0.28 \pm 0.08$  for controls ( $P = 0.04$ ). Values for cg12680131 were  $0.80 \pm 0.09$  and  $0.82 \pm 0.11$  for cases and controls, respectively ( $P = 0.02$ ) and for cg22511877,  $0.56 \pm 0.17$  for cases and  $0.60 \pm 0.16$  for controls ( $P = 0.01$ ).

<sup>1</sup>*P* value for student's *t*-test.**Table 3** White blood cell DNA methylation and hepatocellular carcinoma risk

Locus		Cases/ controls	OR (95%CI)
WNK2 cg10272601	Below median (< 0.279)	56/157	1.0
	Above median (≥ 0.279)	103/155	1.91 (1.27-2.86)
TPO cg12680131	Below median (< 0.836)	102/157	1.0
	Above median (≥ 0.836)	57/155	0.59 (0.39-0.87)
MYT1L cg22511877	Below median (< 0.636)	105/159	1.0
	Above median (≥ 0.636)	54/153	0.50 (0.33-0.77)

The association between DNA methylation of cg10272601, cg12680131, and cg22511877 and HCC are given in Table 3. The OR for those with cg10272601 methylation above the median was 1.91 (95%CI: 1.27-2.86). Individuals with a cg12680131 methylation level above the median had lower risk of HCC, with an OR of 0.59 (95%CI: 0.39-0.87). The OR was 0.50 (95%CI: 0.33-0.77) for those with cg22511877 methylation above median.

Table 4 shows the multiple variables conditional logistic regression model. Overall, HBsAg (+) was associated with increased HCC risk (OR = 5.50, 95%CI: 3.34-9.03) compared with HBsAg(-). Ever smokers had a 2.1-fold increased risk of developing HCC (OR = 2.10, 95%CI: 1.08-4.07). The ORs (95%CI) were 2.26 (1.42-3.61), 0.55 (0.34-0.87), and 0.53 (0.32-0.88) for cg10272601, cg12680131, and cg22511877 hypermethylation.

**Table 4 Multiple variables model for DNA methylation and hepatocellular carcinoma risk**

Variable	OR (95%CI)	P
<i>WNK2</i> cg10272601 <sup>1</sup>	2.26 (1.42-3.61)	0.0006
<i>TPO</i> cg12680131 <sup>2</sup>	0.55 (0.34-0.87)	0.01
<i>MYT1L</i> cg22511877 <sup>3</sup>	0.53 (0.32-0.88)	0.01
HBsAg (positive <i>vs</i> negative)	5.50 (3.34-9.03)	< 0.0001
Alcohol (yes <i>vs</i> no)	2.10 (1.08-4.07)	0.03

<sup>1</sup>Above or below the median of 0.279; <sup>2</sup>Above or below the median of 0.836;

<sup>3</sup>Above or below the median of 0.636. HBsAg: Hepatitis B virus surface antigen.

## DISCUSSION

Alterations in methylation of cg10272601, cg12680131, and cg22511877 were associated with risk for later HCC development. Consistent with our tissue data, we found that a high methylation level in cg10272601 was associated with increased risk of HCC, while high methylation levels in both cg12680131 and cg22511877 were associated with decreased risk. In the 450k data, the mean beta values were  $0.52 \pm 0.22$  for cg10272601,  $0.28 \pm 0.21$  for cg12680131, and  $0.34 \pm 0.26$  for cg22511877 in HCC tumors<sup>[14]</sup>. The corresponding beta values were  $0.10 \pm 0.06$ ,  $0.79 \pm 0.08$ ,  $0.87 \pm 0.05$ , respectively, in adjacent nontumor tissues.

cg10272601 is located at transcription start site (TSS) 200 of *WNK2*, a gene encoding a serine-threonine kinase on chromosome 9q22.31<sup>[17]</sup>. *WNK2* acts as a tumor suppressor gene by suppressing the ERK/MAPK-pathway and downstream cell cycle progression<sup>[18]</sup> and *WNK2* expression inhibited colony formation<sup>[19]</sup>, suggesting a role in cell growth suppression. Dense high methylation at the CpG island was associated with decreased *WNK2* expression<sup>[19]</sup>. Hypermethylation of *WNK2* was reported in many cancers, including pancreatic ductal adenocarcinoma<sup>[20]</sup>, HCC<sup>[14,21]</sup>, and gliomas<sup>[22]</sup>.

cg12680131 is located on chromosome 2p25 at TSS 200 of thyroid peroxidase (*TPO*), a key enzyme in thyroid hormone synthesis. Mutations in *TPO* are associated with several disorders of thyroid hormonogenesis<sup>[23]</sup>. The association of methylation and expression of *TPO* has not been studied and the role of *TPO* in carcinogenesis has not been reported. cg22511877 is located at a shore region of myelin transcription factor 1-like (*MYT1L*) also on chromosome 2p25. *MYT1L* is a main member of the MYT/NZF family of transcription factors<sup>[24,25]</sup>. Limited data suggests a polymorphism in *MYT1L* is associated with gastric cancer outcome in a Chinese population<sup>[26]</sup>. Future studies are needed to understand the mechanisms of hypomethylation of both *TPO* and *MYT1L* in hepatocarcinogenesis.

The main limitation of this study is that we did not adjust for multiple comparisons due to the limited sample size. However, in further data analysis, we also observed significant associations of methylation in these 3 CpG sites with HCC risk after adjusting for HBV infection and alcohol consumption, suggesting an independent effect

in HCC risk.

This study, using prospective study design, allowed us to produce causal evidence on DNA methylation in WBC and cancer susceptibility<sup>[27]</sup>. Using information from HCC tumor tissues, our study investigated the associations of HCC-specific differentially methylated loci observed in tumor tissues in WBC DNA with HCC risk.

In summary, we provide new evidence that specific loci methylation in WBC DNA is associated with increased HCC susceptibility. These finding could lead to development of a simple non-invasive blood measure of DNA methylation to identify people at high risk of HCC.

## COMMENTS

### Background

Hepatocellular carcinoma (HCC) is a highly devastating disease with a poor prognosis. Thus, methods that allow the identification of individuals at elevated risk of HCC should greatly enhance screening for early diagnosis and improve prognosis. While several risk factors are well known such as infection with hepatitis B or C virus, not all viral-infected individuals develop cancer. Additional biomarkers of risk are therefore needed.

### Research frontiers

It is known that tumors release DNA into the blood stream and that this DNA contains the same DNA alterations both mutations and changes in DNA methylation that are found in the tumor. Thus, researchers have been able to develop assays for tumor DNA in plasma/serum for early diagnosis. There is also limited data in some cancers, not HCC, that DNA methylation changes in blood cells differs between cases and controls.

### Innovations and breakthroughs

This study is the first to investigate whether DNA methylation in specific genes in white blood cells is predictive of later HCC development.

### Applications

While the study needs confirmation in another population, it suggests that it may be possible to develop risk prediction models that include white blood cell DNA methylation markers.

### Peer-review

This is a very interesting paper. The authors found the correlation between DNA methylation and HCC occurring. The results provide sufficient experimental evidence or data to draw firm scientific conclusions.

Editorial Board Member of *World Journal of Hepatology*, Yasuhito Tanaka, MD, PhD, Professor, Department of Virology and Liver Unit, Nagoya City University Graduate School of Medical Sciences, Nagoya 467-8601, Japan

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Bacterial infection is common and accounts for major morbidity and mortality in cirrhosis. Patients with cirrhosis are immunocompromised and increased susceptibility to develop spontaneous bacterial infections, hospital-acquired infections, and a variety of infections from uncommon pathogens. Once infection develops, the excessive response of pro-inflammatory cytokines on a pre-existing hemodynamic dysfunction in cirrhosis further predispose the development of serious complications such as shock, acute-on-chronic liver failure, renal failure, and death. Spontaneous bacterial peritonitis and bacteremia are common in patients with advanced cirrhosis, and are important prognostic landmarks in the natural history of cirrhosis. Notably, the incidence of infections from resistant bacteria has increased significantly in healthcare-associated settings. Serum biomarkers such as procalcitonin may help to improve the diagnosis of bacterial infection. Preventive measures (*e.g.*, avoidance, antibiotic prophylaxis, and vaccination), early recognition, and proper management are required in order to minimize morbidity and mortality of infections in cirrhosis.

**Key words:** Bacteria; Infection; Sepsis; Bacteremia; Liver cirrhosis; Vaccination; Spontaneous peritonitis; Immune dysfunction

**Core tip:** Bacterial infection is common and accounts for major morbidity and mortality in cirrhosis. Patients with cirrhosis are immunocompromised and increased susceptibility to develop spontaneous bacterial infec-

tions, hospital-acquired infections, and a variety of infections from uncommon pathogens. Once infection develops, the excessive response of pro-inflammatory cytokines on a pre-existing hemodynamic derangement in cirrhosis further predispose the development of serious complications such as shock, acute-on-chronic liver failure, renal failure, and death. The incidence of resistant bacteria has continually increased, especially in healthcare-associated settings. Preventive measures, early recognition and proper management are necessary to minimize morbidity and mortality of infections in cirrhosis.

Bunchorntavakul C, Chamroonkul N, Chavalitthamrong D. Bacterial infections in cirrhosis: A critical review and practical guidance. *World J Hepatol* 2016; 8(6): 307-321 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i6/307.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i6.307>

## INTRODUCTION

In the past decades, there have been several improvements in the management of cirrhotic patients, such as antiviral therapy and management of portal hypertension and liver transplantation (LT). However, the mortality of infection in cirrhosis is still high and has not changed substantially. Cirrhosis is an immunocompromised state that predisposes patients to spontaneous bacterial infections, hospital-acquired infections, and a variety of infections from uncommon pathogens. Once infection develops, the excessive response of pro-inflammatory cytokines on a pre-existing hemodynamic derangement in cirrhosis further facilitate the development of severe complications such as septic shock, acute-on-chronic liver failure (ACLF), multiple organ failure, and death. Accordingly, bacterial infection in patients with cirrhosis is very common in clinical practice and sepsis is the main reason of intensive care unit admission and death among such patients. The incidence of resistant bacteria has been increasing, especially in healthcare-associated settings. Preventive measures, early recognition, and proper management are necessary to minimize morbidity and mortality of infections in cirrhosis.

