## Contents

Three issues per month Volume 9 Number 1 January 8, 2017

### REVIEW

- 1 Disease monitoring of hepatocellular carcinoma through metabolomics  
*Fitian AI, Cabrera R*
- 18 PI3K/SHIP2/PTEN pathway in cell polarity and hepatitis C virus pathogenesis  
*Awad A, Gassama-Diagne A*

### MINIREVIEWS

- 30 Drug-induced liver injury: Towards early prediction and risk stratification  
*Raschi E, De Ponti F*

### ORIGINAL ARTICLE

#### Basic Study

- 38 Ultrasound shear wave elastography and liver fibrosis: A Prospective Multicenter Study  
*Sande JA, Verjee S, Vinayak S, Amersi F, Ghesani M*

#### Retrospective Study

- 48 Efficacy and safety of tenofovir in chronic hepatitis B: Australian real world experience  
*Lovett GC, Nguyen T, Iser DM, Holmes JA, Chen R, Demediuk B, Shaw G, Bell SJ, Desmond PV, Thompson AJ*
- 57 Clinical usefulness of ursodeoxycholic acid for Japanese patients with autoimmune hepatitis  
*Toritsu Y, Nakano M, Takano K, Nakagawa R, Saeki C, Hokari A, Ishikawa T, Saruta M, Zeniya M*

#### Prospective Study

- 64 Shear wave elastography in hepatitis C patients before and after antiviral therapy  
*Suda T, Okawa O, Masaoka R, Gytoku Y, Tokutomi N, Katayama Y, Tamano M*

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Dr. Ferenc Sipos, MD, PhD, Assistant Professor, Senior Scientist, 2<sup>nd</sup> Department of Internal Medicine, Semmelweis University, 1088 Budapest, Hungary

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

We elucidate major pathways of hepatocarcinogenesis and accurate diagnostic metabolomic biomarkers of hepatocellular carcinoma (HCC) identified by contemporary HCC metabolomics studies, and delineate a model HCC metabolomics study design. A literature search was carried out on Pubmed for HCC metabolomics articles published in English. All relevant articles were accessed in full text. Major search terms included "HCC", "metabolomics", "metabolomics", "metabonomic" and "biomarkers". We extracted clinical and demographic data on all patients and consolidated the lead candidate biomarkers, pathways, and diagnostic performance of metabolomic expression patterns reported by all studies in tables. Where reported, we also extracted and summarized the metabolites and pathways most highly associated with the development of cirrhosis in table format. Pathways of lysophospholipid, sphingolipid, bile acid, amino acid, and reactive oxygen species metabolism were most consistently associated with HCC in the cited works. Several studies also elucidate metabolic alterations strongly associated with cirrhosis, with  $\gamma$ -glutamyl peptides, bile acids, and dicarboxylic acids exhibiting the highest capacity for stratifying cirrhosis patients from appropriately matched controls. Collectively, global metabolomic profiles of the referenced works exhibit a promising diagnostic capacity for HCC at a capacity greater than that of conventional diagnostic biomarker alpha-fetoprotein. Metabolomics is a powerful strategy for identifying global metabolic signatures that exhibit potential to be leveraged toward the screening, diagnosis, and management of HCC. A streamlined study design and patient matching methodology may improve concordance among metabolomic datasets in future works.

**Key words:** Metabolomics; Hepatocellular carcinoma; Biomarkers; Metabolic profiling; Chromatography/mass spectrometry; Noninvasive biomarkers; Cirrhosis

**Core tip:** The high-throughput, validated nature of metabolomics makes it an ideal methodology for rapidly identifying the global metabolic alterations associated with hepatocarcinogenesis - alterations that not only enhance our understanding of the metabolic underpinnings of cirrhosis and hepatocellular carcinoma (HCC), but that can be leveraged to improve HCC diagnostic, therapeutic, and disease monitoring efficacy. Indeed, contemporary HCC metabolomics works time and again demonstrate this promise that metabolomics platforms hold in serving as standalone non-invasive HCC diagnostic and disease monitoring modalities.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the world's third most lethal cancer, possessing a five-year survival rate of 10% that results in between 250000 to 1000000 deaths per year<sup>[1,2]</sup>. HCC culminates from a preexisting long-term condition of cirrhosis in 90% of cases<sup>[3]</sup> and cirrhosis patients are among the best characterized individuals at high risk for developing cancer. Notwithstanding the opportunity for clinical surveillance of these patients, the dismal survival rate persists and HCC has now emerged as the fastest rising cause of cancer related death in the United States<sup>[4,5]</sup>. HCC patients in Asia and sub-Saharan Africa face a particularly grim outlook, with > 90% of patients in rural areas of these regions progressing within the first year of HCC onset<sup>[6]</sup>. A major hindrance to successful early diagnosis of HCC stems from the substandard accuracy of the principal HCC diagnostic modalities. Alpha-fetoprotein (AFP) is the principal biomarker for HCC and despite the inexpensive and reproducible nature of the AFP blood test, its sensitivity of 25%-65%<sup>[7,8]</sup> for HCC has exacerbated early detection of this cancer. The low sensitivity of AFP can be explained by the fact that up to 40% of HCC and cirrhosis patients have normal AFP levels, and that AFP is often elevated in patients without HCC<sup>[9-11]</sup>. Moreover, only 10%-20% of patients with early-stage HCC have elevated AFP levels<sup>[12]</sup>. Exclusion of AFP as an HCC diagnostic modality in the AASLD guidelines for HCC surveillance underscores AFP's unreliability to accurately screen for early HCC<sup>[13]</sup>. Efforts to overcome this substandard performance have resulted in the identification and commercialization of novel HCC biomarkers des-gamma-carboxyprothrombin and lectin-bound AFP (AFP-L3). These markers are ineffective when used alone as HCC biomarkers, however,

and even when combined with AFP still demonstrate poor sensitivity for HCC, particularly in the detection of lesions < 3 cm<sup>[14]</sup>. While magnetic resonance imaging and computed tomography offer better accuracy in HCC diagnosis, these sophisticated diagnostic modalities are both economically and logistically incompatible with the resource-poor areas experiencing the brunt of HCC's mortality rate<sup>[15-17]</sup>. Improving early HCC detection and patient outcome globally requires fulfilling of the urgent need for a reproducible, inexpensive, and accurate HCC diagnostic test.

### Metabolomics as an HCC biomarker discovery tool

Numerous genomic and proteomic screening studies have been employed to identify potential biomarkers of HCC<sup>[18-24]</sup> but to date the markers identified in these studies have not been clinically fruitful. Because the liver is the hub of carbohydrate, amino acid, and lipid metabolism<sup>[25,26]</sup>, chronic liver diseases undoubtedly disrupt normal metabolic function. A metabolomics analysis of HCC and cirrhotic tissue can therefore elucidate not just the metabolic pathways most relevant to the hepatocarcinogenic process, thereby identifying metabolites showing promise as HCC biomarkers, but also global metabolic patterns that serve as comprehensive disease signatures and which may therefore be used to stratify cases from controls. Metabolomics is the comprehensive identification of all small metabolites < 2 kD in a tissue sample. Through combined gas or liquid chromatography/mass spectrometry, surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI TOF-MS) or nuclear magnetic resonance instrumentation, metabolomics platforms enable investigators to rapidly screen hundreds of metabolites in a large series of biofluid or solid tissue samples and are capable of simultaneously detecting metabolites belonging to a diverse array of pathways including amino acids, lipids, carbohydrates, and nucleotides. Metabolomics platforms are translationally optimal and hold potential for clinical implementation because they reveal global metabolite expression pattern differences among cases and controls in an automated, rapid, high-throughput, quality controlled, and reproducible manner. Metabolomics facilitates rapid identification of diagnostic markers, prognostic markers, and lead drug target pathways and their implementation in drug discovery divisions of pharmaceutical giants underscores their important role in the lead target generation realm<sup>[27]</sup>.

Nearly two dozen HCC metabolomics studies have been reported<sup>[28-46]</sup>. These studies illustrate the key pathways involved in stepwise hepatocarcinogenesis and reveal metabolites that may have utility as biomarkers of HCC and cirrhosis. The findings of these studies are summarized in Tables 1 and 2. These works reveal deregulation of bile acid metabolism, fatty acid  $\beta$ -oxidation by way of the carnitine palmitoyltransferase (CPT) shuttle system, amino acid metabolism, and glycerophospholipid metabolism in HCC vs cirrhosis,

and further delineate metabolites with potential utility in stratifying patients with cirrhosis from the healthy population.

### Pathways of importance in hepatocarcinogenesis

**Glycerophospholipids:** The liver is the principal organ of lipid metabolism and the presence of cirrhosis and hepatocellular carcinoma results in a dramatic shift in the normal metabolism of fatty acids. Among the first HCC metabolomics studies to elucidate this massive deregulation of lipid metabolism in HCC was the Yang *et al*<sup>[28]</sup> work in 2007 which employed high resolution magic angle-spinning <sup>1</sup>H nuclear magnetic resonance

to delineate the metabolomic profile differences in low-grade HCC, high-grade HCC, and non-involved adjacent cirrhosis patient biopsy specimens. The group reported higher levels of several phospholipids in HCC vs cirrhosis, including glycerophosphocholine, phosphatidylcholine, choline and the phosphorylethanolamine. Increases in phosphatidylcholine were further observed in low-grade HCC vs uninvolved cirrhotic tissue, suggesting possible deregulation of glycerophospholipid metabolism at the early phases of HCC development. These phospholipids also exhibited a direct, positive relationship to tumor burden.

In Yang *et al*<sup>[28]</sup>, the elevation of choline, the head

group of many phospholipids that comprise the plasma membrane, not only reflects increased plasma membrane synthesis demand by the growing tumor but is also consistent with the observed elevations in bile (cholic) acid concentration in HCC vs control tissue.

**Lysophospholipids, free fatty acids, and acylcarnitines:** Significant alterations in the expression of a subtype of glycerophospholipids known as lysophosphatidylcholines (LPC) have routinely been observed in HCC metabolomics studies<sup>[29,36-39]</sup>. Still other classes of lipids observed to be significantly altered in HCC vs cirrhosis include free fatty acids (FFA)<sup>[29,45]</sup>, very long chain fatty acids<sup>[29]</sup>, and acylcarnitines<sup>[37,45]</sup>. Down-regulated LPCs and FFA in HCC vs cirrhosis were among the major metabolomic trends reported by Patterson *et al.*<sup>[29]</sup>, with LPC (14:0), LPC (20:3), LPC (22:6) and very long chain fatty acids FFA (24:0) (lignoceric acid) and FFA (24:1) (nervonic acid) all trending lower in HCC vs cirrhosis. The decreases of lignoceric and nervonic acid in HCC vs cirrhosis were especially patent and may reflect peroxisome proliferator-activated receptor- $\alpha$  (PPAR- $\alpha$ ) induced enhancement of peroxisomal  $\beta$ -oxidation. Previous reports implicating heightened PPAR- $\alpha$  activity in HCC support this hypothesis<sup>[47,48]</sup>. Decreases in these FFAs may also be related to increased activity of lignoceryl-CoA ligase, the enzyme responsible for very long chain fatty acid catabolism and one acted upon by PPAR- $\alpha$ <sup>[49]</sup>. LPCs are the glycerophospholipid building blocks of cell membranes and elevation of these metabolites may reflect the heightened metabolic needs of growing HCCs. LPCs are also major lipids bound to human albumin<sup>[50]</sup>. Decreased serum albumin is a signature of liver cirrhosis and liver cancer and elevations of systemic LPCs may be attributed to the shortage of appropriate albumin binding sites that results in increased circulating levels of these metabolites.

Further metabolomics work by Xiao *et al.*<sup>[37]</sup> also identified this downregulation of LPCs and LPEs in 40 hepatitis C virus (HCV)-associated HCC patients and 49 cirrhosis controls. Among the novel findings of this investigation included decreased levels of acylcarnitines in HCC vs cirrhosis. Results also showed that as tumor burden worsened, the expression of acylcarnitines and bile acids trended significantly downward. Stage II and III HCC exhibited lower levels of these metabolites in comparison to stage I [staging based on the American Joint Committee on Cancer Tumor Lymph Node Metastatic Disease (TNM) system]. The downregulation of fatty acids, acylcarnitines, and bile acids in HCC vs cirrhosis supports the cancer Warburg effect involving a metabolic shift from tricarboxylic acid (TCA) cycle and mitochondrial  $\beta$ -oxidation to a heightened reliance on glycolysis for energy production. To undergo  $\beta$ -oxidation in the mitochondrial matrix, free fatty acids (fatty acyl-CoA) must link with cytosolic carnitine *via* CPT shuttle system enzymes to form acylcarnitines. Acylcarnitines are capable of penetrating the inner mitochondrial

membrane and once inside the matrix, CPT enzymes liberate fatty acyl-CoA allowing  $\beta$ -oxidation to ensue. Decreased concentration of acylcarnitines in HCC vs cirrhosis suggests impairment of CPT1-mediated formation of these compounds from FFA and carnitine.

**Sphingolipids:** One major lipid expression alteration in HCC reported in HCC metabolomics is a perturbation of sphingosine metabolism, with overexpressed sphingosine-1-phosphate (S1P) and sphingosine reported in HCC vs cirrhosis. The overexpression of LPCs is in agreement with the Patterson study while the upregulation of S1P, a signaling lipid, was a novel finding in HCC metabolomics. S1P has been heavily implicated in promoting the progression of several cancers including HCC<sup>[51,52]</sup> and building the case for this pathway's involvement in HCC development, our HCC metabolomics work identified S1P's precursor sphingosine as one of the most strongly upregulated metabolites in HCC vs cirrhosis<sup>[45]</sup>. Sphingosine is produced *via* acid ceramidase (AC) activity on ceramide. Ceramides are shown to possess apoptotic effects, while sphingosine 1-phosphate is demonstrated as an anti-apoptotic and angiogenic molecule<sup>[53]</sup>. This cell turnover control mechanism is known as the "sphingosine rheostat", and AC is an important modulator of cell death homeostasis. Higher S1P in HCC may also reflect an independent enhancement of sphingosine kinase (SPHK) activity. One study demonstrated the antitumor property of a selective SPHK2 inhibitor in HCC xenografts<sup>[54]</sup>, implicating SPHK as a promoter of HCC progression. Heightened AC activity that results in increased sphingosine may lead to a larger reservoir of S1P *via* sphingosine kinase and may promote the establishment of a microenvironment conducive to HCC initiation.

### Bile acids

Bile acids are synthesized in the liver and aid in fatty acid absorption and digestion. Bile acid elevations in HCC have been reported previously<sup>[55]</sup> and may be explained by HCC invasion and obstruction of the bile duct. Bile duct blockage can impede adequate transfer of bile acids to the small intestine thereby impairing sufficient absorption and digestion of fats and leading to a buildup of both bile acids and cholinergic lipids in the hepatic tumor microenvironment. The majority of studies comparing HCC and cirrhosis metabolomes did not uncover a significant differential expression of bile acids, but where a significant trend was seen<sup>[36-38]</sup>, the metabolites collectively trended downward, in contrast to the aforementioned previous reports<sup>[55,56]</sup>. A significant negative correlation between bile acid levels and tumor burden was also observed<sup>[37]</sup>. Similar to the Yang *et al.*'s work, our metabolomics investigation<sup>[45]</sup> identified a significant elevation of choline in HCC vs cirrhosis, and bile acids in our study were strongly elevated in cirrhosis patients vs healthy subjects. The elevation of choline, a building block of bile acids, is consistent with an impairment of bile acid synthesis. Bile acid down-

regulation in HCC may also reflect a metabolic shift away from  $\beta$ -oxidation and the reduced *de novo* bile acid production caused by the obliteration of healthy hepatocytes during chronic liver disease. Diminished bile acids may also reflect constitutive activation of farnesyl X receptor (FXR), a bile acid-activated nuclear receptor that is also activated by a variety of other lipids including eicosanoids<sup>[57]</sup>. FXR silences Cyp7A1-catalyzed production of bile acids and is implicated in promoting progression of HCC by multiple studies<sup>[58,59]</sup>. In the Fujino study of FXR-induced promotion of HCC progression<sup>[58]</sup>, siR-mediated supplementation of FXR enhanced HepG2, Huh7, and HLE HCC cell line progression while FXR knockdown halted this progression.

### Oxidative stress metabolism

Among the other pathways found to be significantly associated with HCC in metabolomics investigations are pathways of reactive oxygen species metabolism, notable metabolites of which include the  $\gamma$ -glutamyl peptides. A recent capillary electrophoresis-time of flight mass spectrometry analysis involving sera obtained from HCV-associated HCC patients, cirrhosis patients, hepatitis B virus (HBV) and chronic hepatitis C (HCV) patients, and healthy volunteers showed markedly significant variations in  $\gamma$ -glutamyl expression among these groups<sup>[35]</sup>. No differences in  $\gamma$ -glutamyl peptide expression were observed between HCC and cirrhosis controls, but several significant alterations were witnessed in the HCC vs viral hepatitis, HCC vs normal healthy controls (NHC), cirrhosis vs viral hepatitis, and cirrhosis vs NHC comparisons. In general, HCC  $\gamma$ -glutamyl expression was increased in comparison to healthy controls, while  $\gamma$ -glutamyl peptides were decreased in HCC vs viral hepatitis.  $\gamma$ -glutamylglycine,  $\gamma$ -glutamylalanine,  $\gamma$ -glutamylvaline and  $\gamma$ -glutamylserine,  $\gamma$ -glutamyltaurine,  $\gamma$ -glutamylleucine, and  $\gamma$ -glutamyllysine were all strongly ( $0.0001 < P < 0.001$ ) downregulated in HCC vs viral hepatitis B (HBV) and C infection.  $\gamma$ -glutamyl peptides are precursors to glutathione, the chief antioxidant compound primarily synthesized in the liver. The respective elevation of these intermediates in HCC and cirrhosis patients vs NHC suggests that increased oxidative stress contributing to liver dysfunction calls for heightened production of these precursors to combat this deteriorative process. This is consistent with reports implicating oxidative damage as a key pathway in HCC progression and one that increases patient vulnerability for HCC recurrence<sup>[60,61]</sup>.  $\gamma$ -glutamyl peptides are also liberated in free form by gamma-glutamyl transpeptidase (GGT) mediated breakdown of glutathione. GGT is an enzymatic signature of liver disease and a marker routinely used in the clinic to assess the severity of liver dysfunction. Excess breakdown of glutathione may explain the relative elevation of  $\gamma$ -glutamyl peptides in cirrhosis vs NHC and the impaired oxidative stress neutralization commonly witnessed in HCC.

The Wang *et al.*<sup>[38]</sup> study also found an oxidative stress signature in HCC, showed a striking 677-fold elevation

in canavaninosuccinate (CSA) level in HCC patients vs their cirrhosis counterparts ( $P < 0.01$ ). Subsequent receiver operator characteristic (ROC) analysis revealed that the sensitivity and specificity of AFP and CSA for distinguishing the HCC patients from cirrhosis controls were: AFP<sub>20 ng/mL</sub> 74% and 38%; AFP<sub>200 ng/mL</sub> 52% and 90%; CSA 79.3% and 100%; combined CSA and AFP<sub>20 ng/mL</sub> 96.4% and 100%. CSA is the precursor to fumarate, a key metabolite of the TCA cycle, and elevation of CSA may reflect impairment in the formation of TCA intermediates and promotes the above referenced Warburg theory involving a metabolic shift from oxidative to anaerobic energy production in cancer microenvironments, which are often more hypoxic than healthy tissue<sup>[62]</sup>.

In our work<sup>[45]</sup>, a strong oxidative stress signature in HCC was also observed, with xanthine, 2-hydroxybutyrate and several  $\gamma$ -glutamylpeptides trending significantly higher in HCC vs cirrhosis. Still, the work of Gao *et al.*<sup>[46]</sup> uncovered trends suggestive of an opposite phenomenon: Elevations of glutamic acid, lysine and cysteine in HCC compared with healthy controls were observed and are curious in the context of reactive oxygen species (ROS) given that these amino acids are precursors of glutathione (GSH). Increased levels of these amino acids suggest a possible enhancement of GSH production that establishes a microenvironment conducive for tumor survival<sup>[46]</sup>.

### Protein metabolites

The liver is the major organ of protein metabolism and not surprisingly, HCC metabolomics shows that the expression profiles of patients with advanced liver disease exhibit major differences in amino acid expression when compared to metabolic profiles of appropriate diseased or healthy controls. In the Yang *et al.*<sup>[28]</sup> study, significant increases in creatine, glutamine, and glutamate were found in HCC vs cirrhosis, and these trends were juxtaposed by decreases in lactate, alanine, leucine, glutamate, glutamine in HCC vs cirrhosis. The finding of increased amino acids in HCC vs cirrhosis is consistent with numerous studies implicating elevated amino acids and the enzymes responsible for their production in cancer initiation and progression<sup>[63-66]</sup>. In one large scale metabolomics analysis of 60 cancer cell lines, Jain *et al.*<sup>[66]</sup> identified glycine as the most significantly and consistently upregulated metabolite in cancer cells vs healthy lines. Enhanced amino acid production is consistent with the metabolic remodeling hallmark of cancer known as the Warburg effect, which involves a shift from TCA cycle and  $\beta$ -oxidation to a heightened reliance on glycolysis for energy production<sup>[67]</sup>. Amino acids are important glycolytic enzyme activators, and one recent study demonstrated that serine was an activator of pyruvate kinase M2<sup>[68]</sup>, the cancer isoform of glycolytic enzyme pyruvate kinase responsible for conversion of phosphoenolpyruvic acid (PEP) to pyruvate. The group's concomitant observation of elevated lactate in HCC vs cirrhosis is consistent with the Warburg hypothesis.

Gao *et al.*<sup>[46]</sup> propose that their observed elevation of pyruvate, which would seem to counteract the tumor's reliance on the lower-activity PKM2 compared to PKM1, is due to enhanced production of glutamine which is used as an alternative pyruvate precursor. Our study identified a strong amino acid signature associated with HCC with serine, glycine and aspartate being the most significantly upregulated metabolites in HCC vs cirrhosis. These elevations are corroborated by a recent metabolomic analysis of HBV-associated HCC showing a strong upregulation of serine, alanine, glycine, cysteine, aspartic acid, methionine, tyrosine, tryptophan, and phenylalanine in HCC vs healthy controls. Upregulated amino acids in HCC may be explained by the greater protein turnover that transpires in rapidly dividing tumors vs the surrounding non-cancerous tissue along with impaired amino acid utilization in liver.

In addition to very small molecular weight amino acids, metabolomics is also useful for detecting larger protein metabolites weighing near 10 kDa. SELDI TOF-MS metabolomics is a highly versatile methodology for large-scale identification and quantification of these larger metabolites. Wu *et al.*<sup>[31]</sup> tapped this technology to investigate the metabolomic expression profiles of HBV-associated HCC patients, cirrhosis patients, and healthy controls. Their results reveal the upregulation of two proteins, growth related oncogene- $\alpha$  (GRO- $\alpha$ ) and thrombin light chain (TLC), in HCC patients vs cirrhosis controls. To validate these putative markers, serum from an alternative series of HCC, cirrhosis, healthy, and cancer control patients was subjected to Sephadex<sup>TM</sup> Peptide 10/300 GL, Hitrap<sup>TM</sup> CM, and Mono Q 5/50 GL liquid chromatography for protein separation. The separated products were purified using SDS-PAGE and their identities were confirmed using electrospray ionization mass spectrometry. In this alternative series of patients, GRO- $\alpha$  was upregulated four-fold in HCC patients vs cirrhosis controls and its level directly correlated with HCC tumor burden. GRO- $\alpha$  also trended higher in gastric, nasopharyngeal and lung cancers relative to cirrhosis patients, but the magnitude of GRO- $\alpha$  elevation in cancer controls vs cirrhosis was smaller than the elevation witnessed in HCC vs cirrhosis, suggesting that GRO- $\alpha$  may play a more prominent role in HCC progression. Interestingly, TLC was 1.4 times more elevated in HCC patients vs cirrhosis controls but downregulated in the cancer control patients vs cirrhosis, suggesting that TLC is a unique signature of HCC. The combined sensitivity and specificity of GRO- $\alpha$  + TLC + AFP for discriminating HCC patients from cirrhosis and healthy controls was 91.7% and 92.7% respectively. At the 400 ng/mL cutoff for HCC diagnosis, AFP had a sensitivity of 69% and a specificity of 83%.

GRO- $\alpha$  is a chemokine involved in invoking leukocyte cell migration and is associated with pro-inflammatory processes, angiogenesis, and cancer<sup>[69-71]</sup>. Its elevation may be a signature of a viral hepatitis-associated HCC immune deregulation involving heightened monocyte migration and increased inflammation, and a subsequent

increased likelihood for successful host evasion of tumor prophylactic mechanisms<sup>[72]</sup>. TLC is a protein cleavage fragment that is generated from matrix metalloproteinase-associated (MMP) peptide cleavage<sup>[31]</sup>. Its upregulation may be explained by simultaneous E-cadherin loss and MMP activation by Twist1 which has been shown to promote HCC expansion<sup>[73]</sup>. Its utility as a cancer biomarker was also shown in a SELDI TOF-MS study of gastric cancer by Ebert *et al.*<sup>[74]</sup>, where TLC accurately distinguished gastric cancer patients from patients without cancer with a sensitivity of 89.9% and a specificity of 90%.

The destruction of cholinergic receptors in amyloid plaques and neurofibrillary tangles of the brain has also been linked to encephalopathy, a common neurological disorder witnessed in HCC patients<sup>[75]</sup>. The molecular mechanisms linking hepatic encephalopathy (HE) and HCC are not fully understood, but the parallel elevations of choline and glutamine in HCC patients vs cirrhosis controls may partially be associated with a cataclysmic loss in cholinergic receptor concentration and the initial stages of HE onset, respectively<sup>[76]</sup>. A possible neurological metabolic signature was one of the most strongly correlated trends observed in HCC patients vs cirrhosis and vs healthy controls in our study, with 2-pyrrolidinone, a  $\gamma$ -aminobutyric acid (GABA) metabolite, was strongly elevated in HCC when compared to levels in both the cirrhosis controls and the healthy volunteers. GABA is a major inhibitory chemical messenger in the brain, and the sharp elevation of its metabolic byproducts in HCC may reflect heightened production of GABA and may coincide with the neurodegenerative hallmarks of advanced liver disease.

Two previously unidentified fibrinogen cleavage peptides, denoted by amino acid sequence as DSGEGD FXAEGGGVR and ADSGEGDFXAEGGGVR, were observed to be significantly overexpressed in HCC in our study. While they trended higher in HCC vs cirrhosis, their elevation in cirrhosis vs healthy controls was more patent and these metabolites exhibited a better diagnostic utility for cirrhosis. Taken together, the aberrations in protein and amino acid expression in HCC revealed by metabolomics may be harnessed toward the development of clinically fruitful HCC diagnostics.

### Markers of cirrhosis

A number of HCC metabolomics studies report significant alterations between cirrhosis patients and healthy volunteers<sup>[30,32,33,35,38,39,41,42,45,46]</sup> and within these findings are opportunities for development of biomarkers for cirrhosis. Currently, the best cirrhosis diagnostic is liver biopsy, a procedure that by virtue of its invasive nature is not a gold standard diagnostic approach<sup>[77]</sup>. Identification of accurate cirrhosis diagnostic biomarkers can streamline development of a less invasive diagnostic that minimizes patient discomfort and the expenses associated with biopsy while simultaneously enabling early detection of cirrhosis in both industrialized nations and in resource poor areas of the globe. Among the putative markers

of cirrhosis identified in these works include the purine metabolites hypoxanthine<sup>[41,45]</sup> and inosine<sup>[41]</sup>, both significantly downregulated five and six-fold respectively in cirrhosis vs NHC.  $\gamma$ -glutamylalanine,  $\gamma$ -glutamylvaline,  $\gamma$ -glutamylglutamine,  $\gamma$ -glutamylphenylalanine and  $\gamma$ -glutamylcitrulline were also significantly elevated in cirrhosis vs NHCs<sup>[41,45]</sup>. Increases in the  $\gamma$ -glutamyl peptides in cirrhosis vs NHC and HCC vs NHC indicates heightened production of glutathione to combat the oxidative damage process commonly implicated as a promoter of tumor initiation and progression.  $\gamma$ -glutamyl peptides are also liberated in free form by GGT mediated breakdown of glutathione. The elevation of  $\gamma$ -glutamyl peptides in cirrhosis vs NHC may therefore conversely be explained by excessive breakdown of glutathione resulting in impaired oxidative stress neutralization that is commonly witnessed in HCC.