## MECHANISM OF INCREASED SUSCEPTIBILITY AND VULNERABILITY TO INFECTION IN PATIENTS WITH CIRRHOSIS

### *Immune dysfunction in cirrhosis*

Patients with cirrhosis are in a state of immune dysfunction, in parallel with a state of excessive activation of pro-inflammatory cytokines, referred to as cirrhosis-associated immune dysfunction syndrome, which predisposes the patient for infections<sup>[1,2]</sup>. Portosystemic

shunting allows less gut-derived bacteria and their products to be cleared from portal circulation by the liver, which contains about 90% of the reticuloendothelial cells in the body<sup>[1-5]</sup>. Nearly all components of systemic immune response are significantly impaired in cirrhosis, including a decrease in phagocytic activity, a reduction in serum albumin, complement and protein C activities, and an impaired opsonic activity both in serum and ascitic fluid<sup>[1-4,6-10]</sup>. Genetic polymorphisms of toll-like receptor (TLR) and nucleotide-binding oligomerisation domain 2 (NOD2) genes could be responsible for bacterial translocation (BT) and increase infection risk in cirrhosis by altering the TLR's ability to bind to lipopolysaccharide or endotoxins<sup>[11,12]</sup>. Further, cirrhosis-associated immune dysfunction may further complicate by additional factors such as malnourishment<sup>[13]</sup> and alcohol drinking<sup>[14]</sup> (Table 1).

### **BT**

BT is the migration of viable native bacteria from gut lumen through systemic circulation *via* mesenteric lymph nodes (MLN) and portal vein. Although this can be a healthy phenomenon, BT has increased pathologically compromising effects in cirrhosis<sup>[15-17]</sup>. The diagnosis of BT relies on the isolation of viable bacteria in MLN, while the detection of bacterial DNA in serum or ascitic fluid is proposed as a useful surrogated marker<sup>[15-18]</sup>. It has been shown that oral administration of radio-labeled *Escherichia coli* (*E. coli*) to cirrhotic rats revealed the detection of these bacteria not only in the gut lumen but also in the MLN and ascites<sup>[19]</sup>. Several experimental and clinical studies have suggested that small intestinal overgrowth, increased intestinal permeability, impaired intestinal motility, lack of bile acids, sympathetic overactivity, and local innate and adaptive immunological alterations (*e.g.*, impaired leukocyte recruitment, altered T-cell activation, TLR and NOD2 mutation) are important factors involved in the pathogenesis of BT<sup>[11,12,17,20,21]</sup>.

BT is pathogenetically linked to the development of infections, particularly spontaneous bacterial infections, and other serious complications in cirrhosis<sup>[15-17]</sup>. Apart from infections, bacterial DNA and bacterial products, such as endotoxin, can translocate to extra-intestinal sites and promote host immunological and hemodynamic responses, which is associated with the development of systemic pro-inflammatory and hyperdynamic circulatory state in cirrhosis<sup>[16,18]</sup>. The pathological translocation of viable bacteria occurs in the decompensated stage, while the rate and degree of translocating bacterial products also increases in the earlier stages of cirrhosis<sup>[15]</sup>. Notably, treatment with non-selective beta-blockers has been shown to ameliorate intestinal permeability and reduce BT<sup>[22]</sup>.

### **Systemic inflammatory response syndrome and circulatory dysfunction in cirrhosis**

Patients with cirrhosis are susceptible to the development of severe infection, septic shock, and organ

**Table 1** State of immune dysfunction in patients with cirrhosis

Natural barriers	Fragile, thin and/or edematous skin Alteration of GI motility and mucosal permeability Alteration of GI bacterial flora, bacterial overgrowth ↑ GI mucosal ulcerations
Hepatic RES activity	Portosystemic shunting Kupffer cells - ↓ number, impaired function
Cellular defense mechanisms	RES - ↓ activation, ↓ chemotaxis, ↓ phagocytosis, ↓ production of pro-inflammatory cytokines (IL-1, IL-6, IL-18, TNF-α) PMN - ↓ lifespan, ↓ intracellular killing activity, ↓ phagocytosis, ↓ chemotaxis
Serum factors	↓ Complement levels (C3, C4, CH50) ↓ Opsonic activity ↓ Protein C activity
Iatrogenic and treatment-related factors	↑ Invasive procedure and catheters Frequent hospitalization Immunosuppressive agents (autoimmune hepatitis, post-transplantation) Interferon therapy (viral hepatitis) Proton pump inhibitors
Other compelling factors	Malnutrition Alcohol drinking

Adapted from Bunchorntavakul C, Chavalitdharmong D. *World J Hepatol* 2012; 4: 158-168. RES: Reticuloendothelial system; GI: Gastrointestinal; IL: Interleukins; TNF: Tumor necrosis factors; PMN: Polymorphonuclear cells.

failure<sup>[1,2,23]</sup>. In cirrhosis, bacterial infection is associated with a dysregulated cytokine response, which transforms helpful responses against infections into excessive, damaging inflammation<sup>[1,2,23]</sup>. Nitric oxide is strikingly released in cirrhotic patients with sepsis and is a key driver of circulation dysfunction in this setting<sup>[23,24]</sup>. A pre-existing hyperdynamic circulatory state in patients with advanced cirrhosis predisposes detrimental complications from a sepsis-induced nitric oxide and cytokine storm which subsequently leads to intractable hypotension, insufficient tissue perfusion, multiple organ failure and death<sup>[1-3,23]</sup>.

### Epidemiology and types of infection

Bacterial infection accounts for about 30%-50% death in patients with cirrhosis<sup>[3,24,25]</sup>. Infections present in 32%-34% of hospitalized patients with cirrhosis, which is 4-5 folds higher than hospitalized patients in general, and is especially higher in those with gastrointestinal bleeding (45%-60%)<sup>[26-28]</sup>.

Common types of infections in patients with cirrhosis include spontaneous bacterial peritonitis (SBP) (25%-31%), urinary tract infection (UTI) (20%-25%), pneumonia (15%-21%), bacteremia (12%), and soft tissue infection (11%)<sup>[2,27,29]</sup>. The major causative organisms are gram-negative bacteria, *e.g.*, *E. coli*, *Klebsiella* spp. and *Enterobacter* spp., whereas gram positive bacteria, especially *Enterococci* and *Staphylococcus aureus*, comprise about 20% and anaerobes only 3%<sup>[2]</sup>. Risk factors of infection by gram positive bacteria are recent or current hospitalization, receiving quinolones prophylaxis, and invasive procedures<sup>[27,28,30]</sup>.

Healthcare-associated is defined as infections diagnosed within 48 h of hospital admission in patients with any prior 90-d healthcare contact and nosocomial is defined as infections diagnosed after 48 h of admission.

These infections are increasingly common in cirrhosis, frequently resistant to antibiotics (up to 64%) and are associated with bad outcomes<sup>[30]</sup>. In a large prospective study of cirrhotic patients with infections (> 650 infectious episodes)<sup>[31]</sup>, multi-resistant bacteria (18%) were isolated in 4%, 14%, and 35% of community-acquired, healthcare-associated, and nosocomial infections, respectively ( $P < 0.001$ ). The main resistant organism was extended-spectrum  $\beta$ -lactamase (ESBL)-producing *Enterobacteriaceae*, followed by *Pseudomonas aeruginosa*, methicillin-resistant *Staphylococcus aureus* (MRSA), and *Enterococcus faecium*<sup>[31]</sup>. There was a significantly higher incidence of septic shock and death from infections caused by resistant bacteria. Notably, the efficacy of empirical antibiotic treatment was decreased in nosocomial infections (40%), compared to community-acquired and healthcare-associated episodes (83% and 73%, respectively;  $P < 0.0001$ ), especially in SBP, UTI, and pneumonia (26%, 29% and 44%, respectively)<sup>[31]</sup>. Due to an increasingly use of broad spectrum antibiotics (ATB), it is speculated that infections with multi-resistant gram-negative organisms and *Enterococci* will be largely more common and more problematic in the near future.

The common types of infections in cirrhosis and suggested empiric therapy are summarized in Table 2<sup>[32]</sup>. In addition, the common clinical features and risk factors of less common pathogens are summarized in Table 3<sup>[2]</sup>. It should be noted that the data regarding these less common pathogens derived from case reports and series from various regions of the world, in which the patterns of infection and ATB usage varies among reports. In real-life practice, empirical ATB should be selected based upon types of infection, individual risk factors, and the local epidemiological pattern of resistant bacteria, then narrow-downed according to the culture and ATB susceptibility testing.

**Table 2** Types of infection and suggested empirical antibiotic therapy in patients with cirrhosis

Types of infection	Common responsible bacteria	Suggested empirical antibiotic
SBP, spontaneous bacteremia, SBE	<i>Enterobacteriaceae</i> <i>S. pneumoniae</i> <i>S. viridans</i>	1 <sup>st</sup> line: Cefotaxime or ceftriaxone or BL-BI IV Options: Ciprofloxacin PO for uncomplicated SBP <sup>1</sup> ; carbapenems IV for nosocomial infections in areas with a high prevalence of ESBL BL-BI may prefer in those with suspicious for enterococcal infection <sup>2</sup>
Pneumonia	<i>Enterococci</i> <i>S. pneumoniae</i> <i>H. influenzae</i> <i>M. pneumoniae</i> <i>Legionella</i> spp. <i>Enterobacteriaceae</i> <i>P. aeruginosa</i> <i>S. aureus</i>	Community-acquired: ceftriaxone or BL-BI IV + macrolide or levofloxacin IV/PO Nosocomial and health care-associated infections: Meropenem or cefazidime IV + ciprofloxacin IV (IV vancomycin or linezolid should be added in patients with risk factors for MRSA <sup>3</sup> )
Urinary tract infection	<i>Enterobacteriaceae</i> <i>E. faecalis</i> <i>E. faecium</i>	1 <sup>st</sup> line: Ceftriaxone or BL-BI IV in patients with sepsis. Ciprofloxacin or cotrimoxazole PO in uncomplicated infections Options: In areas with a high prevalence of ESBL, IV carbapenems for nosocomial infections and sepsis (+ IV glycopeptides for severe sepsis); and nitrofurantoin PO for uncomplicated cases
Skin and soft tissue infections	<i>S. aureus</i> <i>S. pyogenes</i> <i>Enterobacteriaceae</i> <i>P. aeruginosa</i> <i>Vibrio vulnificus</i> <i>Aeromonas</i> spp.	Community-acquired: Ceftriaxone + cloxacillin IV or BL-BI IV Nosocomial: Meropenem or cefazidime IV + glycopeptides IV
Meningitis	<i>S. pneumoniae</i> <i>Enterobacteriaceae</i> <i>L. monocytogenes</i> <i>N. meningitidis</i>	Community-acquired: Cefotaxime or ceftriaxone IV + vancomycin IV Ampicillin IV should be added if <i>L. monocytogenes</i> is suspected <sup>4</sup> Nosocomial: Meropenem + vancomycin IV

### Biomarkers of bacterial infection in cirrhosis

It is crucial, but often difficult to make an early diagnosis of bacterial infections in cirrhosis due to non-specific manifestations, which are indistinguishable from other non-infectious causes of systemic inflammatory response syndrome (SIRS) and the symptoms of liver deterioration. Therefore, serum biomarkers that are sensitive, reliable and inexpensive are being pursued in order to improve the diagnosis of bacterial infection in the setting of cirrhosis. General inflammatory markers, such as C-reactive protein (CRP, synthesized by the liver), ferritin (synthesized by the liver) or white blood cells (WBC), lack specificity for bacterial infections. Procalcitonin (PCT) is potentially a more specific marker for bacterial infection. PCT is produced by nearly all tissues in response to endotoxin or mediators released in response to bacterial infections [interleukin (IL)-1b, tumor necrosis factor- $\alpha$ , and IL-6]. It highly correlates with the severity of bacterial infections and may be helpful to distinguish bacterial infections from viral infection or other non-infectious causes<sup>[33]</sup>.