Other promising markers of cirrhosis include bile acids<sup>[45]</sup> and dicarboxylic acids<sup>[45,46]</sup>, with these metabolite classes exhibiting the strongest and most significant fold-differences among all markers significantly altered between cirrhotics and healthy controls in the references metabolomic studies.

### **Etiological metabolomic differences**

Because HCC is linked to a variety of diverse etiologies including viral hepatitis, alcoholic cirrhosis, non-alcoholic fatty liver disease, steatohepatitis, and aflatoxin B1, metabolomics is useful for revealing the variation in metabolism these etiologies cause. The majority of studies have focused on characterizing the metabolomic signatures of single HCC etiologies, or have not accounted for etiology. Studies to date have not queried the metabolomic expression pattern differences between the various etiologies of HCC and as the metabolic underpinnings of each etiology are better characterized, HCC etiology metabolome comparison studies will prove vital in establishing the utility for metabolomics as an accurate diagnostic modality of different HCC subtypes. Only one study, by Zhou *et al.*<sup>[39]</sup>, compared the serum metabolomic expression patterns of HCV cirrhosis-associated HCC and HBV cirrhosis-HCC. The group also looked at whether metabolomic alterations in HCV-HCC and HBV-HCC were significantly different from cirrhosis and healthy control metabolomes. The study revealed a greater magnitude decrease of LPC expression in HBV-infected HCC patients vs cirrhosis controls than the magnitude decrease of LPCs HCV-HCC vs cirrhosis. The analysis also showed significant elevation of bile acids, heme pigmentation compounds bilirubin and biliverdin, upregulation of acylcarnitines and downregulation of glycerophospholipids in cirrhosis patients vs healthy controls, suggesting that these metabolites were signatures of the onset of cirrhosis. Metabolomic profile comparison between HBV-cirrhosis patients vs patients with HBV-only revealed a similar global downregulation of LPCs in the cirrhosis cohort vs viral hepatitis controls. The findings of this study suggest a progressive downregulation of LPCs during the course of progression

from viral hepatitis to cirrhosis and a bottomed out expression occurring with HCC. The downregulation of LPC in HCC may be explained by their well-known anti-tumor roles that include induction of apoptosis, anti-invasive effects, and a direct effect on tumor sensitization to treatment. This trend of diminished LPCs may reflect first the substantial cell death that occurs during cirrhosis resulting in diminished LPC levels, followed by a subsequent massive turnover of residual LPCs by the growing HCC that further exhausts the LPC reservoir. The magnitude of LPC decrease in HBV-HCC vs cirrhosis was greater than HCV-HCC vs cirrhosis, suggesting that HBV exerts a more prominent influence on LPC metabolism than HCV.

### **Integrated “omics” approaches**

As the above studies demonstrate, metabolomics is a powerful strategy for identifying a large panel of metabolites that exhibit promise in accurately diagnosing HCC. What is unclear from these works, however, are the genomic and proteomic synergies that culminate in these metabolic manifestations. Integrating two or more “omics” approaches can unveil the complex genomic-proteomic-metabolomic network galvanizing cancer development. Two recent studies tapped the power of such an approach, coupling metabolomics with transcriptomics to identify the genetic underpinnings of metabolomic disruptions. The first study by Budhu *et al.*<sup>[43]</sup> investigated the network of metabolic pathways and corresponding genes involved in HCC aggressivity. Patient demographic and clinical characteristics, including body mass index, were extensively characterized for 356 HCC cases, which were divided into a training set ( $n = 30$ ), a testing set ( $n = 217$ ), and a validation cohort ( $n = 139$ ). The training cohort consisted of 15 epithelial cell adhesion molecule-positive/AFP-positive (EpCAM+AFP+) HpSC-HCC patients, representing aggressive stem-like HCC, and 15 less aggressive (EpCAM-AFP-) mature hepatocyte MH-HCC patients. Analysis of tumor specimens and uninvolved healthy tissue by principal component analysis revealed clear demarcation between tumor and non-tumor metabolomes. Non-targeted metabolic profiling of tumor and non-tumor specimens identified 48 markers that were significantly altered between HpSC-HCC patients and patients with MH-HCC. This metabolite panel resolved aggressive HCC from the less subtype at a sensitivity of 72% and a specificity of 83% ( $P < 0.05$ ). The group further demonstrated that within the subset of 48 metabolites associated with HCC aggressivity, 28 were significantly associated with overall survival. Subsequent microarray gene expression profiling of the paired tumor specimens identified 169 genes that could significantly distinguish the two HCC subtypes. The group then gauged the correlation between this genetic signature and the panel of 28 metabolites that were associated with both HCC aggressivity and overall survival and found that each of the 28 metabolites were associated with at least one of the 169 genes identified by microarray analysis. To determine the principal metabolite-gene

pairs potentially influencing HCC aggressivity, the group performed correlation analysis with randomization and found 15 metabolites and 121 genes most highly associated with the tumor and stem-like HCC genes. Validation of the genetic signature in an independent testing cohort ( $n = 217$ ) revealed a panel of 273 genes that distinguished HpSC-HCC from MH-HCC with a sensitivity of 72% and a specificity of 91% ( $P < 0.01$ ), and this genetic signature was also strongly ( $P < 0.0001$ ) associated with overall survival. This gene set was also a significant independent predictor of overall survival, progression free survival and recurrence, highlighting its utility as a prognostic panel of aggressive HCC. Many of the genes were associated with fatty acid metabolism and the phosphatidylinositol 3-kinase signaling pathway. Elevated palmitoleate expression in HpSC-HCC tumor vs paired non-tumor specimens reflected overexpression or enhanced activity of stearoyl-CoA dehydrogenase (SCD), an important cell turnover regulatory pathway. Significant downregulation of arachidonate and linoleate, the parent molecules of the eicosanoid signaling cascade, suggested overconsumption of these metabolites from hyperactivity of cyclooxygenase, lipoxygenase, and/or cytochrome P450c in aggressive HCC. SCD, which converts saturated palmitic acid to palmitoleic acid, was among the gene set. To validate the possible role of SCD in cancer aggressivity, *in vitro* and *in vivo* analysis was done and showed that selective SCD inhibitor CGX0168 abrogated Huh7 cell migration and invasion. Supplementation of Huh7 with palmitoleate, the end product of SCD activity, enhanced cell migration and invasion. Xenografted tumors in nude mice showed that SCD-siRNA inhibited tumor migration and colony formation and increased apoptosis, likely owing to the accumulation of pro-apoptotic palmitate. Taken together, this approach showed a strong lipid signature associated with HCC aggressivity. Elevated palmitoleate reflected upregulated SCD, a key regulator of the ratio between saturated and unsaturated fatty acids. A tilt in the delicate balance between saturated and unsaturated fatty acids toward unsaturated has been implicated in cancer aggressiveness.

Remarkably, the integrated metabolomics-transcriptomics study by Beyoğlu *et al.*<sup>[44]</sup> also revealed a consistent role for palmitate, linoleate, and the PI3K pathway in HCC. Microarray analysis found that 11 genes involved in fatty acid were associated with HBV-positive HCC cases. More broadly, the comparison of tumor vs paired non-tumor tissues identified a metabolic shift toward glycolysis reflective of the Warburg effect implicated in other HCC metabolomics works. Levels of glucose, glycerol 3-phosphate, glycerol 2-phosphate, malate, alanine, and myo-inositol were all significantly decreased in tumor vs non-tumor specimens, indicating both impaired mitochondrial respiration and enhanced glycolysis. Myo-inositol is the metabolic precursor of the messenger molecule inositol triphosphate (PI3) required by PI3K-AKT-mTOR, and its downregulation in tumor vs non-tumor specimens is consistent with the hyperactivity of this pathway implicated in numerous cancers. Further-

more, the group showed that 1-stearoylglycerol and 1-palmitoylglycerol were decreased in tumor vs non-tumor. 1-acylglycerols are synthesized by phospholipase activity on LPCs and the routinely reported decrease in LPCs in HCC vs controls may explain the reduced 1-acylglycerols in this study. Through integration of metabolomics and transcriptomics, these groups together show a possible role for SCD in HCC, implicate the PI3K pathway as important to HCC progression, and show a strong lipid signature associated with HCC, in agreement with other HCC metabolomics works. More broadly, these works demonstrate that the achievement of consistent trends in independent, integrated “omics” studies can be achieved and lay important groundwork for future studies of this nature.

### **Sensitivity and specificity of metabolomics in HCC diagnosis**

To evaluate the utility for metabolomic profiles to distinguish between patients with cirrhosis and patients with HCC, these studies primarily employed principal component analysis, orthogonal projection to latent structures, supervised projection to latent structures discriminant analysis, the random forest machine learning algorithm, or ROC curve class prediction analyses. Reported sensitivity/specificity/area under the curve values reflecting the accuracy of metabolomics in distinguishing HCC from cirrhosis are shown in Table 3. In general, metabolomics was a highly accurate diagnostic method and clear demarcation between healthy controls and/or cirrhosis controls vs HCC patients were realized. Where metabolomics profile class prediction was compared with AFP, the metabolomics approach showed greater class prediction power. In general, the focus of these works was the potential standardization of metabolomics as a high-throughput clinical diagnostic platform-big-data biomarkers rather than single metabolite alterations—which may explain the lack of emphasis on the sensitivity and specificity of individual metabolites for diagnosing HCC. Just two studies verified the metabolite expression patterns *in vitro*, and with the exception of the *in vivo* validation performed by Budhu *et al.*<sup>[43]</sup>, no studies used *in vivo* models to validate their metabolomics data. It is therefore recommended that future validation of HCC metabolomics data include preliminary information on metabolite concentrations in HCC cases vs cirrhosis controls as measured *in vitro* or *in vivo* to reveal their utility as potential biomarkers that can be employed in a rapid *in vitro* diagnostic.

## **DISCUSSION**

### **Summary of major findings**

The results of these studies show that aberrations in bile acid, LPC, acylcarnitine, ROS, and protein metabolism may be signatures of HCCs emerging in the setting of cirrhosis. Bile acids trended lower in HCC vs cirrhosis controls in all studies reporting a significant difference in expression of these metabolites<sup>[36-38]</sup>. In general, LPCs were shown

to be downregulated in HCC vs cirrhosis<sup>[37-39,45]</sup>. But the works by Ressom *et al.*<sup>[36]</sup> and Wang *et al.*<sup>[38]</sup> found that LPCs and LPEs were consistently elevated in the HCC vs cirrhosis comparison. Acylcarnitines, which function as liaisons of fatty acid  $\beta$ -oxidation by enabling fatty acid importation to the mitochondrial matrix, were significantly downregulated in HCC vs cirrhosis. Amino acids also trended higher in HCC in all studies reporting significant expression differences between HCC and cirrhosis. The hemoglobin metabolite bilirubin was also consistently elevated in HCC vs cirrhosis<sup>[29,39,41,45]</sup>, consistent with the clinical utility this metabolite possesses for diagnosing advanced liver disease. Biliverdin, another heme catabolite, was significantly upregulated in HCC vs cirrhosis in two studies<sup>[29,45]</sup> and a metabolic derivative of biliverdin downregulated in a third<sup>[37]</sup>.

The elevation of LPCs in HCC vs cirrhosis seen by Ressom *et al.*<sup>[36]</sup> is consistent with increased demand of glycerophospholipids by the growing tumor. LPCs comprise only 3% of the total phospholipids in plasma membranes, however, and a better explanation for their elevation may be that LPCs are major lipids bound to albumin. The loss of albumin commonly witnessed in chronic liver disease and HCC may mean a shortage of docking sites for LPCs, resulting in increased systemic levels of these glycerophospholipids. Diminished bile acids in HCC vs cirrhosis reinforces the Warburg effect commonly witnessed in cancer studies involving a shift in energy production away from oxidative processes like  $\beta$ -oxidation and the TCA cycle toward anaerobic glycolysis, which is more suitable to the hypoxic or anoxic tumor microenvironment. The loss of bile acids in HCC significantly impairs fatty acid absorption and digestion and is consistent with the general trend of increased circulating lipids in HCC vs cirrhosis and cirrhosis vs appropriate controls. The elevation of bile acids has historically served as a clinical indicator of chronic liver disease and specifically cirrhosis and consistent with this function, our metabolomics work showed a global upregulation of bile acids in cirrhosis vs healthy volunteers<sup>[45]</sup>. Decreased acylcarnitines further reflects diminished reliance on  $\beta$ -oxidation, and it may also signify impairment of the mitochondrial carnitine palmitoyltransferase shuttle system.

### **Metabolomic heterogeneity attributed to differences in study design**

While perturbations in phospholipid, bile acid, hemoglobin, acylcarnitine and amino acid metabolism were routinely encountered in these studies, the referenced works did not achieve uniform conclusions regarding the directional shifts of the metabolites' expression in HCC vs cirrhosis, with examples including contradictory patterns of LPC<sup>[36,39]</sup> and amino acid<sup>[28,46]</sup> expression in HCC vs cirrhosis. The heterogeneity among these studies' metabolomes is likely due to differences in study design. Although some studies matched patients by age and gender, the majority of the referenced HCC metabolomics

studies did not extensively characterize HCC and cirrhosis patients by demographic and clinical characteristic parameters. Only four studies reported MELD scores for HCC and cirrhosis patients<sup>[36,37,40,45]</sup>, and just three studies indicated the Child-Pugh status of their HCC or cirrhosis cohorts<sup>[29,40,45]</sup>. This lack of information on whether liver function of the study participants is compensated or decompensated complicates interpretation of metabolomic data. Body mass index (BMI) also went unreported for HCC, cirrhosis, and healthy study subjects in all but two studies<sup>[43,45]</sup> referenced in this review. BMI can have a significant influence on the relative metabolite expression differences between patients, particularly with regard to adiposity. Because these studies did not control for BMI, is likely that the patients recruited for these metabolomics studies had wide-ranging BMIs that may further explain the noticeably different trends of LPC, FFA, and acylcarnitine expression in HCC vs controls. To limit the influence of potential cofounders such as comorbidity, BMI, age or gender, and etiology on HCC metabolomes, patient clinical characteristics should be controlled for more conscientiously in future HCC metabolomics studies.