In the meta-analysis included 10 diagnostic studies (1144 cirrhotic patients and 435 bacterial infection

episodes), PCT displayed an area under the curve of 0.92, a sensitivity of 0.79, and a specificity of 0.89 in diagnosing bacterial infection<sup>[34]</sup>. The pooled sensitivity estimates were 79% for PCT and 77% for CRP tests, whereas the pooled specificity were higher for both PCT (89%) and CRP tests (85%)<sup>[34]</sup>. The results were consistent when stratified to patients with SBP or patients with systemic infection. The authors suggested that the PCT test can be used as a rule-in diagnostic tool (positive likelihood ratio 7.38), CRP test can be used as a rule-out diagnostic tool (negative likelihood ratio 0.23) in patients without signs of infection<sup>[34]</sup>. However, the diagnostic accuracy of CRP in the detection of bacterial infections decreased in setting of advanced liver disease. The combination of CRP and PCT may slightly improve the diagnostic accuracy of bacterial infection<sup>[35]</sup>.

### SBP

#### Epidemiology and clinical features of SBP

SBP is common and quite unique in patients with cirrhosis. The prevalence of SBP in cirrhotic patients with ascites admitted to the hospital ranges from 10%-30%;

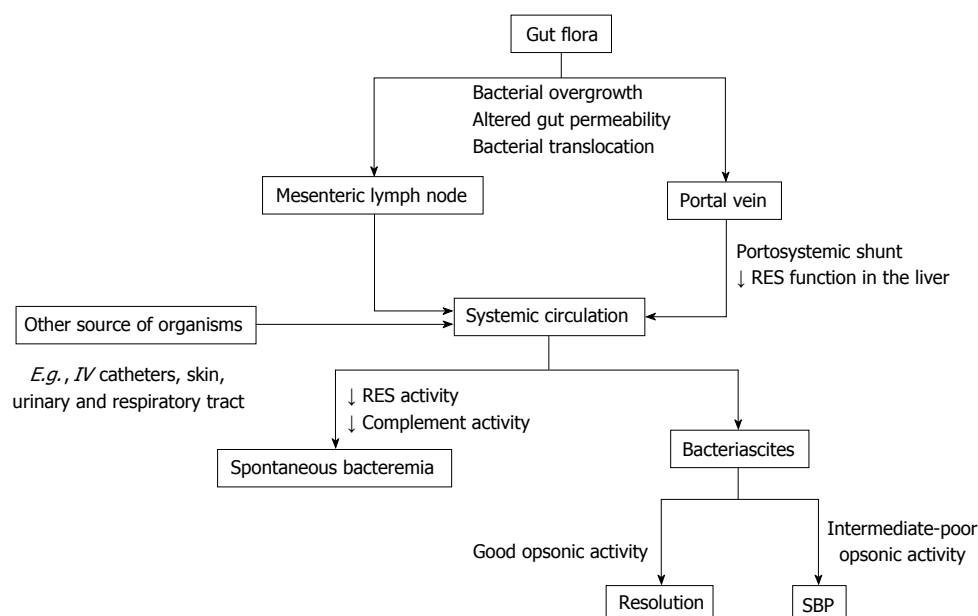

**Table 3** Common manifestations and risk factors of bacterial pathogens in patients with cirrhosis

Pathogens	Common clinical syndrome	Risk factors	Remarks
<i>Aeromonas</i> spp. ( <i>A. hydrophila</i> , <i>A. sobria</i> , <i>A. aquariorum</i> ) <sup>[120-126]</sup>	SBP, bacteremia, SSTI, enterocolitis	Contaminated food and water Diabetes	Increased incidence High mortality (20%-60%), especially when presence of hypotension on admission
<i>Campylobacter</i> spp. <sup>[127,128]</sup>	Bacteremia, SBP	Most reports were from East Asia Alcoholic	Increased incidence High mortality (10% in bacteremia)
<i>Clostridium</i> spp. ( <i>C. perfringens</i> , <i>C. bifermentans</i> , <i>C. septicum</i> ) <sup>[4,129,130]</sup>	SSTI	Diabetes	Increased incidence Very high mortality (54%-65%)
<i>Clostridium difficile</i> <sup>[108,131-133]</sup>	ATB-associated diarrhea and colitis	Broad-spectrum ATB Hospitalization PPIs	Increased incidence Higher mortality (14%) when compare to non-cirrhotics Increased cost and length of hospital stay
<i>Enterococcus</i> spp. ( <i>E. faecium</i> , <i>E. faecalis</i> , <i>E. gallinarum</i> ) <sup>[134-136]</sup>	SBP, bacteremia, UTI, endocarditis, biliary tract infection	Healthcare-associated infection Quinolone prophylaxis	Increased incidence High mortality (30% in bacteremia; 60% in SBP) Increased incidence of VRE colonization and infection in liver transplant setting
<i>Listeria monocytogenes</i> <sup>[137,138]</sup> <i>Mycobacterium</i> TB <sup>[2,139,140]</sup>	SBP, bacteremia, meningitis Pulmonary TB, TB peritonitis, TB lymphadenitis, disseminated TB	Hemochromatosis Alcoholic Developing countries Exposed to TB case	Increased incidence Increased incidence, especially extrapulmonary forms (> 50% of TB peritonitis cases in the United States had underlying cirrhosis) High mortality (22%-48%) Increased risk for multi-drug resistant TB Increased risk for anti-TB-induced hepatotoxicity
<i>Pasteurella multocida</i> <sup>[141-143]</sup>	SBP, bacteremia septic arthritis, meningitis	Presence of ascites (TB peritonitis) Domestic animal (cats or dogs) bites or scratches	Increased incidence High mortality (10%-40% in bacteremia)
<i>Staphylococcus aureus</i> <sup>[45,144,145]</sup>	SSTI, UTI, SBP, bacteremia, endocarditis	Alcoholic Invasive procedures Hospitalization	Increased incidence of MRSA carriage and infection High mortality (30% in bacteremia) Removal of the eradicable focus was associated with decreased mortality
<i>Streptococcus bovis</i> <sup>[146,147]</sup>	Bacteremia, SBP meningitis, endocarditis, septic arthritis	Quinolone prophylaxis Colonic lesion(s): Adenoma or adenocarcinoma (presence in 18%-40% of cases) Alcoholic	Increased incidence High mortality (up to 40% in bacteremia with advanced cirrhosis) Colonic lesion(s) was present in 18%-40% of cases
<i>Streptococcus group B</i> <sup>[148-150]</sup>	SSTI, bacteremia, SBP, meningitis, pneumonia	Post endoscopic sclerotherapy and banding ligation	Increased incidence High mortality (10%-25% in SBP and bacteremia; 45% in meningitis)
<i>Streptococcus pneumoniae</i> <sup>[89-92]</sup>	Pneumonia, SBP bacteremia, SSTI, meningitis	Alcoholic Post-splenectomy Not vaccinated	Increased incidence of invasive pneumococcal disease High mortality (10%-20%)
<i>Vibrio</i> spp. ( <i>V. vulnificus</i> , non-o1 <i>V. cholera</i> , <i>V. parahemolyticus</i> ) <sup>[151-153]</sup>	SSTI, bacteremia, gastroenteritis, diarrhea, SBP	Hemochromatosis Exposed to seawater and undercooked seafoods Most reports were from East Asia	Increased incidence Very high mortality (50%-60% in bacteremia; 24% in SSTI)
<i>Yersinia</i> spp. ( <i>Y. enterocolitica</i> , <i>Y. pseudotuberculosis</i> ) <sup>[154,155]</sup>	Bacteremia, SBP, hepatosplenic abscesses	Hemochromatosis Exposed to animals and contaminated foods	Increased incidence (in hemochromatosis) High mortality (50% in bacteremia)

SBP: Spontaneous bacterial peritonitis; SSTI: Skin and soft tissue infection; UTI: Urinary tract infection; ATB: Antibiotics; PPIs: Proton-pump inhibitors; TB: Tuberculosis; MRSA: Methicillin-resistant *Staphylococcus aureus*; *A. hydrophila*: *Aeromonas hydrophila*; *A. sobria*: *Aeromonas sobria*; *A. aquariorum*: *Aeromonas aquariorum*; *C. perfringens*: *Clostridium perfringens*; *C. bifermentans*: *Clostridium bifermentans*; *C. septicum*: *Clostridium septicum*; *E. faecium*: *Enterococcus faecium*; *E. faecalis*: *Enterococcus faecalis*; *E. gallinarum*: *Enterococcus gallinarum*; *Mycobacterium* TB: *Mycobacterium tuberculosis*; *V. vulnificus*: *Vibrio vulnificus*; *V. cholera*: *Vibrio cholera*; *V. parahemolyticus*: *Vibrio parahemolyticus*; *Y. enterocolitica*: *Yersinia enterocolitica*; *Y. pseudotuberculosis*: *Yersinia pseudotuberculosis*; VRE: Vancomycin-resistant *Enterococci*.

about 50% of cases are present at the time of hospitalization and 50% develop during the hospitalization<sup>[1,29,36]</sup>. BT, systemic, and local immune dysfunction, particularly a decreased opsonic activity in ascitic fluid, are the main elements in the pathogenesis of SBP<sup>[1,15,17,37]</sup> (Figure 1). Accordingly, gut microflora including *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Enterococci*, and *Streptococci* are common causative organisms<sup>[1,15,17,37]</sup>. The classical symptoms of SBP include fever, abdominal pain, and worsening of pre-existing ascites, although these

symptoms may be absent in up to one-third of cases<sup>[38]</sup>. Therefore, diagnostic paracentesis is recommended to perform in all cirrhotic patients with ascites at the time of admission and/or in case of gastrointestinal (GI) bleeding, shock, signs of inflammation, hepatic encephalopathy, worsening of liver or renal function<sup>[37,39-41]</sup>. The hospital mortality for SBP ranges from 10%-50% depending on various factors<sup>[37]</sup>. Predictors for poor prognosis in SBP include older age, higher Child-Pugh scores, nosocomial origin, encephalopathy, elevated serum creatinine

**Figure 1 Pathogenesis of spontaneous bacterial peritonitis and bacteremia (reproduced from Bonnel *et al*<sup>[41]</sup>. *Clin Gastroenterol Hepatol* 2011; 9: 729. With permission). SBP: Spontaneous bacterial peritonitis; RES: Reticuloendothelial system; IV: Intravenous.**

and bilirubin, ascites culture positivity, presence of bacteremia, and infections with resistant organisms<sup>[42-45]</sup>. Notably, the modifiable factors to reduce morbidity and mortality in SBP include prompt diagnosis, proper first-line ATB treatment and prevention of subsequent renal failure<sup>[37]</sup>. SBP is one of the important prognostic landmark in the natural course of cirrhosis as the overall one-year mortality rate after a first episode of SBP are 30%-93% regardless of its recurrence<sup>[37,46,47]</sup>.

### Diagnosis of SBP

The diagnosis of SBP is relied on the cell count of the ascitic fluid, determined either by microscope or appropriate automated cell counters, and bacterial culture<sup>[40,41,48]</sup>. Ascitic fluid culture is important and should be performed before initiating ATB therapy by bedside inoculation of ascites  $\geq 10$  mL into blood culture bottles<sup>[49]</sup>. Reagent strips to assess leucocyte esterase activity of activated polymorphonuclear cells (PMN) are not recommended for rapid diagnosis of SBP due to unacceptable false-negative rates<sup>[50]</sup>. To date, most of reagent strips (LERS) that had been evaluated were developed for UTI with a threshold of  $> 50$  PMN/mm<sup>3</sup><sup>[37]</sup>. More recently, ascites-calibrated reagent strips (cut-off of  $> 250$  PMN/mm<sup>3</sup>) have been introduced for SBP with promising preliminarily results<sup>[51]</sup>. Based on available evidences, LERS seem to have low sensitivity for SBP, but have reliably given a high negative predictive value ( $> 95\%$  in most studies), which supports the potential role of LERS as a screening tool for SBP<sup>[52]</sup>. In addition, neutrophil gelatinase-associated lipocalin (NGAL), a protein involved in iron metabolism and links to the inflammation, and bacterial DNA in ascitic fluid have the potential to improve the diagnosis of SBP. The pivot study of using NGAL to differentiate bacterial peritonitis (30% were SBP) from nonbacterial peritonitis reported

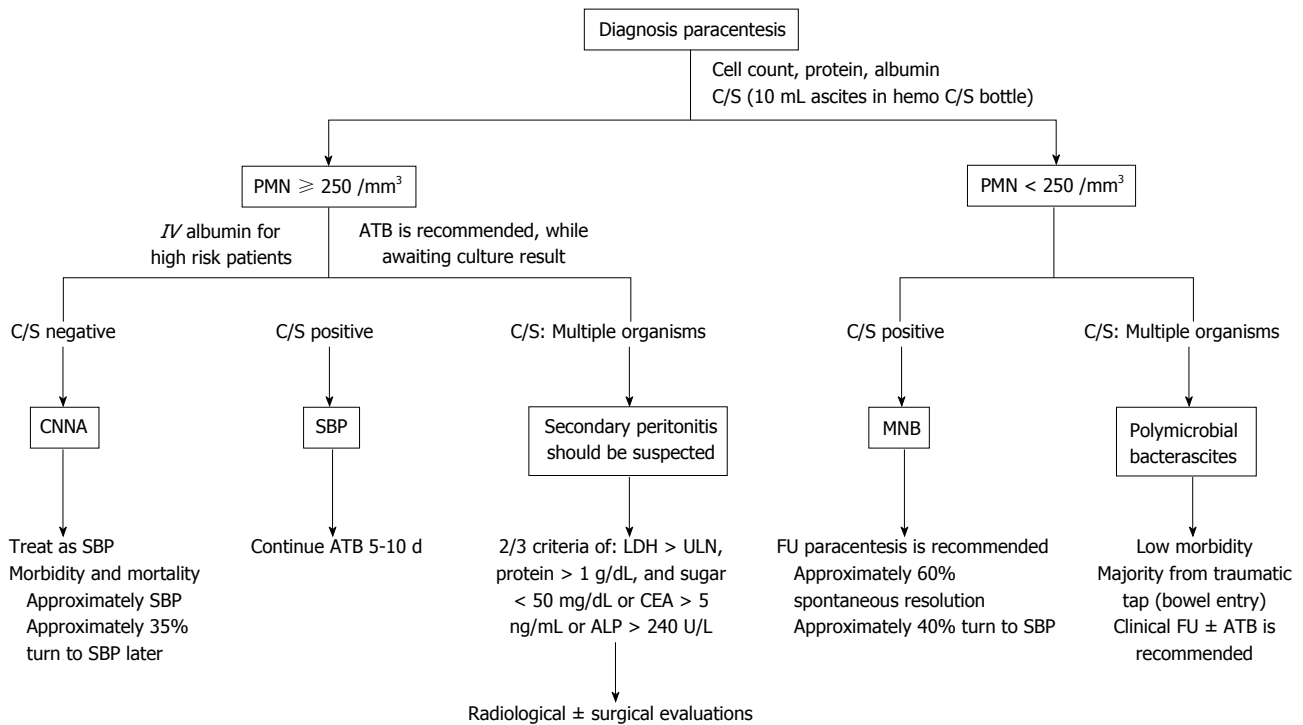

that AUC were 0.89 for NGAL and 0.94 for combination of NGAL and lactate dehydrogenase<sup>[53]</sup>. Detection of bacterial DNA by real-time polymerase chain reaction and sequencing of *16S rDNA* gene demonstrated poor results with negative results in almost half the culture-negative SBP episodes<sup>[54]</sup>. In contrast, another study using newly *in situ* hybridization method to detect global bacterial DNA demonstrated high sensitivity (91%) and specificity (100%) for detecting phagocytized bacterial DNA in the WBC of SBP ascites, with all test results obtained within one day<sup>[55]</sup>.

### Management of SBP

Empirical ATB should be given promptly to all cirrhotic patients with ascites PMN counts  $> 250$  cells/mm<sup>3</sup> in clinical settings that suggestive for ascitic fluid infection (culture results are often unavailable at this time)<sup>[40,41]</sup> (Figure 2). The choice of empirical ATB should be based on the origin of infection, individual risk factors for resistant organism and local microbial epidemiology. In general, the suggested initial treatments of community-acquired SBP are third-generation cephalosporins (mostly preferred), amoxicillin-clavulanate or quinolones (Table 2). These empirical ATB should be given intravenously for a duration of 5-10 d<sup>[40,41]</sup>. In countries with low rate of quinolone-resistant *Enterobacteriaceae*, oral quinolones may be used for uncomplicated SBP, as defined by cases without shock, ileus, GI bleeding, hepatic encephalopathy ( $\geq$  grade II) or renal impairment (creatinine  $> 3$  mg/dL)<sup>[56]</sup>. In nosocomial SBP, use of the antibiotics recommended above can be associated with unacceptable failure rates because resistance to third-generation cephalosporins (23%-44%) and quinolones (38%-50%) are increasingly reported<sup>[37,57,58]</sup>.

Notably, the incidence of SBP causing by with gram-positive and resistant bacteria (mainly ESBL-producing

**Figure 2** Algorithm for the management of cirrhotic patients with suspicious for ascitic fluid infection (adapted from Bonnel *et al*<sup>[1]</sup>. *Clin Gastroenterol Hepatol* 2011; 9: 732. With permission). PMN: Polymorphonuclear cells; SBP: Spontaneous bacterial peritonitis; ATB: Antibiotics; CNNA: Culture-negative neutrocytic ascites; MNB: Monobacterial non-neutrocytic bacterascites; LDH: Lactate dehydrogenase; CEA: Carcinoembryonic antigen; ALP: Alkaline phosphatase; ULN: Upper limit of normal; FU: Follow-up; C/S: Culture.

bacteria and multi-resistant gram-positive bacteria such as *Enterococci* or MRSA) has been increasingly reported in the healthcare associated and especially in nosocomial settings<sup>[37,57]</sup>. In patients with typical presentation and clinical improvement after ATB, a repeat of paracentesis is not necessary to assess for resolution of SBP<sup>[1,37,40,41]</sup>. However, in cases with questionable diagnosis or in those who did not satisfactorily improve with ATB, repeated paracentesis should be performed to document the response of treatment<sup>[37,40]</sup>. If the PMN count does not reduce by at least 25% after 2 d of ATB, changing treatment and/or reevaluation for other possible cause(s) of symptoms should be considered<sup>[37,59]</sup>.

Renal impairment develops in 30%-40% of SBP cases and is a strong predictor of death during hospitalization<sup>[39,40,60]</sup>. The use of intravenous albumin (1.5 g/kg within 6 h of SBP diagnosis followed by 1 g/kg on day 3) in conjunction with intravenous (IV) antibiotic was found to reduce the incidence of renal impairment from 33% to 10% and mortality from 29% to 10%<sup>[61]</sup>. Notably, albumin infusion was particularly effective in patients with baseline serum creatinine  $\geq 1$  mg/dL, blood urea nitrogen  $\geq 30$  mg/dL or bilirubin  $\geq 4$  mg/dL<sup>[39,61]</sup>. Unfortunately, albumin infusion in high-risk SBP has been underutilized, even in the United States, with > 50% of cases did not follow the guidelines<sup>[62]</sup>. It is unclear whether crystalloids or artificial colloids could replace albumin in this setting<sup>[39-41,63]</sup>.