There was also marked variation in how each group diagnosed and staged their HCC patients. Three studies<sup>[29,43,45]</sup> staged according to the Barcelona Clinic for Liver Cancer staging criteria. The TNM Classification of Malignant Tumors (TNM) was used to diagnose HCC in five studies<sup>[28,30,37,38,43]</sup>, imaging in two, histopathology in one<sup>[36]</sup>, and six studies made no mention of their HCC diagnosis method<sup>[31,33,35,39,41,42]</sup>. Differences in HCC diagnosis and staging among these studies likely contributed to the discordant global metabolomic alterations in HCC vs cirrhosis among these studies and further confounded the interpretation of these metabolomic trends.

### **Lack of emphasis on HCC vs cirrhosis comparison**

The critical metabolomic comparison between HCC patients and cirrhosis controls was reported in just ten out of the twenty studies referenced in this review<sup>[28,29,31,35-39,45,46]</sup>, with half of the cited works instead focusing on the metabolomic profile differences between HCC patients and NHC subjects. While this comparison sheds light on altered pathways during hepatocarcinogenesis, it may not be as applicable from a clinical standpoint as the trends elucidated through a comparison of HCC vs cirrhosis. This owes to the fact that the majority of primary liver cancer cases occur in patients with a preexisting condition of cirrhosis. Therefore, the metabolomic comparison between HCC and cirrhosis is more clinically informative and potentially translational than the comparison of HCC vs NHC. HCC is a complex heterogeneous disease and HCC patients often present with multiple comorbidities. It is therefore likely that marked metabolomic differences will be observed between HCC patients and healthy subjects. Differences between HCC patients and cirrhosis controls are subtler than HCC vs NHC<sup>[45,46]</sup> and it would be expected that conspicuous metabolomic differences

exist between HCC/NHC and cirrhosis/NHC. Given that HCC arose in the background of cirrhosis in all reported HCC metabolomics studies, it is impossible to determine whether the alterations witnessed in HCC vs NHC are related to HCC or cirrhosis, further reinforcing the need for future metabolomic comparisons between HCC and cirrhosis.

## CONCLUSION

Bile acids, acylcarnitines, amino acids, free fatty acids, LPCs, and heme pigmentation molecules exhibited utility in stratifying HCC patients from patients with cirrhosis. Canavaninosuccinate, which showed a striking 680-fold elevation in HCC patients vs cirrhosis controls and outperformed AFP in sensitivity and specificity. Sphingosine 1-phosphate (↑), sphingosine (↑), GRO-α (↑), and thrombin light chain (↑) were other putative HCC biomarkers that had superior predictive utility for HCC than AFP. Bile acids, fibrinogen cleavage byproducts, dicarboxylic fatty acids, and ROS-related γ-glutamyl peptides exhibited strong association with cirrhosis and the further development of these metabolites as diagnostic markers of cirrhosis may be valuable. In addition to individual metabolites, global patient metabolomes exhibited superior sensitivity for diagnosis of HCC vs AFP where a comparison was made<sup>[31,35,38,45]</sup>.

Although these data are preliminary in nature, they reflect the early promise that metabolomics platforms hold in potential clinical implementation for disease diagnosis. Future metabolomics studies with larger, better demographically and clinically characterized patient cohorts may resolve the heterogeneous metabolomic expression patterns in HCC vs cirrhosis.

Given that > 90% of HCCs emerge in the setting of cirrhosis, future HCC metabolomics studies will be most impactful and clinically relevant if they compare the expression patterns of HCC patients vs cirrhosis controls. Moreover, patients with HCC and cirrhosis should be matched by etiology (viral vs non-viral), liver function, and BMI to limit the influence of data confounders. Furthermore, it is paramount the appropriate metabolomic profile comparisons are made, namely HCC vs cirrhosis, cirrhosis vs etiology of cirrhosis (viral or non-viral), and cirrhosis vs NHC. In a recent study, the entire stepwise hepatocarcinogenic process from NHC to HBV, through cirrhosis, and culminating in HCC was analyzed. Appropriately, Gao *et al.*<sup>[46]</sup> focused their expression profile comparisons on HCC vs cirrhosis, and cirrhosis vs HBV/NHC. This approach enables investigators to make adequate conclusions about the interval at which putative biomarkers become relevant in the hepatocarcinogenic process and demonstrates the relevance of the dataset comparisons. Moreover, investigation of the pathways involved in the progression from the initial liver insult to cirrhosis remains a largely untapped realm of biomarker discovery within metabolomics, and may streamline the identification of potential cirrhosis diagnostic markers. More broadly, metabolomics is well-suited for clarifying

the entirety of the metabolic remodeling that occurs throughout hepatocarcinogenesis, and can hence streamline biomarker discovery efforts at each pathological interval.

The findings of these works demonstrate the powerful resource that is metabolomics for identifying potential novel diagnostic biomarkers of HCC. The translational optimality of metabolomics is underscored by its capability to simultaneously process high volumes of patient specimens and interpret metabolic expression profiles through robust, validated and automated software. Still greater, metabolomics holds promise as a novel disease screening and diagnostic modality that, through characterization of a patient's global metabolic profile, can in a more sophisticated and comprehensive fashion accurately predict the presence of disease.

### Abstract

Hepatitis C virus (HCV) infects hepatocytes, polarized cells

in the liver. Chronic HCV infection often leads to steatosis, fibrosis, cirrhosis and hepatocellular carcinoma, and it has been identified as the leading cause of liver transplantation worldwide. The HCV replication cycle is dependent on lipid metabolism and particularly an accumulation of lipid droplets in host cells. Phosphoinositides (PIs) are minor phospholipids enriched in different membranes and their levels are tightly regulated by specific PI kinases and phosphatases. PIs are implicated in a vast array of cellular responses that are central to morphogenesis, such as cytoskeletal changes, cytokinesis and the recruitment of downstream effectors to govern mechanisms involved in polarization and lumen formation. Important reviews of the literature identified phosphatidylinositol (PtdIns) 4-kinases, and their lipid products PtdIns(4)P, as critical regulators of the HCV life cycle. SH2-containing inositol polyphosphate 5-phosphatase (SHIP2), phosphoinositide 3-kinase (PI3K) and their lipid products PtdIns(3,4)P<sub>2</sub> and PtdIns(3,4,5)P<sub>3</sub>, respectively, play an important role in the cell membrane and are key to the establishment of apicobasal polarity and lumen formation. In this review, we will focus on these new functions of PI3K and SHIP2, and their deregulation by HCV, causing a disruption of apicobasal polarity, actin organization and extracellular matrix assembly. Finally we will highlight the involvement of this pathway in the event of insulin resistance and nonalcoholic fatty liver disease related to HCV infection.

**Key words:** Hepatitis C virus; Phosphoinositide 3-kinase; SH2-containing inositol polyphosphate 5-phosphatase; Epithelial cell polarity; Phosphoinositides

**Core tip:** Chronic hepatitis C virus (HCV) infection leads to liver cirrhosis and cancer. HCV infection modulates the lipid metabolism. Phosphoinositides are minor phospholipids that are also modified by HCV infection. phosphatidylinositol (PtdIns)(3,4,5)P<sub>3</sub> is mainly formed by phosphoinositide 3-kinase (PI3K), and

can be dephosphorylated by SH2-containing inositol polyphosphate 5-phosphatase (SHIP2) to generate PtdIns(3,4)P<sub>2</sub>. In this review, we will discuss the effects of SHIP2 and PI3K on the formation of cell polarity and how their expression and activation are modulated by HCV infection, leading to the disruption of cell polarity. This pathway is also discussed in the event of insulin resistance and nonalcoholic fatty liver disease related to HCV infection.

## INTRODUCTION

Chronic Hepatitis C virus (HCV) infection leads to cirrhosis that will develop complications such as liver failure and liver cancer<sup>[1]</sup>. The principal target of HCV is hepatocytes, which are highly polarized cells, their plasma membranes being separated by tight junctions into apical (canalicular) and basolateral (sinusoidal) domains<sup>[2,3]</sup>. After it enters the hepatocytes, the life cycle of HCV is very closely linked to cell lipid metabolism. The very low density lipoprotein (VLDL) pathway is required for the assembly and secretion of new viral particles<sup>[4,5]</sup>. However, the effect of lipid droplets (LD) on the replication of HCV is becoming increasingly clear<sup>[6]</sup>. HCV induces an accumulation and change to the cellular distribution of LDs, moving from a dispersed profile in the cytoplasm of non-infected cells to their perinuclear localization in infected cells. This relocation permits the interaction of LDs with viral proteins and genomes<sup>[7]</sup>. While much is known about the role of lipoproteins and LDs in the HCV life cycle, studies are only now emerging on the modulation of phosphoinositides (PI) by HCV infection<sup>[8]</sup>.

PIs are phosphorylated derivatives of phosphatidylinositol (PtdIns). They are minor phospholipids (10%-20%) on the inner surface of the lipid bilayer and an important constituent of the cell membrane. The phosphorylation and dephosphorylation of PIs is achieved by various isoforms of PI kinases and PI phosphatases, distributed in a specific way in the cell, this result in the distribution of different PIs in cell compartments. These complex reactions are mediated by 19 kinases and 28 phosphatases that have been identified in mammals<sup>[9,10]</sup>. Figure 1 illustrates the phosphorylation and dephosphorylation cycles of different monophosphate, diphosphate and triphosphate PIs, as well as the most widely studied kinases and phosphatases. PIs are secondary messengers responsible for transmitting receptor signals to the effectors that induce a cellular response. PIs interact with these effectors *via* specific binding domains that are known to interact with the membrane, either by specific recognition of the membrane components or through attraction by its properties such as charge,

structure, curvature and amphiphilicity<sup>[11]</sup>. As well as acting as precursors of secondary messengers, PIs are spatiotemporal regulators of several target proteins involved in vesicular trafficking [such as PtdIns(4)P and PtdIns(3)P] and cytoskeletal rearrangement [PtdIns(4,5)P<sub>2</sub>], by which they control cell polarity, migration, proliferation and differentiation [PtdIns(3,4)P<sub>2</sub>] and PtdIns(3,4,5)P<sub>3</sub><sup>[12,13]</sup>.

Given the importance of PI metabolism to cellular signaling and trafficking events, numerous intracellular pathogens modulate and exploit PIs in order to ensure their survival and efficient intracellular replication<sup>[14,15]</sup>. A considerable body of literature has addressed the modulation of PIs by HCV<sup>[8]</sup>. Changes to the localization of PtdIns(4)P and activation of PI4KIII $\alpha$  following HCV infection have been identified as being key to membrane network formation and viral replication<sup>[1,16,17]</sup>. In this review we will focus on the roles of phosphoinositide 3-kinase (PI3K), SH2-containing inositol polyphosphate 5-phosphatase (SHIP2) and phosphatase and tensin homologue deleted on chromosome 10 (PTEN) and their lipid products in the establishment of plasma membrane polarity. We will also discuss how HCV infection modulates these polarity mechanisms to invade host cells and replicate. Finally, we will consider the involvement of the PI3K/PTEN/SHIP2 pathway in insulin resistance and nonalcoholic fatty liver disease (NAFLD) related to HCV infection.

## HCV

HCV is an enveloped virus with linear, single-stranded RNA contained in a capsid protein called core. Following entry of the virus into a host cell and uncoating of the viral genome, the translation of viral RNA produces a polyprotein that will be degraded to form three structural proteins (core, E1 and E2), six non-structural proteins (NS2, NS3, NS4A, NS4B, NS5A and NS5B) and p7 protein. The structural and non-structural proteins will mate with viral RNA to form new viral particles. This viral assembly occurs near the endoplasmic reticulum, and then new viral particles are released from the cell through fusion with the cell membrane<sup>[18,19]</sup>. Chronic infection with HCV, especially in cases of cirrhosis or advanced fibrosis, remains the leading cause of hepatocellular carcinoma (HCC) worldwide through the modulation of different pathways such as inflammation, proliferation and differentiation, and DNA damage<sup>[20]</sup>. Effective treatments for HCV have recently been developed, and over 95% of patients can now be cured<sup>[21,22]</sup>, but pathologies such as cancer induced by HCV infection remain a health problem for those already infected. Interactions between viral proteins and host cell mechanisms therefore remain central to understanding the pathogenesis of HCV.

## POLARITY IN THE LIVER AND THE ENTRY OF HCV

The polarity of epithelial cells is a property that is ess-

PI3Ks phosphorylate the hydroxyl group 3-position of the inositol ring of PtdIns. The PI3K family of enzymes contains three different classes ( I , II and III ), based on their substrate specificity and molecular structure<sup>[36]</sup>. PtdIns(3)P can be formed by PI3K- II and PI3K-III, and PtdIns(3,4)P2 is generated by the activity of PI3K- II. The activity of PI3K- I produces PtdIns(3,4,5)P3 which, once produced at the membrane, exercises its vital role of second messenger by recruiting different proteins containing a pleckstrin homology (PH) domain. The protein kinase Akt possesses a PH domain which was the first to be discovered and displays high affinity binding to phosphoinositides. The interaction between Akt and PtdIns(3,4,5)P3 induces a conformational change in

the Akt structure which permits its phosphorylation by phosphoinositide-dependent kinase 1 (PDK1) at threonine 308, and the mammalian target of rapamycin complex 2 (mTORC2) at serine 473 (Figure 2). Activated Akt is responsible for triggering numerous cellular signaling pathways involved in proliferation, survival, apoptosis and autophagy<sup>[12-37]</sup>. PI3K and its lipid product PtdIns(3,4,5)P3 have been identified as key regulators of apicobasal polarity<sup>[38,39]</sup>. Watton and Downward showed that the adhesion of epithelial cells to the extracellular matrix provides protection from apoptosis *via* the activation of PI3K and Akt/PKB. They confirmed the localization of PI3K at the basolateral membrane producing PtdIns(3,4,5)P3<sup>[38]</sup>. Another study also revealed PI3K activation after interaction of the cell with the ECM and cell-cell contact. They showed that E-cadherin, which is responsible for cell-cell junctions, joins the p85 sub-unit of PI3K and activates PI3K/Akt to generate PtdIns(3,4,5)P3 during the early stages of cellular polarization<sup>[40]</sup>. Gassama-Diagne *et al.*<sup>[39]</sup> studied the localization of PtdIns(3,4,5)P3 at the basolateral membrane in madin darby canine kidney (MDCK) polarized cells. This study confirmed that the formation of PtdIns(3,4,5)P3 at the basolateral membrane is essential to the initiation of basolateral polarization through the activation of Rac1. In fact, the experimental addition of exogenous PtdIns(3,4,5)P3 at the apical pole of polarized MDCK cells on transwell filters led in five minutes to the formation of PtdIns(3,4,5)P3 and basolateral protein-rich protrusions above the apical surface, from which apical proteins were excluded<sup>[39]</sup>. In MDCK 3D culture on matrigel, the formation of basolateral protein-rich protrusions was observed after three minutes of treatment with exogenous PtdIns(3,4,5)P3. The location and PI3K activity of these protrusions is important because the action of the PI3K inhibitor LY294002 inhibits the formation of protrusions, even when treating the cells with PtdIns(3,4,5)P3. By testing different ATP-competitive isoform-selective inhibitors of PI3K on the apicobasal polarity of MDCK grown in a 3D culture on Matrigel. Peng *et al.*<sup>[41]</sup> recently showed that treatment with the p110 $\delta$  inhibitors IC87114 and CAL-101 inverted the cell polarity of cysts displaying the apical marker Podocalyxin in contact with the ECM. The treatment of cells with other inhibitors such as PI-103, a multi-targeted inhibitor of p110 $\alpha$ /p110 $\beta$ /p110 $\gamma$ , and AS-605240 which targets p110 $\gamma$ , led to the formation of either multi-lumen or lumen-free cysts. Taken together, these data indicate that the P110 $\delta$  isoform plays a role in establishing the apicobasal polarity axis. Next, the p110 $\delta$  isoform was localized at the basolateral membrane of polarized cysts, and colocalized with the ECM receptor dystroglycan. The depletion of p110 $\delta$  at the basolateral membrane disrupted laminin and type IV collagen assembly by down-regulating  $\beta$ 1-integrin, which is a transmembrane protein with a specific role in ECM assembly and remodeling<sup>[42]</sup>. Overall, these findings revealed the role of epithelial p110 $\delta$  in the orientation of cell polarity and lumen formation by

regulating ECM assembly and interactions<sup>[41]</sup>.