### Prophylaxis of SBP

After recovering from SBP, the rate of recurrence is

around 43% at 6 mo and 69% at 1 year<sup>[46]</sup>. Therefore, secondary prophylaxis of SBP should be given indefinitely or until LT<sup>[37,40,61,64]</sup>. Intermittent dosing of prophylactic ATB may select resistant flora, thus daily dosing is preferred<sup>[37,40]</sup> (Table 4).

Primary prophylaxis of SBP is justified for patients with high risk for developing SBP. A meta-analysis of ATB prophylaxis in cirrhotic patients with GI hemorrhage (5 RCT;  $n = 534$ ) revealed 32% reduction of infections including SBP and/or bacteremia ( $P < 0.001$ ) and 9% increase in survival ( $P = 0.004$ )<sup>[28]</sup>. Further, a subsequent meta-analysis of 8 oral antibiotic trials ( $n = 647$ ) demonstrated 72% reduction in mortality at 3 mo; only 6 patients were additionally treated in order to prevent another death<sup>[65]</sup>. Oral norfloxacin is often utilized for primary prophylaxis in most settings, however IV ceftriaxone has been shown to be more effective than oral norfloxacin in patients with particularly advanced cirrhosis<sup>[66]</sup> (Table 4).

In cirrhotic patients with low ascitic fluid protein < 1.5 g/dL, the risk of developing a first episode of SBP is 13%-45% at 1 year<sup>[32,39]</sup>. However, several studies evaluating primary prophylaxis of SBP with norfloxacin in this setting yielded heterogeneous results<sup>[39]</sup>. Notably, a well-designed, randomized, controlled trial conducted in patients with severe liver disease and ascites protein < 1.5 g/dL without prior SBP demonstrated that norfloxacin (400 mg/d) reduced the development of SBP (from 61% to 7%) and improved survival at 1 year (from 48% to 60%)<sup>[67]</sup>. Notably, primary prophylactic ATB for SBP should be considered only for selected patients with

**Table 4** Vaccinations and other preventive measures for bacterial infections in patients with cirrhosis

Avoidance	
Raw/uncooked foods, especially seafood	
Close contact to at-risk animals or sick people	
Wound exposure to flood or seawater	
Vaccination <sup>[87]</sup>	
Influenza	Recommended yearly for all patients with chronic liver disease
Pneumococcal (polysaccharide)	Recommended for all cirrhotic patient Booster dose after 3-5 yr
Hepatitis A	Recommended for all non-immune, cirrhotic patient, 2 injections 6-12 mo apart Anti-HAV should be checked 1-2 mo after the second dose
Hepatitis B	Recommended for all cirrhotic patient without serological markers of HBV ( <i>e.g.</i> , negative HBsAg, anti-HBs, and anti-HBc antibodies) 3 injections (at month 0, 1 and 6) Anti-HBs should be checked 1-2 mo after the last dose Patients with advanced cirrhosis should receive 1 dose of 40 µg/mL (Recombivax HB) administered on a 3-dose schedule or 2 doses of 20 µg/mL (Engerix-B) administered simultaneously on a 4-dose schedule at 0, 1, 2 and 6 mo Recommendations are as same as general adult population
Other vaccines, <i>e.g.</i> , Td, Tdap, MMR, varicella	
Prophylactic antibiotics	
Secondary prophylaxis for SBP <sup>[32,41]</sup>	Recommended for all cirrhotic patients who recovered from SBP Norfloxacin 400 mg PO daily Alternatives: TMP/SMX 1 double-strength tablet or ciprofloxacin 500 mg PO daily
Primary prophylaxis in GI bleeding <sup>[32,41]</sup>	Recommended for all cirrhotic patients with GI hemorrhage Norfloxacin 400 mg PO twice daily or ceftriaxone 1 g IV daily for 7 d IV ceftriaxone is preferred, in patients with advanced cirrhosis as defined by the presence of at least two of the following: Ascites, severe malnutrition, encephalopathy or bilirubin > 3 mg/dL
Primary prophylaxis in patients with low ascitic fluid protein <sup>[32,41]</sup>	Recommended for cirrhotic patients with ascitic fluid protein < 1.5 g/dL and at least one of the following is present: Serum creatinine > 1.2 mg/dL, blood urea nitrogen > 25 mg/dL, serum sodium < 130 mEq/L or Child-Pugh > 9 points with bilirubin > 3 mg/dL
Prophylaxis before undergoing endoscopic and surgical procedures	Prophylactic antibiotics are recommended for the moderate-high risk invasive endoscopic or surgical procedures (choice of antibiotics should be individualized) Prophylactic antibiotics are not routinely recommended for diagnostic endoscopy, elective variceal band ligation or sclerotherapy, and abdominal paracentesis

HBV: Hepatitis B virus; SBP: Spontaneous bacterial peritonitis; Td: Tetanus-Diphtheria; Tdap: Tetanus-Diphtheria-Pertussis; MMR: Measles/Mumps/Rubella; GI: Gastrointestinal; TMP/SMX: Trimethoprim/sulfamethoxazole; PO: Per oral; IV: Intravenous.

advanced cirrhosis and ascitic fluid protein < 1.5 g/dL since more liberal use of these ATB in long-term would lead to subsequent infection by resistant bacteria as well as *Clostridium difficile*-associated diarrhea (Table 4)<sup>[39-41]</sup>.

### Consequences of bacterial infections in cirrhosis

Bacterial infections in cirrhosis are associated with poor outcomes (increased mortality about 4 folds)<sup>[47]</sup>. Both short- and long-term mortality rates of sepsis in cirrhotic patients are very high; 26%-44% of patients die within 1 mo after infection and another one-third die in 1 year<sup>[4,47]</sup>. The clinical predictors of death during or following infection are advanced liver disease, nosocomial origin, gastrointestinal hemorrhage, encephalopathy, liver cancer, presence of shock and organ failure (especially renal failure)<sup>[4,47]</sup>.

The suggested strategies for the management of cirrhotic patients with severe sepsis are discussed in depth in other articles<sup>[23,32,68,69]</sup>. Broad spectrum empirical ATB<sup>[70]</sup> and fluid resuscitation, with either crystalloids or colloids (albumin, gelatins or hydroxyethyl starches), should be promptly initiated and followed an early goal-directed therapy approach (stepwise emergent resuscitation with predefined goals to keep mean arterial pressure  $\geq$  65 mmHg, central venous

pressure between 8-12 mmHg, central venous oxygen saturation  $\geq$  70% and urine output  $\geq$  0.5 mL/kg per hour)<sup>[23,32,68]</sup>. Resuscitation with crystalloids requires more fluid to attain the same targets and results in more edema, particularly in cirrhotic patients with hypoalbuminemia<sup>[32]</sup>. The benefit of resuscitation with albumin in non-cirrhotic patients with sepsis has been reported<sup>[71]</sup>. However, the role of albumin infusion for sepsis other than from SBP in cirrhosis is still unclear. The RCT from Spain found beneficial effects on renal and circulatory functions with a potential benefit on survival<sup>[72]</sup>. Conversely, more recent RCT from France reported that albumin delayed the onset of renal failure, but did not significantly improve 3-mo renal failure and survival rates. Thus, pulmonary edema developed in 8% of patients in the albumin group<sup>[73]</sup>. Norepinephrine and dopamine have been considered as the first-choice vasopressor agents in patients with septic shock<sup>[23,32,68,69]</sup>. Cirrhotic patients with septic shock are often associated with vascular hyporeactivity to these vasopressor agents. Thus, inotropic drugs are not generally effective since they already present high cardiac outputs<sup>[23,32,68]</sup>. Relative adrenal insufficiency is common (51%-77%) in cirrhotic patients with septic shock, however the effects of corticosteroids on such patients' outcomes

are unclear<sup>[23,32,68]</sup>. Therefore, stress dose corticosteroid is currently recommended only for patients with vasopressor-unresponsive septic shock<sup>[23,32,68]</sup>. Blood sugar should be maintained in the range of 140-180 mg/dL<sup>[69]</sup>.

Acute kidney injury following infections develop in 27%-34% of patients with advanced cirrhosis<sup>[2,61,74,75]</sup>, and is a strong predictor of death (40%-50% mortality)<sup>[47,74,75]</sup>. Risk factors for infection-induced renal failure in cirrhosis include advanced liver disease<sup>[74-76]</sup>, pre-existing kidney disease<sup>[76]</sup>, hypovolemia or low cardiac output<sup>[2,75]</sup>, unresolved infection<sup>[74]</sup> and not receiving prompt albumin infusion<sup>[61]</sup>. It should be noted that most studies that reported poor survival in patients with infection-induced renal failure have defined renal failure as a serum creatinine level of > 1.5 mg/dL. Recently, the International Ascites Club and the Acute Dialysis Quality Initiative group proposed that acute kidney injury (AKI) in cirrhosis should be redefined as an increase in serum creatinine level of 0.3 mg/dL in less than 48 h or a 50% increase in serum creatinine level from a stable baseline reading within the previous 6 mo, irrespective of the final serum creatinine level<sup>[77,78]</sup>. This new definition was then evaluated and found to accurately predict 30-d mortality in patients with cirrhosis and infection (10-fold higher among those with irreversible AKI than those without AKI)<sup>[79]</sup>. Renal failure during infection (without septic shock) that does not respond to albumin infusion is considered hepatorenal syndrome<sup>[80]</sup>.

Bacterial infection can trigger a rapid deterioration of liver functions in patients with cirrhosis and it is one of the most common precipitating cause of ACLF, which represents > 30% of the cases<sup>[3,23,81,82]</sup>. The most common sites of bacterial infection are ascites and lungs<sup>[81]</sup>. Moreover, infections were the second most common cause of death at 28 d among patients with ACLF (28%), behind multiple organ failure without septic or hypovolemic shock (44%). However, there was no difference in 28 d mortality among ACLF patients with or without the bacterial infection at admission (37% and 33%, respectively)<sup>[81]</sup>. Independent predictors of poor survival in patients with bacterial infections and ACLF were presence of organ(s) failure, second infections, admission values of high MELD, low blood pressure, leukocytosis, and low albumin<sup>[83]</sup>.

Pulmonary complications are commonly observed in cirrhotic patients with infections. Aspiration is common in encephalopathic patients. Acute respiratory distress syndrome is increasingly seen in cirrhosis that may develop in association with exaggerated SIRS in severe sepsis<sup>[84]</sup>. Prognosis of cirrhotic patients with respiratory failure is poor, with a mortality rate up to 33%-60%<sup>[69,85]</sup>. Additionally, sepsis-induced cytokines can further worsen pre-existing coagulation and platelet abnormalities in patients with cirrhosis<sup>[2,24]</sup>.

### Prevention measures

Preventive measures must be emphasized to all patients with cirrhosis and prophylactic ATB is suggested for

those who are at high risk of developing infections (Table 4)<sup>[2]</sup>. Notably, antibiotic prophylaxis has been associated with the development of multi-drug resistant bacteria and *C. difficile* infection. Therefore it should be judiciously used in those patients with proper indications.

Active immunization against hepatitis A and B viruses, influenza and pneumococcus are recommended since these preventable infections carry accompanied by higher morbidity and mortality in patients with cirrhosis (Table 4)<sup>[86-88]</sup>. Both cellular and humoral immune responses are suboptimal in cirrhosis, particularly in the advanced stage, which can be associated with inadequate post-vaccination antibody response, as well as loss of immunogenicity in the long-term<sup>[86-88]</sup>. Therefore, it is important to address immunization needs in patients with chronic liver disease or compensated cirrhosis early on, when immunizations are most effective.

Although there is no clear recommendation whether we can safely utilize live and attenuated vaccines in patients with cirrhosis, inactivated or killed-type vaccinations are generally preferable<sup>[86-88]</sup>. The incidence and severity of *Streptococcus pneumoniae* infections are increased in patients with cirrhosis<sup>[89-92]</sup>. Pneumococcal vaccination is less effective in patients with cirrhosis, with a further decline in protective antibodies after LT<sup>[93]</sup>. It is therefore recommended with booster doses every 5 years<sup>[86-88]</sup>. Incidence of seasonal flu is not obviously increased in cirrhosis; however, influenza may precipitate liver decompensation<sup>[86,87,94]</sup>. Influenza vaccine is well-tolerated and effective in cirrhotic patients, despite a mildly decreased immunogenicity<sup>[95,96]</sup>. All other vaccinations recommended for general adult population are also indicated in patients with cirrhosis as the Centers for Disease Control and Prevention recommendation for adults<sup>[97]</sup>.

### Proton pump inhibitors and the risk of infections in cirrhosis

Proton pump inhibitors (PPIs) have been widely used in patients with cirrhosis (sometimes over-utilized)<sup>[98]</sup>. Patients with cirrhosis have high prevalence of gastroduodenal mucosal lesions<sup>[99,100]</sup> and are associated with increased mortality rate from peptic ulcer bleeding (adjusted OR = 3.3; 95%CI: 2.2-4.9)<sup>[101]</sup>. However, clear evidence for a protective role of PPIs in cirrhosis is limited.

A state of gastric acid suppression induced by PPIs, particularly in long-term users, is known to be associated with small bowel bacterial overgrowth, alteration of gut flora and reduction of gastrointestinal motility<sup>[102-104]</sup>. By these effects, PPIs may enhance BT and possibly increase the risk of various infections in patients with cirrhosis. In addition, impairment of neutrophil function caused by PPIs has also been reported<sup>[105-107]</sup>. There have been several studies, including case-control, retrospective and prospective cohorts, and meta-analyses, suggesting that PPIs are associated with increased risk of bacterial infections, such as SBP, bacteremia, *Clostridium difficile*-associated diarrhea, and enteric

**Table 5** Studies demonstrated risk of bacterial infections in cirrhotic patients receiving proton pump inhibitors

Ref.	Design	n	Results
Campbell <i>et al</i> <sup>[116]</sup>	Case-control	116	NS for SBP (OR = 1.05; 95%CI: 0.43-2.57)
Bajaj <i>et al</i> <sup>[108]</sup>	Case-control	83230	PPI use were significantly higher in those with CDAD (74% vs 31%, <i>P</i> = 0.0001)
Bajaj <i>et al</i> <sup>[112]</sup>	Retrospective, propensity-matched	1268	↑ Serious infections (HR = 1.66; 95%CI: 1.31-2.12)
de Vos <i>et al</i> <sup>[119]</sup>	Case-control	102	PPI were more frequently used in SBP patients than in controls, but did not influence prognosis of SBP
Min <i>et al</i> <sup>[113]</sup>	Retrospective cohort	1554	↑ SBP (HR = 1.39; 95%CI: 1.057-1.843)
Mandorfer <i>et al</i> <sup>[117]</sup>	Retrospective	607	PPI neither predisposes to SBP (HR = 1.38; 95%CI: 0.63-3.01) or other infections (HR = 1.71; 95%CI: 0.85-3.44)
Terg <i>et al</i> <sup>[118]</sup>	Prospective	770	PPI therapy was not associated with a higher risk of SBP and other infections
Merli <i>et al</i> <sup>[114]</sup>	Cross-sectional	400	↑ Bacterial infections (OR = 2; 95%CI: 1.2-3.2)
O'Leary <i>et al</i> <sup>[115]</sup>	Prospective	188	↑ Infections: CDAD and SBP (OR = 2.94; 95%CI: 1.39-6.20)

NS: Not significance; SBP: Spontaneous bacterial peritonitis; PPI: Proton pump inhibitor; CDAD: Clostridium difficile associate disease.

infections, in patients with cirrhosis<sup>[108-115]</sup>. However, the association between PPIs and infections in cirrhosis remains somewhat controversial since many studies have reported conflicting results<sup>[116-119]</sup> (Table 5). Though randomized controlled studies are required to draw firm conclusions whether or not PPIs increase infections in cirrhosis, PPI should be used only if clinically indicated.

## ACKNOWLEDGMENTS

The authors are grateful to Professor K Rajender Reddy at the University of Pennsylvania, PA, United States for supportive guidance.

### Abstract

**AIM:** To investigate effects of severe burn injury (BI) in rat liver through the histopathological and inflammatory markers analysis.

**METHODS:** Forty-two male Wistar rats were distributed into two groups, control (C) and subjected to scald BI (SBI). The animals were euthanized one, four and 14 d post sham or 45% of the total body surface BI. Liver fragments were submitted to histopathological, morphoquantitative (hepatocyte area and cell density), ciclooxigenase-2 (COX-2) immunoexpression, and gene expression [real-time polymerase chain reaction for tumor necrosis factor (TNF)- $\alpha$ , inducible nitric oxide synthase (iNOS) and caspase-3] methods.

**RESULTS:** Histopathological findings showed inflammatory process in all periods investigated and hepatocyte degeneration added to increased amount of connective tissue 14 d post injury. Hepatocyte area, the density of binucleated hepatocytes and density of sinusoidal cells of SBI groups were increased when compared with control. COX-2 immunoexpression was stronger in SBI groups. No differences were found in TNF- $\alpha$ , iNOS and caspase-3 gene expression.

**CONCLUSION:** BI induces histopathological changes, upregulation of COX-2 immunoexpression, and cell proliferation in liver of rats.

**Key words:** Burn injury; Morphology; Histopathology; Liver; Cyclooxygenase-2

**Core tip:** Severe burn injuries result in serious complications that involve host response related to inflammation and multiple organ dysfunction. The goal of this study was to investigate the temporal effects of extensive experimental burn injury (BI) in rat liver through the histopathological and morphoquantitative aspects, immunoexpression of cyclooxygenase-2 (COX-2) and liver gene expression of tumor necrosis factor- $\alpha$ , inducible nitric oxide synthase and caspase-3. Our results revealed that BI induces histopathological changes, upregulation of COX-2 immunoexpression, and cell proliferation in liver of rats.

Burn injury induces histopathological changes and cell proliferation in liver of rats. *World J Hepatol* 2016; 8(6): 322-330 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i6/322.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i6.322>

## INTRODUCTION

Burn injuries (BIs) represent one of the greatest public health problems, which induce to significant patient morbidity and mortality<sup>[1]</sup>. Scalds are most common cause of BI and preferentially occurs in children under the five years<sup>[2]</sup>. In pediatric patient population persistent protein catabolism may lead to delay in growth for up to 2 years after burn<sup>[3]</sup>.

Severe BI greater than 40% is a process that involves several host responses, including organ damage by inflammation and immune response<sup>[4]</sup>. Hypermetabolism is characterized by the inflammatory response, negative nitrogen balance, increase in resting energy consumption, and alterations in glucose and lipid metabolism<sup>[5]</sup>. Excessive systemic inflammatory response syndrome (SIRS) following burns to damage distant organ and provoke multiple organ dysfunction syndrome<sup>[6]</sup>.

According to Jeschke *et al.*<sup>[7]</sup> liver has been shown to play a crucial role after a BI. In a study of 102 children, the authors found that liver size and weight increased during the first week post BI, peaked at 2 wk post burn, and remained increased at 6, 9 and 12 mo after trauma. In autopsy of severely burned pediatric patients hepatomegaly with fatty infiltration was related to elevated occurrence of sepsis and mortality<sup>[8]</sup>. Jeschke *et al.*<sup>[9]</sup> showed liver weight was increased by 140% to 150% compared with estimated liver weight at 6, 9 and 12 mo post BI, indicating prolonged alterations in hepato-structure.

Apoptosis from liver cells was evaluated by terminal

deoxyuridine nick end labeling (TUNEL) assay in rats that have severe BI greater than 40% total body surface area<sup>[10]</sup>. Moreover, compensatory hepatocyte proliferation is detected due to increased apoptosis<sup>[7]</sup>.

Severe BI is associated with host responses related to inflammation and apoptotic process and liver clearly plays an important role in metabolic processes post burn. The present study proposes to investigate effects of severe BI in liver of rats through the histopathological and morphoquantitative aspects, immunoexpression of cyclooxygenase-2 (COX-2) and liver gene expression of tumor necrosis factor (TNF)- $\alpha$ , inducible nitric oxide synthase (iNOS) and caspase-3.