A growing body of evidence in the literature has revealed that PIs and their metabolic enzymes are essential to HCV replication at different stages of the cell cycle<sup>[16,43,44]</sup>. Some studies validated activation of the PI3K/Akt pathway following infection by HCV<sup>[45]</sup>. Epidermal growth factor receptor (EGFR), which activates the PI3K/Akt pathway, was recently shown to be a co-factor for HCV entry in a cell<sup>[46]</sup>. Moreover, Street *et al.*<sup>[47]</sup> demonstrated an interaction between the viral protein NS5A and the p85 subunit of PI3K. This interaction is responsible for activating the p110 subunit of PI3K, which induces the formation of PtdIns(3,4,5)P3. The same study also showed that the NS5A protein induces the phosphorylation of Akt at tyrosine 308, thus causing anti-apoptotic activity. Other than its role in cell proliferation, transcription and migration, PI3K is also responsible for membrane expression of the SR-B1 receptor in HepG2 cells, promoting viral entry into the cells<sup>[48]</sup>. Furthermore, the NS4B protein induces lipogenesis in infected cells by activating the Akt pathway<sup>[49]</sup>. It has been shown that HCV core protein is expressed at the basal membrane of polarized cells, which leads to a deregulation of actin organization and affects focal contacts by increasing the expression of phosphorylated paxillin at the basal membrane<sup>[50]</sup>. The same study showed that the deregulation of actin is due to RhoA inhibition and Rac1 activation in cells expressing HCV core protein. These results also suggest that HCV core disrupts cell adhesion, inducing a reorganization of the actin cytoskeleton and a loss of cell polarity. Is PI3K involved in HCV core expression, thus inducing a disruption of cell adhesion? Many studies have revealed activation of the PI3K/Akt pathway and the formation of PtdIns(3,4,5)P3 following HCV infection<sup>[8,45,51,52]</sup>. This work focused on virus entry and replication and the epithelial to mesenchymal transition, but the effect of PI3K expression on the loss of cell polarity induced by HCV infection was not investigated. Nevertheless, the phenotype of cysts from MDCK cells expressing HCV core protein was of a multi-lumen type<sup>[50]</sup> which differed markedly from that of the inverted polarity cysts obtained from MDCK cells treated with the p100 $\delta$  inhibitors IC87114 and CAL-101, but was similar to those from MDCK cells treated with the p110 $\gamma$  and p110 $\beta$  inhibitors AS-605240 and TGX115, respectively<sup>[41]</sup>. This observation reveals a potential role for p110 $\gamma$  and p110 $\beta$  in the loss of cell polarity induced by HCV infection. Interestingly, Peng *et al.*<sup>[41]</sup> studied an MDCK phenotype involving an over-expression of the PI3K p110 subunit. These cysts displayed a marked ECM assembly (laminin and type IV collagen) at the basal membrane and a loss of cell polarity, and they were flatter than control cells. This result allows us to advance the hypothesis that p110 $\delta$  may be over-expressed in the context of HCV infection, leading to an accumulation of ECM which is responsible for cirrhosis. Taken together, these findings suggest a potential effect of PI3K and PtdIns(3,4,5)P3 on the deregulation of cell polarity induced by HCV infection.

## SHIP2 ACTIVITY, CELL POLARITY AND HCV INFECTION

The level of PtdIns(3,4,5)P3 is maintained through its dephosphorylation by the phosphatases SHIP1/2 and PTEN to produce PtdIns(3,4)P2 and PtdIns(4,5)P2, respectively<sup>[53]</sup> (Figure 3). A recent study highlighted the role of PtdIns(3,4)P2 and SHIP2 as additional determinants of basolateral membrane formation<sup>[50]</sup>. In non-polarized cells, SHIP2 is localized in the perinuclear and cytoplasmic domains. After stimulation with serum, SHIP2 may be localized at focal contacts in the plasma membrane<sup>[53]</sup>. In 3D cultured MDCK cells, Awad *et al.*<sup>[50]</sup> demonstrated a basolateral localization of SHIP2 and its lipid product PtdIns(3,4)P2. The enzymatic activity of SHIP2 gives rise to PtdIns(3,4)P2 and is essential for cell polarization. Indeed, SHIP2 inhibition by siRNA, and exogenous expression of the catalytic mutant of SHIP2 (D607A)<sup>[54,55]</sup> lead to a deregulation of cell polarity and the formation of multi-lumen cysts. Indeed, PtdIns(3,4)P2 is capable of binding Dlg1, the master regulator of basolateral polarity<sup>[56]</sup>. The inhibition of SHIP2 leads to a delocalization of the basolateral polarity proteins  $\beta$ -catenin, Scribble and Dlg1 from cell-cell contacts; moreover, their expression is markedly reduced. Overall, these data suggest that SHIP2 is required for the localization and expression of the basolateral complex proteins Dlg1 and Scribble in order to maintain cell morphogenesis<sup>[50]</sup>. Moreover, the Rho family of GTPases, and particularly RhoA and Rac1 which regulate the formation of stress fibers and lamellipodia, respectively<sup>[57]</sup>, play a pivotal role in cell polarity<sup>[58]</sup>. It has been reported that SHIP2 increases the activation of RhoA in epithelial cells<sup>[50]</sup>. This activation is required for the polarization and migration of glioma cells<sup>[59]</sup>. Awad *et al.*<sup>[50]</sup> confirmed that SHIP2 is an additional target for HCV infection. Their study examined the expression of SHIP2 and PtdIns(3,4)P2 in MDCK cells grown in a 3D culture on Matrigel, and in a 2D culture on transwell filters. MDCK cells expressing HCV core protein displayed a reduction of SHIP2 and PtdIns(3,4)P2 expression at the basal membrane. Interestingly, HCV core protein was localized specifically at the basal membrane in contact with the ECM. Together, these findings indicate that HCV core protein is able to subvert SHIP2 expression in order to disrupt cell membrane morphology<sup>[50]</sup>. In these cells, the down-regulation of SHIP2 and PtdIns(3,4)P2 leads to down-regulation of the expression of Dlg1 and Scribble at the basolateral membrane. These disturbances to the expression of polarity proteins lead accordingly a loss of apicobasal cell polarity and the formation of multi-lumen cysts. HCV core expression also displays a loss of RhoA activation, in the same way as SHIP2 depleted cells. Interestingly, an over-expression of SHIP2 cDNA in HCV core-expressing cells has been seen to restore single lumen formation, RhoA activation and cell polarity. Taken together, these data indicate that HCV core is able to subvert SHIP2 in order to disrupt cell polarity and infected polarized cells<sup>[50]</sup>.

## PTEN AND PTDINS(4,5)P2, CELL POLARITY AND HCV INFECTION

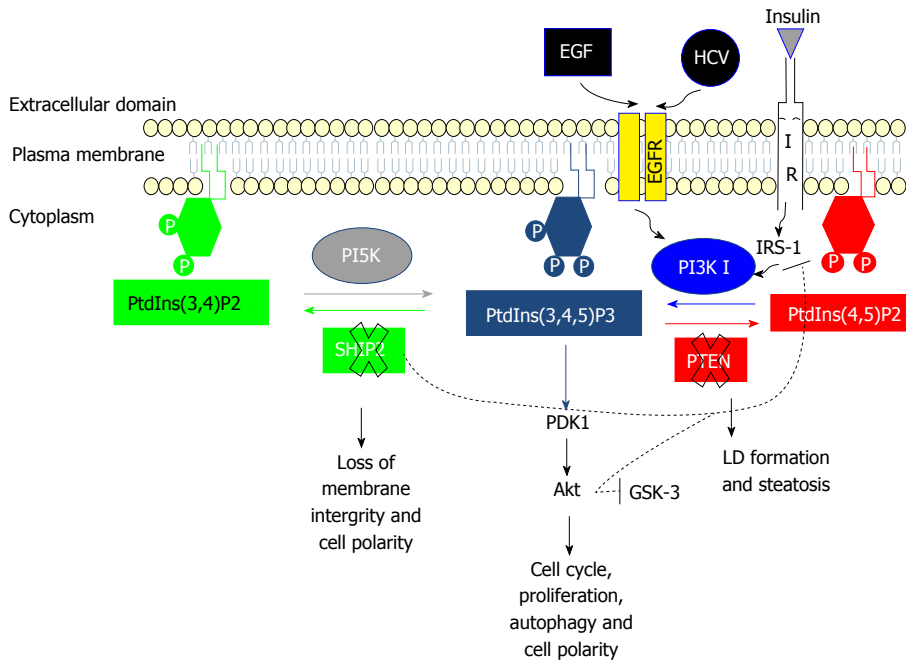

PTEN, the other phosphatase which antagonizes PI3K, is also implicated in cell polarity. Martin-Belmonte *et al.*<sup>[60]</sup> identified PtdIns(4,5)P2 as a key regulator of the apical membrane. During the early stages of cyst formation, PtdIns(3,4,5)P3 and PtdIns(4,5)P2 are co-localized at the plasma membrane of non-polarized cells, while PtdIns(4,5)P2 becomes concentrated at the apical surface of polarized cells. The role of PIP5K in apical membrane trafficking, by which synthesizing PtdIns(4,5)P2, has recently been reported and confirmed the possible production of PtdIns(4,5)P2 at the apical membrane<sup>[61,62]</sup>. Meanwhile, PTEN regulates the apical recruitment of Par3, Par 6, Cdc42 and annexin 2 (Anx2), and is required for lumen development<sup>[63]</sup>. In addition, it has been shown that Par3 membrane targeting is dependent on the binding of its PDZ domain to PtdIns(4,5)P2, the product of PTEN<sup>[64,65]</sup>. The inhibition of PTEN by siRNA, or by a specific inhibitor bpV(pic), prevents the formation of a single central lumen in the cysts and causes a defective segregation of PtdIns(3,4,5)P3 and PtdIns(4,5)P2. This study also identified the fact that PTEN binds Anx2, which is responsible for the recruitment of Cdc42 and hence of apical aPKC, causing polarization of the apical membrane<sup>[60]</sup>.

HCV replication is dependent on PtdIns(4,5)P2<sup>[66]</sup> the lipid product of PTEN. HCV infection leads to a down-regulation of PTEN, triggering an acceleration of lipid droplet formation and insulin resistance<sup>[67,68]</sup>. The down-regulation of PTEN causes a malformation of the apical domain in an MDCK 3D culture<sup>[60]</sup>, suggesting that the multi-lumen phenotype in MDCK cells expressing HCV core protein may be caused not only by RhoA down-regulation<sup>[50]</sup> but also by modifying PTEN expression. It has been shown that the core protein of HCV genotype 3a Core decreases the expression of PTEN by blocking the translation of messenger RNA and causing an accumulation of lipid droplets in the cells. In addition, PTEN over-expression in these cells is capable of reducing the accumulation of lipid droplets. This study therefore suggests that this down-regulation of PTEN by HCV infection is a critical mechanism leading to steatosis and its progression toward fibrosis and hepatocellular carcinoma<sup>[67]</sup>.

## INSULIN RESISTANCE AND HCV INFECTION

Type II diabetes, and more generally insulin resistance, is very common in the context of chronic HCV infection, as has been established by several recent epidemiological studies<sup>[69-71]</sup>. Other studies have also shown that HCV infection can cause insulin resistance by the phosphorylation of IRS-1 at a serine residue (Ser307) followed by a decreased phosphorylation of Akt Thr(308), FoxO1 Ser(256) and GSK3 $\beta$  Ser(9), downstream players

**Figure 3 PI3K/Akt pathway and its activation by hepatitis C virus infection.** When EGF binds to EGFR this will activate PI3K I. PI3K activation will increase the level of PtdIns(3,4,5)P3 to phosphorylate Akt and induce cell proliferation and cell polarity. Hepatitis C virus (HCV) is able to bind EGFR at its entry into a cell, thus increasing PI3K activation and the level of PtdIns(3,4,5)P3, the latter being sustained by the down-regulation of SHIP2 and PTEN. The down-regulation of SHIP2 by HCV induces a loss of membrane integrity and cell polarity, while the down regulation of PTEN induces lipid droplet (LD) formation and steatosis. PtdIns: Phosphatidylinositol; PI3K: Phosphoinositide 3-kinase; SHIP2: SH2-containing inositol polyphosphate 5-phosphatase; PTEN: Phosphatase and tensin homologue deleted on chromosome 10; EGFR: Epidermal growth factor receptor.

in the insulin signaling pathway<sup>[72,73]</sup>. These data raise the question whether insulin resistance is the cause of liver steatosis in patients with chronic HCV infection, or the consequence of viral molecular expression. Indeed, Shintani *et al.*<sup>[74]</sup> showed that insulin resistance preceded the onset of steatosis in transgenic mice expressing HCV core protein, suggesting that insulin resistance was not a consequence of hepatic steatosis in these animals. Another study confirmed that the pathophysiology of fatty liver-associated chronic hepatitis C differed in patients infected with genotypes 1 and 3, showing that insulin resistance in genotype 1 patients is the cause rather than the consequence of hepatic steatosis and fibrosis, and suggesting that elevated circulating insulin levels are a risk factor for fibrosis through steatosis induced by insulin resistance. In genotype 3-infected patients, steatosis was related to HCV viral load<sup>[75]</sup>. These findings suggest that antiviral therapy in genotype 1-infected patients will not be sufficient. But does an improvement in metabolic syndrome increase the success rates of antiviral therapy? Walsh *et al.*<sup>[76]</sup> confirmed that in patients with chronic HCV viral genotype 1, an increased expression of factors inhibiting interferon signaling could be a mechanism by which obesity reduces the biological response to IFN- $\alpha$ . In 2006, Tarantino *et al.*<sup>[77]</sup> also confirmed that by improving metabolic syndrome, a lowering of the body mass index could play a key role in reducing the importance of metabolic co-factors and improving the foundations for a good antiviral response. For this reason, insulin sensitizers such as metformin are known to improve the response to HCV treatment and have been associated

with a lower risk of developing HCC. Very recently, a clinical trial was initiated by the Ottawa Hospital Research Institute to evaluate the effects of metformin on liver fibrosis in HCV-HIV co-infected and HCV mono-infected patients suffering from insulin resistance. If metformin proves to be effective in reducing liver fibrosis in this patient population, it will represent a well-tolerated, easy-to-administer, inexpensive therapy that could protect against negative HCV outcomes. This study will also provide an opportunity to evaluate the impact of insulin resistance and hyperglycemia on viral clearance in HCV-infected patients treated with interferon-free regimens<sup>[78]</sup>.

## PI3K/SHIP2/PTEN PATHWAY AND INSULIN RESISTANCE

Akt activity is essential for the translocation and fusion of glucose transporter 4 (GLUT4) to the plasma membrane of cells in the skeletal muscle and adipose tissue. In turn, GLUT4 plays a crucial role in the absorption of glucose. Akt induced by insulin signaling is also critical to the regulation of gluconeogenesis and glycolysis in the liver. When binding insulin to its receptor, SHIP2 also binds to the cell membrane and negatively regulates insulin signaling. An over-expression of SHIP2 in adipocyte 3T3-L1 cells inhibits insulin signaling, and expression of the catalytic mutant SHIP2 enhances the activity of Akt induced by insulin and thus generates glucose uptake and glycogen synthesis<sup>[79]</sup>. In 2001, Clément *et al.*<sup>[80]</sup> developed transgenic mice deficient in SHIP2.

They showed that adult mice with the heterozygous SHIP2 mutation increased their glucose tolerance and insulin sensitivity, which was also associated with an increase in recruitment of the glucose transporter GLUT4. Homozygous mice with a SHIP2 deficiency experienced severe neonatal hypoglycemia and died within three days. These results show that SHIP2 is a potent negative regulator of insulin signaling and insulin sensitivity *in vivo*. A second SHIP2 deficient mouse model was studied by Sleeman *et al.*<sup>[81]</sup> in 2005. They found that SHIP2 deficient mice were viable, with normal glucose levels and normal tolerance to insulin. However, they were very resistant to putting on weight when fed a high-fat diet<sup>[81]</sup>. Although these two models had different phenotypes, the results suggest that SHIP2 is a key regulator of glucose, and its inhibition would be useful regarding efforts to improve diet-induced obesity. Furthermore, transgenic mice expressing catalytically-inactive SHIP2 have displayed altered lipid metabolism and insulin secretion<sup>[82]</sup>. In addition transgenic mice over-expressing SHIP2 WT are obese and suffer from hepatic insulin resistance<sup>[83]</sup>. These results show that the inhibition of SHIP2 may influence lipid metabolism and insulin signaling. For these reasons, the use of antisense oligonucleotides against SHIP2 in model diabetic rats produced a rapid improvement in insulin sensitivity<sup>[84]</sup>. Taken together, these *in vivo* studies suggest that an inhibition of SHIP2 expression may be effective in the treatment of type 2 diabetes. The relationship between SHIP2 and insulin resistance has also been studied in patients with type II diabetes whose SHIP2 gene (*INPPL1*) had a deletion of the 3' extremity. This mutation enhanced the expression of SHIP2 in the adipose tissue and skeletal muscles of diabetic patients, causing insulin resistance<sup>[85]</sup>. Overall, these findings suggest that SHIP2 is a key regulator of glucose homeostasis and could be targeted when treating diseases that affect insulin metabolism such as diabetes type II. This central role of SHIP2 as a negative regulator of insulin signaling encouraged Sumie *et al.*<sup>[86]</sup> to investigate changes to SHIP2 expression in HCC patients with HCV infection. They showed that the cumulative survival rate was significantly lower in the glucose intolerance group than that in the normal glucose tolerance group, and that the level of SHIP2 expression fell in a context of HCC when compared to that seen in non-tumor tissues. This study therefore indicated a prognostic role for glucose tolerance and SHIP2 expression in HCC patients with HCV infection.

PTEN is the second phosphoinositide phosphatase that negatively regulates insulin signaling<sup>[83-87]</sup>. Studies using 3T3-L1 adipocytes clearly demonstrated that PTEN over-expression inhibited the production of insulin-induced PtdIns(3,4)P<sub>2</sub> and PtdIns(3,4,5)P<sub>3</sub>, the activation of Akt/PKB, the translocation of GLUT4 to the cell membrane and glucose uptake<sup>[88,89]</sup>. By contrast, the down-regulation of PTEN by small interfering RNAs enhanced Akt/PKB activation and glucose uptake in response to insulin<sup>[90]</sup>. Furthermore, an over-expression of catalytically-inactive or dominant-negative PTEN mutants also indicated

that it is the lipid phosphatase activity of PTEN which is necessary to down-regulate Akt/PKB signaling and glucose uptake in response to insulin<sup>[89-91]</sup>. Finally, all these studies showed that the PI3K/Akt pathway offers a target to improve steatosis and insulin resistance during the development of NAFLD. Different treatments such as Silibinin and FAM3A (cytokine-like gene family) activate PI3K p110 $\alpha$ /Akt signaling in order to ameliorate hepatic gluconeogenesis and lipogenesis<sup>[92,93]</sup>. Flanovol Quercetin is another treatment with favorable effects on the progression of NAFLD, acting *via* the PI3K/Akt pathway. Treatment with quercetin has been shown to reduce oxidative/nitrosative stress and inflammation, and genes related to lipid metabolism displayed a tendency to normalize in both *in vivo* and *in vitro* models<sup>[94]</sup>.

### PI3K/SHIP2/PTEN PATHWAY AND NAFLD

NAFLD is often associated with HCV infection. NAFLD is frequently described as encompassing a histological spectrum from nonalcoholic fatty liver to simple hepatic steatosis (SHS) plus a characteristic pattern of steatohepatitis [nonalcoholic steatohepatitis (NASH)]. HCV infection also gives rise to liver steatosis. So is the PI3K/SHIP2/PTEN pathway implicated in NAFLD in a context of HCV infection? In the liver, insulin controls lipid metabolism through its cell surface receptor and intracellular mediators such as PI3K and serine-threonine kinase Akt. It has been shown that insulin inhibits apoB100 secretion through the activation of PI3K. And insulin signaling *via* PI3K inhibited the maturation of VLDL lipoprotein particles by preventing lipidation of the VLDL precursor<sup>[95]</sup>. For this reason, a disruption of phospholipid metabolism is present in NAFLD. Indeed, a recent study demonstrated that plasma phospholipids differed between liver biopsies from NAFLD patients and healthy subjects. Phosphatidylinositol levels were higher in SHS and NASH patients compared with healthy controls<sup>[96]</sup>. Another study also identified the role of dietary phosphatidylinositol (and particularly phosphatidylcholine and phosphatidylserine) in preventing NAFLD in a rat model of metabolic syndrome<sup>[97]</sup>. Furthermore, in transgenic mice with hepatic steatosis and developing a tumor, alongside an abnormal accumulation of fatty acids, the study demonstrated activation of the Akt/mTOR pathway, and a reduction in the expression of tumor suppressor genes, including *Pten*. This confirmed that an accumulation of fatty acids may have a role in promoting *in vivo* hepatic tumorigenesis under constitutive activation of the PI3K pathway<sup>[98]</sup>. Another study confirmed that high unsaturated fatty acid levels significantly decreased PTEN mRNA expression in hepatic cells by means of a mechanism involving the sequential activation of mTOR and NFB, which were found to form a complex in cultured cells<sup>[99]</sup> which led to a significant alteration of PTEN expression. It is important to remember that inflammatory cytokines such as transforming growth factor  $\beta$ , tumor necrosis factor  $\alpha$ , interleukin-6

**Figure 4** Effects of hepatitis C virus infection on cell polarity. In a 3D culture, MDCK form a cyst comprising a monolayer of cells around a lumen (the basolateral membrane is indicated in green, the apical membrane in red and the tight junctions in black). The right-hand column shows a zoom of a polarized cell. PI3K is activated by E-cadherin. The p110 $\delta$  subunit is activated by ECM (Laminin and collagen IV). SHIP2 and PI(3,4)P2 at the basal membrane are responsible for the Dlg1/Scribble complex at the basolateral membrane. PTEN interacts with Par3 at the tight junctions and its lipid product PtdIns(4,5)P2 is localized at the apical membrane. The bottom column represents the multi-lumen phenotype of cysts expressing HCV core protein. The presence of this core protein at the basolateral membrane activates PI3K and inhibits SHIP2 and PTEN, leading to a loss of cell polarity and an accumulation of lipid droplets (LDs). HCV: Hepatitis C virus; PtdIns: Phosphatidylinositol; PI3K: Phosphoinositide 3-kinase; SHIP2: SH2-containing inositol polyphosphate 5-phosphatase; PTEN: Phosphatase and tensin homologue deleted on chromosome 10; MDCK: Madin darby canine kidney; DG: Dystroglycan.

and interleukin-1, which are produced in the course of NAFLD, also significantly alter PTEN expression, as has been shown in non-liver cells. These studies offer an interesting link between insulin resistance and steatosis, which may also explain (at least in part) the high risk of developing HCC associated with diabetes and obesity<sup>[100]</sup>. PTEN deregulation has also been demonstrated during *in vivo* studies. First, a study of heterozygous PTEN deletion was confirmed as inducing atypical adenomatous liver hyperplasia<sup>[101]</sup>. Subsequently, a genetic inhibition of PTEN expression, specifically in the liver of rodents, was shown to trigger liver steatosis, insulin hypersensitivity and HCC<sup>[102]</sup>. Because of the lack of PTEN activity, there may be an increase in fatty acid uptake by hepatocytes, and in fatty acid synthesis<sup>[103]</sup>. Hepatocyte-specific PTEN deficient mice display similar histological features to human NASH patients. These hepatocytes display enhanced lipid accumulation, inflammatory changes and hyperoxidation, and also develop into HCC<sup>[104]</sup>. Therefore, an impairment of PI3K/PTEN signaling could be involved in some NASH/HCC cases in humans. These results are very compatible with the down-regulation of PTEN in HCV infection, which leads to an acceleration of lipid droplet formation and insulin resistance<sup>[67,68]</sup>. Taken

together, these studies have suggested a role for PTEN in regulating lipogenesis in liver cells; however, less information is available on the effects of another lipid phosphatase, SHIP2, on lipid and lipoprotein metabolism in the liver. A very recent study found a molecular link between SHIP2 expression and metabolic dyslipidemia using the over-expression or suppression of the *SHIP2* gene in HepG2 cells. SHIP2 over-expression led to higher lipid production and secretion *via* apoB100 secretion and *de novo* lipogenesis<sup>[105]</sup>. Another study confirmed that PBX-regulating protein 1 enhances *Ship2* transcription, leading to hepatic lipogenesis and steatohepatitis in mice. However, Prep1 hypomorphic heterozygous [Prep1 (i/+)] mice displayed lower SHIP2 levels, and significantly decreased serum triacylglycerol levels and the liver expression of fatty acid synthase<sup>[106]</sup>. We have discussed above the down-regulation of SHIP2 in HCV core-expressing cells, so is this down-regulation of SHIP2 the cause of lipid droplet accumulation in these cells? Overall, these findings confirm that SHIP2 is responsible for hepatic lipogenesis and secretion. To conclude, the PI3K/SHIP2/PTEN pathway, which is markedly deregulated in the context of HCV infection, activates Akt causing an over-expression of fatty acids, leading subsequently to liver steatosis, insulin hypersensitivity and HCC.

## CONCLUSION

PI3K and SHIP2 have been widely studied for their roles in intracellular signaling and membrane trafficking. However, their membrane segregation and the effects of their enzymatic activity on the establishment of cell polarity are only now starting to be investigated. Recent studies have defined the manipulation of these PI enzymes and their lipid products by the hepatitis C virus, so that it can enter and replicate in epithelial host cells (Figure 4). The PI3K/PTEN/SHIP2 pathway is now better understood in the context of HCV infection, inasmuch as it induces changes to cell polarity and lipid metabolism which can generate several pathologies such as insulin resistance, liver steatosis, NAFLD and HCC.

### Abstract

Drug-induced liver injury (DILI) is a hot topic for clinicians, academia, drug companies and regulators, as shown by the steadily increasing number of publications and agents listed as causing liver damage ([\[livertox.nih.gov/\]\(http://livertox.nih.gov/\)\). As it was the case in the past decade with drug-induced QT prolongation/arrhythmia, there is an urgent unmet clinical need to develop tools for risk assessment and stratification in clinical practice and, in parallel, to improve prediction of pre-clinical models to support regulatory steps and facilitate early detection of liver-specific adverse drug events. Although drug discontinuation and therapy reconciliation still remain the mainstay in patient management to minimize occurrence of DILI, especially acute liver failure events, different multidisciplinary attempts have been proposed in 2016 to predict and assess drug-related risk in individual patients; these promising, albeit preliminary, results strongly support the need to pursue this innovative pathway.](http://</a></p>

**Core tip:** The interest in drug-induced liver injury (DILI) is growing, especially in 2015-2016, with pioneering studies addressing DILI annotation, *i.e.*, risk stratification of drugs capable of causing liver damage. The latest experiences from worldwide consortia provided promising data, although there is still room for improvement before reaching an algorithm capable of discriminating hepatotoxic from non-hepatotoxic compounds, or at least of classifying high, intermediate and low risk drugs within the same therapeutic class. We should take advantage of integration of real-world data (*i.e.*, registries, healthcare databases, spontaneous reporting systems, literature) with cheminformatics to provide a comprehensive DILI risk score.