## MATERIALS AND METHODS

### Experimental design

Male Wistar rats ( $n = 42$ ), *Rattus Norvegicus*, with 21-d-old was chosen in the present study to mimic a developing organism. The rats were individually housed cages for five days, distributed into two groups: Control (C) and subjected to scald BI (SBI). The temperature room was controlled (22 °C) with regular light-dark cycle with 12 h, water and food were offered ad libitum. On the sixth day, the animals were anesthetized with an intraperitoneal (IP) injection of Ketamine (50 mg/mL) and Xilazine (10 mg/mL) and dorsal and ventral hair were removed. The group SBI ( $n = 21$ ) was submitted to nonlethal scald BI by immersing 45% of each rat's body, in 87 °C water as described by Walker *et al.*<sup>[11]</sup>. The C group ( $n = 21$ ) were submitted to sham of the SBI. Each animal had 30% of its dorsal and 15% of ventral area exposed to SBI for 10 and 3 s, respectively<sup>[12]</sup>. The rats in both groups were subcutaneously injected with the analgesic Buprenorphine (0.2 mg/kg) immediately after sham or SBI and again 24 h later. One, 4 and 14 d following the SBI, all animals from each group were euthanized with a lethal IP injection of Ketamine (150 mg/kg) and Xilazine (30 mg/kg).

### Compliance with ethical requirements

All institutional and national guidelines for the care and use of laboratory animals were followed. The procedures were approved by the Committee of Ethics and Research from Federal University of São Paulo (protocol No. 329/12).

### Histopathological and morphoquantitative analysis

Liver of euthanized rats from SBI and C groups were examined. The specimens was immediately fixed in 10% formalin phosphate buffer for 24 h for histological analyzes and routinely embedded in paraffin blocks and cut in transversal sections (4  $\mu$ m). The slides were stained with hematoxylin and eosin (H and E) and Sirius Red<sup>[13]</sup>, whose photomicrographs were made under normal and polarized light to differentiate type I (red and yellow) and III (green) collagen.

The hepatocyte area ( $\mu$ m<sup>2</sup>) was determined from

**Table 1** Primers sequences

Gene	Forward	Reverse
TNF- $\alpha$	5'-CCCAGAAAAGCAAGCAACCA-3'	5'-GCCTCGGGCCAGTGTATG-3'
Caspase-3	5'-TCTACCGCACCCGGTTACTA-3'	5'-TGTCGTCAATGCCACCACTG-3'
GAPDH	5'-GCTCTCTGCTCCTCCCTGTTTC-3'	5'-GACGCTGGCACTGCACAA-3'

TNF- $\alpha$ : Tumor necrosis factor- $\alpha$ ; GAPDH: Glyceraldehyde-3-Phosphate Dehydrogenase.

the measurement of 50 cells stained with H and E per animal. These fibers were randomly chosen from each animal comprising each experimental group. The cell density (number of cells/mm<sup>2</sup>) was determined as described by Mandarim-de-Lacerda *et al.*<sup>[14]</sup>. For this purpose, it was used five sections chosen randomly and stained with H and E and two fields of each section was analyzed, totaling ten photomicrographs per animal. It was determinate the density of mononucleated hepatocytes, binucleated hepatocytes and sinusoidal cells. For to investigate the hepatocyte area and density, it was used a computerized imaging equipment (Axio Visio 4.5 - Zeiss®) attached to a binocular microscope (Axio Observer D1, Zeiss®) with a 63 × objective.

### COX-2 immunohistochemical analysis

The paraffin of liver sections (4  $\mu$ m) was removed with xylene and cuts were rehydrated in graded ethanol, after pre-treated with 0.01 mol/L citric acid buffer (pH 6) in a microwave for 15 min at 850 W for antigen retrieval. The sections were pre-incubated for 5 min in 0.3% hydrogen peroxide in phosphate buffered saline (PBS) solution to inactive the endogenous peroxidase. Then the material blocked was with 5% normal goat serum in PBS solution for 10 min and then incubated with anti-COX-2 polyclonal primary antibody (Santa Cruz Biotechnology, Santa Cruz, CA), at concentration of 1:200. Sections were incubated overnight at 4 °C in a refrigerator. After this was washes in PBS and incubated with biotin conjugated secondary antibody anti-rabbit IgG (Vector Laboratories, Burlingame, CA) at a concentration of 1:200 in PBS for 30 min, washed with PBS. Followed by the application of avidin-biotin complex conjugated to peroxidase (Vector Laboratories) for 30 min. Then continued with the application of a 0.05% solution of 3-3-diaminobenzidine solution and counterstained with Harris hematoxylin (Merck).

### Real-time polymerase chain reaction for TNF- $\alpha$ and caspase-3

Liver of animals was homogenized with 1 mL Trizol® (Invitrogen®, CA, United States), was added chloroform, isopropanol and ethanol 75% and centrifuged. In 40  $\mu$ L of DEPC-treated water the pellet formed was re-suspended. The RNA purity and integrity were guaranteed by optical density (260/280 nm ratio > 1.9; Nanodrop® 2000 c, Thermo Scientific, Canada). Successively, the samples were kept in -80 °C. And were treated with DNAase (deoxyribonuclease I Amp Grade®, Invitrogen®, CA, United States) as fixed by the

producer. The total RNA extraction was according with the protocol adapted by Chomczynski *et al.*<sup>[15]</sup>.

The total RNA was treated with DNAase and was built the cDNA by reverse transcriptase [real-time polymerase chain reaction (RT-PCR)], with the High-Capacity cDNA kit Reverser Transcription® (Applied Biosystems®, United States). The primers previously designed for genes of interest and endogenous control (Glyceraldehyde-3-Phosphate Dehydrogenase) were used for gene expression analysis and the detection of amplification was through intercalating DNA (Sybr Green®, Applied Biosystems®, United States). The primers sequences are show in the Table 1.

The samples in duplicate are pipetted on the equipment RT-PCR 7500 Fast (Applied Biosystems®, United States) and subsequent the program of cycling was selected: Holding stage -95 °C for 10 min, 30 cycles of 15 s at 95 °C and 60 °C for 1 min, finish with the melting curve: 95 °C for 15 s, 60 °C for 1 min and 95 °C for 15 s. The results were acquired by relative quantification (method2<sup>- $\Delta\Delta$ Ct</sup>) at which the Cycle-threshold (Ct) values obtained for C group was compared to the SBI group.

### Statistical analysis

Statistical analysis for hepatocyte area, cell density and RT-PCR were evaluated by analysis of variance with two factors (group and time), and followed with a Tukey's test for multiple comparisons, when necessary.  $P < 0.05$  was considered to statistical significance.

## RESULTS

### Histopathological and morphoquantitative analysis

Liver cuts from Control group revealed hepatocytes arranged equidistantly with sinusoidal cells distributed in sinusoidal space (Figure 1A-C). Histopathological evaluation of SBI group investigated one day post injury revealed the presence of erythrocytes in sinusoidal space associated with inflammatory infiltrate (Figure 1D). Four days after injury, an increased sinusoidal space persisted (Figure 1E) and fourteen days post injury, liver sections showed inflammatory cells rounding hepatocytes in degeneration (Figure 1F).

SBI group following 14 d after lesion exhibited increase in connective tissue in the hepatic parenchyma (Figure 2C and D) when compared with controls (Figure 2A and B). The data concerning SBI group 1 and 4 d post BI not have been present for the reason that similar to control groups. Under polarized light connective tissue analysis showed type III collagen (green) preponderance.

**Figure 1** Sections of rat liver stained with hematoxylin and eosin; panels show groups control (A-C) and submitted to scald burn injury (D-F) evaluated in different periods. A-C: Hepatocytes and sinusoidal cells with normal aspect; D: Sinusoidal space filled by erythrocytes (arrows) and inflammatory infiltrate; E: Sinusoidal space increased (arrows); F: Sinusoidal space increased and inflammatory cells rounding hepatocytes in degeneration process (arrows). SBI: Scald burn injury.

**Figure 2** Liver sections stained with Sirius Red with normal (B, D, F and G) and polarized light (A, C, E and H). Panels show control group 14 d after sham (A and B) or burn injury (C-H). Notes connective tissue was increased in SBI group when compared with Control. SBI: Scald burn injury.

**Figure 3** Mean + SD of hepatocyte area. <sup>a</sup> $P < 0.05$  - hepatocyte area of SBI group increased than control; <sup>c</sup> $P < 0.05$  - animals with 14 d sham or post burn injury showed hepatocyte larger than other periods investigated. SBI: Scald burn injury.

Further details in increased magnification of SBI group are demonstrated in Figure 2E-H.

Hepatocytes area was significantly higher in the SBI group investigated 4 and 14 d after BI (Figure 3). Moreover, the mean of cells area in animals with 14 d was statistically larger than 1 and 4 d post BI.

In relation to cell density (cells number/mm<sup>2</sup>) represented in Figure 4, mononucleated hepatocyte density decrease in SBI groups 1 and 14 d post BI ( $P < 0.05$ ). Binucleated hepatocyte density in SBI groups showed significantly decreased cell density one day post injury and increased cell density in 4 and 14 d after BI when compared with respectively controls. Sinusoidal cells presented significantly increased cell density for SBI group in all periods investigated.

### COX-2 immunohistochemistry

COX-2 immunoexpression was encountered in the cytoplasm of hepatocytes. Control groups presented weak immunoexpression for all periods investigated in this setting. However a strong and focal immunoexpression was detected in SBI groups after 1 and 4 d and persisted weakly 14 d post BI (Figure 5).

### RT-PCR for TNF- $\alpha$ , iNOS and caspase-3

TNF- $\alpha$  and iNOS, related to inflammation, and caspase-3 related to apoptosis, were evaluated in liver (Figure 6). The results showed no statistically differences between control and SBI groups for all periods investigated.

## DISCUSSION

Extensive burn injuries outcomes in critical complications that involve host response related to SIRS and multiple organ dysfunction being liver as a putative target-organ. The dynamic of organism adaptation as a result of liver response of hypermetabolism has been recognized in numerous studies but molecular

and morphological occurrences still need to be better clarified. The aim of this paper was to investigate effects of severe BI in rat liver through the histopathological and morphoquantitative aspects, immunoexpression of COX-2 and liver gene expression of TNF- $\alpha$ , iNOS and caspase-3.

The results showed morphological alterations in liver such as sinusoidal space filled by erythrocytes and inflammatory infiltrate associated with hepatocytes in degeneration following 14 d post injury. Damage resulting from severe BI initiates a SIRS as far as serious metabolic disturbances. Systemic signs manifested in the first hours post severe burns is related to enlarged systemic capillary permeability with protein escapement into the interstitial space<sup>[16]</sup>. Burns greater than 40% of body surface area commonly are followed by stress, inflammation, hypermetabolism, in addition the circulatory response associated to altered glycolysis, proteolysis, glycogenolysis, gluconeogenesis and lipolysis<sup>[9]</sup>. Our current results are consistent with this stress response of liver after BI.