Raschi E, De Ponti F. Drug-induced liver injury: Towards early prediction and risk stratification. *World J Hepatol* 2017; 9(1): 30-37 Available from: URL: <http://www.wjgnet.com/1948-5182/>

## INTRODUCTION

The year 2015 witnessed an outstanding scientific production of studies dealing with drug-induced liver injury (DILI) and the list of drugs capable of causing liver dysfunction needs constant update, thus making DILI an emerging safety issue requiring attention by academia, regulators, drug companies and clinicians, both in specialty and general practice<sup>[1,2]</sup>.

A search in MEDLINE using the strategy "DILI or drug-induced liver injury or drug-induced liver damage or herb-induced liver injury or herb-induced liver damage or hepatotoxicity" yielded 2196 publications in 2015 (performed on June 7<sup>th</sup>, 2016) (Figure 1), with more than 2000 studies per year published in the past 4 years. The proportion among the different types of studies has not substantially changed over time, with pre-clinical investigations representing the majority of publications (more than 60% of total studies in 2015). This body of evidence has generated concern within the scientific community, especially among clinicians, who are not fully aware that a number of drugs are likely to affect liver function and must be therefore considered among the differential diagnoses in patients presenting with elevated transaminases.

DILI has tremendous impact on medical prescribing attitudes: The latest data confirmed that hepatotoxicity was the most commonly reported adverse drug reaction leading to drug withdrawal worldwide (81 cases; 18%)<sup>[3]</sup>. Several global registries (in United States, Latin America, Europe and China) have continued to update case series and implement completeness and accuracy of data<sup>[4]</sup>. It is interesting to note that antineoplastic/antimicrobials are the most frequently implicated drugs in DILI reports across all data registries and population-based studies, with herbal and dietary supplements being an emerging concern especially in United States<sup>[5-7]</sup>.

While population-based studies are useful to estimate DILI incidence (despite suffering the inability to account for genetic backgrounds), prospective registries across various DILI consortia allow careful case adjudication. It is worth mentioning that registries consistently enrolled sicker patients as compared to epidemiological studies, with 70% of the patients jaundiced at presentation and half of them requiring hospitalization, thus the proportion of non-"true" DILI cases is probably negligible. This selection bias, probably related to the fact that DILI patients are mainly recruited in hospital units, is useful to appreciate phenotypes of liver damage (hepatocellular, cholestatic and mixed) and investigate specific features or drug signatures: Female sex, hepatocellular type of damage and high bilirubin levels emerged as risk factors for fulminant liver failure and death<sup>[8]</sup>, with higher mortality risk in patients with preexisting liver disease<sup>[9]</sup>.

In this minireview, we highlight advances in DILI re-

search, focusing on recent studies that, in our opinion, provide key contribution towards an unmet clinical need: Risk stratification of drugs capable of causing liver damage, also known as DILI annotation.

## SUSPECTING AND DIAGNOSING DILI: A CURRENT DILEMMA

### *The contribution of drugs in DILI occurrence*

Different drugs have been convincingly documented to cause liver injury in numerous case reports and case series<sup>[10]</sup>. Paracetamol has been consistently reported as a leading cause of acute liver failure, whereas chlorpromazine, halothane, sulpiride and amoxicillin-clavulanate such as found to be the most common drugs leading to hepatotoxicity in all prospective studies<sup>[11]</sup>. Apart from antibiotics, the list of top 10 drugs implicated in DILI cases (in terms of frequency) comprises statins (only rarely severe liver injury was likely to be associated with statins), antitumor necrosis factor antagonists (with infliximab being the most common implicated agent, with autoimmune features), and herbal and dietary supplements (with weight loss and bodybuilding products being the most frequent causes of serious hepatotoxicity)<sup>[12]</sup>.

A risk of DILI greater than 100 per 100000 users was found for chlorpromazine and sulpiride. Drugs with an intermediate risk were amoxicillin-clavulanic acid and emerged with a risk of 10 per 100000 users<sup>[13]</sup>. All other drugs were found to be less than 10 per 100000 users.

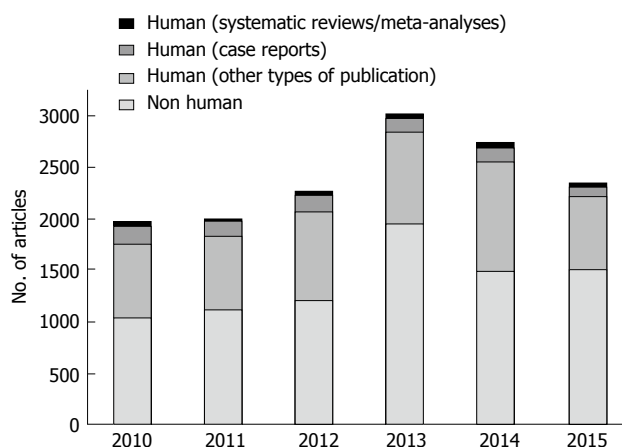

Unfortunately, in most of the cases, DILI is unpredictable because of its idiosyncratic nature; in fact, only rarely have the precise underlying mechanisms been identified (*e.g.*, mitochondrial injury, reactive metabolites, biliary transport inhibition, and immune responses). Paracetamol is a well-known example of drug causing dose-dependent DILI.

### *Obtaining evidence-based data to support DILI diagnosis*

DILI is a diagnosis of exclusion, thus strengthening the importance of anamnesis and clinical experience. Apart from ruling out competing causes (*e.g.*, viral infections), it is crucial in the clinician's mind to have information on the notoriety, *i.e.*, whether the drug is known or has the potential to cause hepatotoxicity. However, these evidence-based data are not always easily accessible<sup>[11]</sup>.

The first aid is represented by the product information or summary of the product characteristics (in United States and Europe, respectively), which however is variable in terms of details and may also substantially differ in the labeling of liver risk<sup>[14]</sup>. The key information to be checked is the existence of contraindications in patients with pre-existing liver diseases and the presence of specific warnings on the risk of liver damage, with relevant precautions in appropriate monitoring and management. It must also be kept in mind that the wording of these documents follows rules that are not always patient- and physician-friendly. Other sources of information are therefore highly needed.

**Figure 1** Trend in publication of articles on drug-induced liver injury, classified in terms of types of evidence. The search was performed in MEDLINE on June 7<sup>th</sup>, 2016, through automatic filters and keywords.

Ascertainment of the literature is the second step, which is a more challenging and time-consuming task. While some drugs have been convincingly documented to cause liver injury and clinical signatures have been demonstrated (e.g., isoniazid, amoxicillin-clavulanic acid), for some agents only a few case reports are available and, most importantly, only in a minority critical clinical data are provided to ascertain the causative role of drugs<sup>[15]</sup>.

The third source of data is represented by LiverTox<sup>®</sup> (<http://livertox.nih.gov/>), a public website set up to provide up-to-date, accurate, and easily accessible information on the diagnosis, causes, frequency and patterns of liver injury attributable to both prescription and nonprescription medications. Although LiverTox<sup>®</sup> is based on a thorough literature analysis, the quality of the published reports and the causality of the suspected liver injury reported are not provided.

Specific algorithms, such as the Roussel Uclaf Causality Assessment Method scale, have been proposed and validated to assess causality, although it should be recognized that these scores are particularly useful for regulatory and research purposes, *i.e.*, to verify a posteriori the likelihood of the association rather than to support a prospective diagnosis<sup>[16]</sup>. During the preapproval development process, Hy's Law (*i.e.*, ALT/AST > 3 ULN in combination with total bilirubin > 2 ULN in the absence of cholestatic injury - alkaline phosphatase < 2 ULN) is an essential part of the stopping rules to prevent hepatotoxicity, although it was never specifically validated in a clinical trial. Different research group have recently attempted to optimize the definition of Hy's Law and develop models for predicting acute liver failure in DILI, in combination with other biomarkers such as total bilirubin and platelet count<sup>[8,17]</sup>. However, whether such revised definitions can become part of clinical practice is yet to be determined.

### **Risk stratification of DILI in clinical practice: A dream or a reality?**

Current expectations regard the development and im-

plementation of risk stratification tools to assign a certain liver risk to a given drug. In other words, clinical research is trying to establish the so-called DILI annotation, a global score reflecting the frequency, causal role and severity of DILI for each drug<sup>[18]</sup>. This scenario recalls what occurred in the past decade with drug-induced QT prolongation and Torsade de Pointes (DITdP), which has been a largely debated regulatory issue for the past 20 years with still suboptimal tools for risk stratification in clinical practice<sup>[19]</sup>. With this experience in mind, we should immediately understand the importance of coordinating and harmonizing the various ongoing projects and the need to set up a global response to efficiently assess drug-related hazards. A parallel between DILI and DITdP is presented in Table 1.

Identification of baseline risk is the first step towards final risk stratification. DILI has a multifactorial nature with both environment- drug- and patient-related risk factors that may coexist and increase the likelihood of DILI occurrence.

Apart from age and sex, genetics plays a role, at least for some drugs. A recent genome-wide association study involving 620 European cases of DILI and 10588 population controls, the DRB1\*16:01-DQB1\*05:02 haplotype was identified as a risk factor for flupirtine-induced liver damage<sup>[20]</sup>. Although the inclusion of genetic tests in causality assessment may improve consistency and precision of DILI diagnosis as well as appropriateness of drug administration, there is only initial positive experience in clinical application of N-acetyltransferase 2 genotyping to determine the appropriate dose of isoniazid<sup>[21]</sup>.

A current area of research deals with the identification of biomarkers, keeping in mind the aim of detecting patient's susceptibility to DILI prior to and during drug exposure, predicting the course of DILI once it occurs and differentiate DILI from other causes of liver injury. Among others, miR-122 expression was demonstrated to be a liver specific biomarker of paracetamol hepatotoxicity; high levels of High Mobility Group Box-1 with circulating colony stimulating factor-1 were correlated to poor prognosis and outcome in patients with established acute liver injury following paracetamol overdose; likewise, the prognostic utility of Keratin-18 has been proposed; notably, up-regulation of Kidney Injury Molecule-1, a marker of renal proximal tubular epithelia, could be a determinant of mortality in patients with paracetamol overdose and secondary kidney damage; finally, Glutamate Dehydrogenase might indicate hepatocellular necrosis, although lacking specificity in discriminating benign transaminases elevation from severe DILI occurrence. All these biomarkers, however, still require formal qualification before being considered for routine clinical use<sup>[22]</sup>.

Among drug-related features, oral medications with high lipophilicity (*i.e.*, logP ≥ 3) administered at daily doses of ≥ 100 mg (known as the concept of the "Rule-of-2") have been associated with higher risk of DILI<sup>[23]</sup>. Bile salt export pump and multidrug resistance-associated protein 4 inhibitions have been also identified

**Table 1** Similarities and differences between drug-induced torsade de pointes and drug-induced liver injury

	DITdP	DILI
Endpoint/biomarker	Surrogate, but well defined biomarker of risk (QT prolongation with specific thresholds)	Surrogate, but well defined biomarker of risk (transaminase elevation with specific thresholds)
Key mechanism	Largely described (dose-dependent hERG K <sup>+</sup> channel inhibition)	Only partially understood (different hypotheses)
Dose-response relationship	Dose dependent (with only a few exceptions)	Idiosyncratic, although dose-dependence exists
Regulatory impact	Pre-clinical and clinical guidelines (pre-marketing)	Clinical guideline (pre-marketing)
Clinical impact	Significant (a leading cause of drug withdrawal worldwide)	Significant (a leading cause of drug withdrawal worldwide)
Predictivity of pre-clinical assays	Reasonably good (new models under investigation)	Sub-optimal (especially for <i>in vivo</i> models)
Predictivity of clinical studies	Good (thorough QT study), albeit imperfect	Good (Hy's law), albeit imperfect
Role of genetics	Important (long QT syndrome)	Partially defined (only for some drugs)
Awareness (clinicians, regulators, drug developers, researchers)	Significant at all levels	Significant at some levels (drug developers, researchers)
Risk assessment tools (clinical)	Drug- and patient-related risk factors are well recognized (www.crediblemeds.org); CDSSs are under implementation	Drug- and patient-related risk factors are only partially recognized (www.livertox.nih.gov)
Causality assessment tools (clinical)	Not present, but the majority of TdP cases are drug induced (the so-called designated medical event); phenotype standardized	Specific, but challenging (several differential diagnoses)
Therapy	Magnesium sulphate, electrical cardioversion or isoproterenol (isoprenaline) or transvenous pacing (refractory TdP cases); removal or correction of precipitants, including drugs	No specific treatment other than drug discontinuation; liver transplantation may be required in acute liver failure cases

For details on DITdP<sup>[50-53]</sup>. CDSSs: Clinical decision support systems; DILI: Drug-induced liver injury; DITdP: Drug-induced torsade de pointes.

as important determinants of cholestatic DILI risk in humans<sup>[24,25]</sup>. However, the contents and the extent of information of these transporters in the summaries of the product characteristics may vary considerably between United States and Europe, especially for novel drugs<sup>[26]</sup>.

Therefore, the recent literature attempted to annotate DILI risk through different approaches, all of which rely on the assessment of already available data. Among the various experiences, risk categories were created based on the information extracted from drug compendium, such as Physicians Desk Reference, and case reports (alone or integrated with literature and drug labeling)<sup>[18,27-32]</sup>. However, the validity of these published annotations is still a matter of debate because all methods present limitations and a gold standard to define DILI risk is lacking<sup>[33]</sup>. This is an unresolved concern, common to all drug-related safety issues.

Very recently, two different approaches stimulate interest in annotating DILI risk. Chen *et al.*<sup>[34]</sup> combined the rule-of-two with the capacity to produce reactive metabolites and implemented a model to assess the risk of DILI onset and severity. Both dose-based and C<sub>max</sub> based-scores were calculated. Initial validation of this score indicated that half (19/38) of DILI cases with a dose-based DILI score  $\geq 7$  were associated with severe clinical outcome (e.g., hepatic failure or death), while none of the cases with a DILI score  $< 3$  were linked to severe liver injury. Statistical analysis revealed that a DILI score  $\geq 7$  and  $< 3$  was significantly associated with higher or lower risk for severe hepatic outcome.