BI causes liver injury which persists over a prolonged time. In children, at 6, 9 and 12 mo post burn, liver weight was incremented by 140% to 150% compared with estimated liver weight, showing longstanding alterations in liver morphology up to 12 mo after BI<sup>[7,9]</sup>. Morphoquantitative aspects on hepatocytes investigated in this setting detected increased hepatocyte area 4 and 14 d after BI in SBI group. Additionally, hepatocyte proliferation was present as result of increased binucleated hepatocyte density (number of cells/mm<sup>2</sup>) 4 and 14 d post BI. These data show that despite liver increase weight gain is caused by edema formation<sup>[7]</sup>, hepatocyte area gain and proliferation should be an important factor for hepatomegaly in burns. The compensatory hepatic cell proliferation are related to liver necrosis and liver apoptosis<sup>[10]</sup> but the underlying mechanisms, in which extensive burn provoke apoptosis in hepatocytes are not established so far<sup>[7]</sup>. This requires further study.

Regarding binucleated hepatocyte density, it is important to emphasize that because mitotic figures do not occur in adult liver, binucleated cells are usually assumed to be result of amitosis which implies splitting of the nucleus and these amitosis has been associated both with replacement of aged cells in abnormal tissue and with regenerative growth after injury<sup>[17]</sup>. Although binucleated hepatocytes are present in both groups (C and SBI), the presence of binucleated hepatocytes in SBI groups are related to regenerative growth as a response of skin BI. Interestingly mononucleated hepatocyte density decrease in SBI groups 1 and 14 d after trauma probably related to degeneration process showed in histopathological findings.

To further elucidate the molecular mechanisms induced by cutaneous BI, caspase-3 gene expression was evaluated in liver and no remarkable differences between groups were detected. Studies using TUNEL assay in liver of post BI experimental models showed apoptosis process<sup>[9,10]</sup>. Jayaraman *et al.*<sup>[18]</sup> related that

**Figure 4** Mean + SD of cell density (number of cells/mm<sup>2</sup>). Cell density of mononucleated hepatocytes (A), binucleated hepatocytes (B) and sinusoidal cells (C). <sup>a</sup>*P* < 0.05, SBI different from control. SBI: Scald burn injury; C: Control.

the up-regulation of some acute-phase genes as STAT3, leptin receptor and HNF4 $\alpha$ , are related to infection 7 d post injury in 20% of total body surface area in rats, suggesting bacterial infection of the wound post BI in animals. These authors showed up-regulation of Birc4, a protein that block caspase-3 and caspase-7 that are associated to apoptosis post burn. In this way, the present study suggests that the proliferation of hepatocytes cells was due to inflammatory process following necrosis. Following hepatocyte death, growth factors are secreted, and hepatocyte proliferation is triggered in liver.

Post BI, liver modulates the immune responses and the inflammatory processes. Protein catabolism owing to extensive BI is all guided by systemic inflammatory response, with enhanced activation of pro-inflammatory cytokines<sup>[19]</sup>. In a local investigation of liver, inflammatory infiltrate was viewed in histopathological findings and confirmed with immunohistochemical investigation a result of strong and focal immunoexpression COX-2 in SBI group. COX-2 is responsible for the conversion of arachidonic acid to prostaglandins<sup>[20]</sup>. Although severe burn in children is related to increased blood cytokine levels<sup>[21]</sup>, experimental studies with murine model

**Figure 5 Liver cyclooxygenase-2 immunohistochemistry.** Control (A-C) and SBI (D-F) evaluated 1, 4 or 14 d after burn injury. Notes stronger cytoplasmic immunoreactivity in SBI groups when compared with control. SBI: Scald burn injury; COX-2: Cyclooxygenase-2.

**Figure 6 Mean + SD of liver tumor necrosis factor- $\alpha$ , inducible nitric oxide synthase and caspase-3 mRNA expression.** TNF- $\alpha$ : Tumor necrosis factor- $\alpha$ ; iNOS: Inducible nitric oxide synthase; C: Control; SBI: Scald burn injury.

submitted to BI for water vapor of 18% of the body surface showed enhanced expression of TNF- $\alpha$  and iNOS in initial stages of BI evaluated by means of peritoneal fluid of RT-PCR analysis<sup>[22]</sup>. Conversely, the present investigation of these inflammatory mediators (directly on the liver and not in a corporal fluid evaluation) showed no differences between groups.

Liver sinusoidal endothelial cells (LSECs) provide liver regeneration post injury of this organ<sup>[23]</sup>. In the sinusoidal space, there are four cell types: LSECs, Kupffer cells, stellate cells and pit cells. Kupffer cells

generate cytokines and pro-inflammatory factors that stimulate neutrophils activation and change sinusoids porosity and may lead to cirrhosis<sup>[24]</sup>. Herein, LSECs and Kupffer cells constitute the hepatic reticuloendothelial system<sup>[25]</sup>. In the present study the density of sinusoidal cells was significantly increased in SBI group for all periods when compared with controls. This should be associated to phagocytic activity of Kupffer cells since local inflammation, erythrocytes invasion activation of neutrophils and disturbance of porosity in the sinusoids walls leading to erythrocytes invasion of sinusoidal space. Severe haemolysis was observed immediately after BI<sup>[26]</sup>. LSECs are separated from liver parenchyma by space of Disse, which is represented for a perisinusoidal extravascular space. Space of Disse contains collagen type I, III, V and VI and the changes related with perisinusoidal basal lamina in livers, should increase collagen deposition in the space of Disse<sup>[25]</sup>. Furthermore, agglomeration of connective tissue inside the space of Disse may obstruct the normal traffic between blood and hepatocytes, reducing the release of macromolecules, diffculting the interaction between cells and leading to a liver dysfunction<sup>[27]</sup>.

Hepatocyte growth factor (HGF) develops a key function in cell regeneration, motility, growth and morphogenesis. Hepatic stellate cells provide as the main source of HGF in liver, however, after lesion, HGF expression is increased in LSECs<sup>[23,28]</sup>. In addition, hepatic stellate cells activated may initiate liver fibrosis process. Healthy LSECs inhibit the activation of hepatic stellate

cells<sup>[23]</sup>. In this study, increased density of sinusoidal cells should be related with enhanced of accumulation of the collagen, specially type III, in hepatic parenchyma in SBI animals when compared with controls 14 d after injury.

In conclusion, severe burn in greater than 40% of the body surface induces, in liver, histopathological changes, inflammation related to COX-2 immunoexpression, and cell proliferation not related to caspase-3 expression. Because modulating function of liver after burn injuries, the treatment of severe burns can be focused in liver disarrangements.

## COMMENTS

### Background

Scalds are most common cause of burn injury (BI) and preferentially occur in children under the five years. The persistent protein catabolism may lead to delay in growth for up to 2 years after injury. In addition, severe burn injuries result in serious complications that involve host response related to inflammation and multiple organ dysfunctions, including liver damage.

### Research frontiers

Studies involving autopsy of severely burned pediatric patients showed data about liver weight increased with fatty infiltration, but molecular and morphological investigation *in vivo* is necessary to elucidate better the liver damage process during great BI. For this, the present study investigated effects of severe BI in liver of young rats through the histopathological and morphoquantitative aspects, immunoexpression of COX-2 and liver gene expression of tumor necrosis factor- $\alpha$ , inducible nitric oxide synthase and caspase-3.

### Innovations and breakthroughs

The liver damage process during severe BI are related with histopathological and morphoquantitative changes such as presence of erythrocytes in sinusoidal space associated with inflammatory infiltrate and inflammatory cells rounding hepatocytes in degeneration. Moreover, increased connective tissue, hepatocyte area larger than control, altered binucleated hepatocyte and sinusoidal cells density, were described in the present study.

### Applications

Emphasize the importance of global treatment in burn great than 40% of total body surface area mainly in children. Highlight the damage caused in liver morphology clarifying morphological changes to possible treatments to prevent major consequences of BI.

### Terminology

Severe BI greater than 40% in children causes chronic morphological liver consequences ignored in numerous treatment centers. To emphasize the liver dysfunction as a result of extensive skin BI because hypermetabolic consequences was the purpose of the present paper.

### Peer-review

The aim of the authors was to investigate the temporal effects of extensive experimental burn injury in rat liver. There are some studies focused on this issue. This is well designed study. This article will provide new information about liver problems developing after BI.

Randomized Controlled Trial

## Boceprevir plus peginterferon/ribavirin for treatment of chronic hepatitis C in Russia

Vasily Isakov, Igor Nikitin, Vladimir Chulanov, Pavel Ogurtsov, Ekaterina Lukyanova, Jianmin Long, Janice Wahl, Frans A Helmond; The P08160 Trial Investigators

Vasily Isakov, Department of Gastroenterology and Hepatology, Institute of Nutrition, Moscow 115446, Russia

Igor Nikitin, Department of Gastroenterology and Hematology, Russian Academy of Sciences, Moscow 117593, Russia

Vladimir Chulanov, Clinical Diagnostics and Research Center, Central Research Institute of Epidemiology, Moscow 111123, Russia

Pavel Ogurtsov, Hospital Medicine, Peoples' Friendship University of Russia, Moscow 117198, Russia

Ekaterina Lukyanova, Medical Affairs, MSD Pharmaceuticals LLC, Moscow 115093, Russia

Jianmin Long, Janice Wahl, Frans A Helmond, Clinical Research, Merck & Co., Inc., Kenilworth, NJ 07033, United States

**Author contributions:** Isakov V, Long J, Wahl J and Helmond FA designed the study; Isakov V, Nikitin I, Chulano V and Ogurtsov P enrolled patients; Isakov V, Lukyanova E, Long J and Helmond FA analyzed the data; Isakov V and Helmond FA wrote the first draft; all authors critically reviewed and approved the final draft of the paper.

Supported by Merck & Co., Inc., Kenilworth, NJ, United States.

**Institutional review board statement:** The protocol P08160 of the study registered at ClinicalTrials.gov with identifier NCT01425203 presented in the manuscript of Isakov V *et al* "Boceprevir plus peginterferon/ribavirin for treatment of chronic hepatitis C in Russia" was reviewed and approved by the Institute of Nutrition (Moscow, Russia) Institutional Review Board.

**Clinical trial registration statement:** Protocol P08160 (The Effect of Boceprevir in Russian Participants Diagnosed with Chronic Hepatitis C Genotype 1) is registered at ClinicalTrials.gov (Identifier: NCT01425203).

**Informed consent statement:** All procedures followed were in accordance with the ethical standards of the responsible