Conversely, Björnsson *et al.*<sup>[35]</sup> classified drugs listed in LiverTox<sup>®</sup> website. Specifically, drugs were categorized based on the number of case reports (Category A  $\geq 50$  published reports, B = 12-50, C = 4-12, and D = 1-3)

and another category, T, was added for agents leading to hepatotoxicity mainly in higher-than-therapeutic doses. In this study, fewer drugs than expected emerged with a documented hepatotoxicity. Among 671 drugs available for analysis, 353 (53%) had published convincing case reports of hepatotoxicity. Thus, overall, 47% of the drugs listed in LiverTox actually do not have evidence of hepatotoxicity. However, the main limitation of this analysis is that new drugs approved within the last five years were not included. Therefore, old drugs with consolidated clinical use are likely to result in higher risk. In fact, drugs in categories A and B were more likely than those in C and D to have been marketed for a long time, and both were more likely to have at least one fatal case of liver injury and reported cases of positive rechallenge. While there is little doubt that the majority drugs in category A and B are hepatotoxic, it is still unclear whether agents listed in C and D are really liver offenders.

## A CRITICAL ANALYSIS OF THE DILI RISK SCORE: THE CASE OF DIRECT-ACTING ORAL ANTICOAGULANTS

Liver safety of direct-acting oral anticoagulants (DOACs) was highly debated in 2014-2015, when several publications highlighted possible occurrence of liver damage (including acute liver failure) during DOAC administration<sup>[36-39]</sup>. The majority of data are derived from case reports/series, which emphasized the relatively rapid time-to-onset and the concomitant reporting of drug that are implicated in liver damage or have the potential to result in drug interactions<sup>[39]</sup>. In particular, the time-to-onset from published case reports suggests

**Table 2** Chemical and pharmacological properties of direct-acting anticoagulants likely to be associated with drug-induced liver injury risk in humans

	Dabigatran etexilate	Rivaroxaban	Apixaban	Edoxaban
Max daily dose (indication) <sup>1</sup>	220 (DVT prophylaxis) - 300 (NVAf)	5 (post ACS <sup>2</sup> ) - 10 (DVT prophylaxis) - 20 (NVAf) - 30 (treatment of DVT/PE)	5 (DVT prophylaxis) - 20 (acute treatment of DVT/PE)	60 (NVAf and DVT)
Bioavailability <sup>1</sup>	6.50%	80%-100%	50%	62%
Protein binding	35%	> 90%	87%	55%
Cmax (ng/mL)	697 (at steady state after 400 mg/3 die) <sup>[54]</sup>	450 (multiple dose 30 mg/die) <sup>[55]</sup>	469 (single 20 mg dose) <sup>[56]</sup>	424 (90 mg daily at day 10) <sup>[57]</sup>
Lipophilicity (LogP) <sup>5</sup>	5.17	1.74	2.22	1.61
Biotransformation <sup>1</sup>	Conjugation forming 4 pharmacologically active acylglucuronides	Oxidative degradation of the morpholinone moiety and hydrolysis of the amide bonds	O-demethylation and hydroxylation at the 3-oxopiperidiny moiety	Hydrolysis (mediated by carboxylesterase 1), conjugation or oxidation by CYP3A4/5 (< 10%)
Hepatic metabolism <sup>1</sup>	Only the prodrug is a substrate of P-gp; no induction/inhibition of principal isoenzymes of cytochrome P450	CYP3A4, CYP2J2 and CYP-independent mechanisms. Substrate of P-gp and BCRP	CYP3A4/5. Substrate of P-gp and BCRP	Substrate of P-gp
Structural alerts associated with RM formation	NO (aniline motif) <sup>[58,59]</sup>	NO (chlorothiophene and bis-anilide motifs) <sup>[42,58]</sup>	NO (para-methoxyaniline and bis-anilide motifs) <sup>[41,58]</sup>	ND (no published data in the literature)
Dose-based DILI Risk Score <sup>3</sup>	2.68	1.29	1.29	1.45 <sup>4</sup>
Cmax-based DILI Risk Score <sup>3</sup>	2.98	1.87	2.02	1.82 <sup>4</sup>

<sup>1</sup>From official European Summary of Product Characteristics; <sup>2</sup>Only in EU; <sup>3</sup>Calculated based on formulas reported by Chen *et al*<sup>[34]</sup>; <sup>4</sup>Calculated based on formulas reported by Chen *et al*<sup>[34]</sup> and assuming no RM formation; <sup>5</sup>Data obtained from Drug Bank (www.drugbank.ca; source: ALOGPS). ACS: Acute coronary syndrome; BCRP: Breast cancer resistance protein; DVT: Deep vein thrombosis; NVAf: Non valvular atrial fibrillation; ND: Not determined; RM: Reactive metabolites; DITdP: Drug-induced torsade de pointes.

that early evaluation of hepatic enzymes (*i.e.*, within the first month) may be considered at least in patients under complex treatment regimen with comorbidities; subsequently, liver function can be monitored on a yearly basis<sup>[40]</sup>. This is especially the case of rivaroxaban, for which a probable but unquantified association is likely to exist. Notably, rivaroxaban is the only DOAC reported in the list provided by Björnsson *et al*<sup>[35]</sup> and classified in category B.

Therefore, we applied the score developed by Chen *et al*<sup>[34]</sup> to DOACs and found intriguing data (Table 2). Based on these results, different issues emerge: (1) no DOAC appears to be associated with risk of severe liver damage (they all received a score well below the threshold of 7); (2) the highest score emerged for dabigatran; (3) the risk does not appear to be strongly influenced by dose or Cmax (there is only a small increase in Cmax-based score), or chemical motifs; (4) DOACs pose a lower risk as compared to warfarin (the dose-based risk score is 4.67, according to Chen *et al*<sup>[34]</sup>).

However, among DOACs, it is difficult to discriminate the agent with the highest risk, keeping in mind that post-marketing data have reported rivaroxaban to be most likely associated with DILI<sup>[40]</sup>. Therefore, these data suggested that current performance of this risk stratification tool is still suboptimal. In fact, this algorithm is based on pharmacokinetics characteristics and chemical features. Based on published data, apixaban, rivaroxaban and dabigatran contain structural moieties

that suggest some alerts (para-methoxyaniline and bis-anilide motifs in apixaban; chlorothiophene and bis-anilide motifs in rivaroxaban; bis-anilide motifs in dabigatran), which, however, do not seem to undergo metabolism and/or generate reactive metabolites<sup>[41,42]</sup>. In the case of rivaroxaban, the pendant chlorothiophene motif is also essential for pharmacology and cannot be replaced. The aniline structural moiety is also present in the oral direct thrombin inhibitor dabigatran, which, however is not subject to oxidative metabolism by CYP enzymes in humans<sup>[43]</sup>. In summary, only partially may these peculiarities explain the risk observed in humans for rivaroxaban. This is also emphasized by the case of ximelagatran, which does not possess structural moieties implicated in liver toxicity (dose-based risk score = 2.55; Cmax-based risk score = 1.90, according to Chen *et al*<sup>[34]</sup>), thus suggesting that additional mechanisms are likely to be implicated in DILI occurrence in humans.

Therefore, our hypothesis is that there should be additional aspects that may modify the likelihood of DILI occurrence in DOAC users. Apart from host-related factors (which are not modifiable), we propose that: (1) concomitant drug with hepatotoxic and/or interacting potential may cause a subclinical liver damage that can results in symptomatic injury in susceptible patients (a concept similar to the repolarization reserve postulated for DITdP<sup>[44]</sup>); and (2) the underlying disease for which the DOAC is prescribed may contribute in increasing the likelihood of DILI with unknown mechanisms. In fact, the

majority of published case reports occurred in surgical patients with venous thromboembolism rather than with atrial fibrillation.

This calls for monitoring of liver safety when making treatment changes (addition of drugs with recognized hepatotoxicity potential, especially for long-term use) considering the different therapeutic indications of DOACs, where their role is still incompletely defined (e.g., heparin-induced thrombocytopenia, cancer, triple therapy, coronary diseases, heart failure)<sup>[45]</sup>. In the meantime, chemists, pharmacologists and clinicians should join efforts to understand drug signature subtending the mechanistic basis of DILI and establish causality.

## CONCLUSION AND PERSPECTIVE

Early detection, prediction and accurate risk stratification represent an urgent need for clinicians, basic scientists, regulators and drug companies. As compared to DITdP, predictivity of pre-clinical assays for DILI is still suboptimal. The role of animal studies remains questionable, mainly because of the incomplete understanding of the mechanisms underlying DILI, as well as marked species differences in response to, and in the metabolism of, xenobiotics.

As a result, there is currently no universally accepted animal model. It seems unlikely that a single *in vitro* system will be able to mimic the complex interactions in the human liver. Three-dimensional multicellular systems together with toxicogenomics-based methodologies and next-generation sequencing technologies are promising tools to develop predictive models in the near future<sup>[46]</sup>. In particular, pluripotent stem cells, which include embryonic and induced pluripotent stem cells, are being investigated to replace human primary hepatocytes (the current gold standard for preclinical toxicological screening), because they provide a stable source of hepatocytes and can be exploited for multiple applications, including early preclinical hepatotoxicity screening<sup>[47]</sup>.

Risk stratification in humans is even more challenging, especially for herbals/food supplements as well as biotechnological products, because of their unpredictable kinetics and sometimes variable content.

Case reports are of course of great importance for timely detection of safety signals, although they cannot be formally used *per se* for a reliable risk assessment and stratification, but should be integrated with other data sources such as clinical trials, cohort and case-control analyses.

The importance of this global approach in the overall assessment of drug-related toxicities is recommended by the recent Pharmacovigilance legislation, which calls for integrated risk/benefit assessment based on an integrated view of all pieces of evidence<sup>[48]</sup>. This was the case of pancreatitis with incretin-based drugs: While the signal emerged from case reports, the actual existence and the magnitude of a true association was later investigated through multiple data sources, including a recent systematic review with meta-analysis of both

clinical trials and observational studies, which suggested that the incidence of pancreatitis in users of incretin-based therapy is low and that the drugs do not increase the risk of pancreatitis<sup>[49-59]</sup>.

In conclusion, existing consortia should pursue a joint effort along this innovative pathway aiming to develop algorithms capable not only of discriminating hepatotoxic from non-hepatotoxic compounds, but also to differentiate the risk among agents belonging to the same therapeutic class. In particular, in the era of big data, it is important to integrate real-world information (i.e., registries, healthcare databases, spontaneous reporting systems, literature) with cheminformatics in order to provide a comprehensive DILI risk score and fulfill clinicians' and patients' expectations about "primum non nocere".

### Abstract

#### AIM

To assess the accuracy of shear wave elastography (SWE) alone and in combination with aminotransferase platelet ratio index (APRI) score in the staging of liver fibrosis.

#### METHODS

A multicenter prospective study was conducted to assess the accuracy of SWE (medians) and APRI to predict biopsy results. The analysis focused on distinguishing the different stages of liver disease, namely, F0 from F1-4, F0-1 from F2-4, F0-2 from F3-4 and F0-3 from F4; F0-F1 from F2-F4 being of primary interest. The area under the receiver operating characteristic (AUROC) curve was computed using logistic regression model. The role of age, gender and steatosis was also assessed.

#### RESULTS

SWE alone accurately distinguished F0-1 from F2-4 with a high probability. The AUROC using SWE alone was 0.91 compared to 0.78 for using the APRI score alone.

The APRI score, when used in conjunction with SWE, did not make a significant contribution to the AUROC. SWE and steatosis were the only significant predictors that differentiated F0-1 from F2-4 with an AUROC of 0.944.

### CONCLUSION

Our study validates the use of SWE in the diagnosis and staging of liver fibrosis. Furthermore, the probability of a correct diagnosis is significantly enhanced with the addition of steatosis as a prognostic factor.

**Key words:** Shear wave elastography; Aminotransferase platelet ratio; Liver fibrosis; Liver biopsy

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The gold standard in the diagnosis and staging of liver fibrosis is an invasive liver biopsy. The accuracy of non-invasive tools such as ultrasound shear wave elastography either alone or in combination with the use of the aspartate transaminase platelet ratio index score compared to histology to guide management of liver fibrosis is not known. We addressed this question in a multicenter trial in patients with chronic progressive liver disease in a low to middle income country.

### INTRODUCTION

Liver fibrosis is a progressive condition that if diagnosed early and staged accurately, allows early clinical intervention that may arrest or slow down progression to end stage decompensated cirrhosis. The spectrum of chronic liver disease and fibrosis that leads to end stage decompensated cirrhosis, is an important cause of morbidity and mortality in the world<sup>[1]</sup>. Early diagnosis, accurate staging and re-evaluation of liver fibrosis is aimed at avoiding the progression from normal to minimal to significant fibrosis and timely management of patients with advanced disease.

There are several chronic progressive liver diseases that lead to liver fibrosis. Non-alcoholic fatty liver disease (NAFLD) is one of the most common. NAFLD is closely associated with obesity and insulin resistance. Pathological changes in the biochemical profile of the liver that lead to liver fibrosis also occur due to chronic metabolic conditions such as diabetes and degenerative conditions like atherosclerosis<sup>[2,3]</sup>. Other common causes of liver fibrosis include infections such as chronic viral hepatitis and human immunodeficiency virus. Drugs and other toxins also play an important role. This list

is not exhaustive but this paper focuses on the last four causes. Liver fibrosis is characterized by excessive accumulation of extracellular matrix due to the release of inflammatory mediators and free radicals to cause oxidative stress and liver fibrogenesis. During this process hepatic stellate cells activation occurs. Platelet derived growth factor, tumor necrosis factor  $\alpha$ , transforming growth factor  $\beta$  or reactive oxygen species play a role in the progression to liver fibrosis. Several phenotypic alterations occur with the end result being irreversible<sup>[4]</sup>.

The current gold standard in the diagnosis and staging of liver fibrosis is liver biopsy. Liver biopsy and more recently ultrasound guided liver biopsy only evaluates 1/50000 of the liver parenchyma. It is invasive, has a complication rate (albeit small,) and is subject to intra and inter-observer variability<sup>[5]</sup>. Because of the imperfect nature of liver biopsies, over the last several years there has been a growing trend to validate non-invasive tools to diagnose and stage liver fibrosis. Alkaline aminotransferase platelet ratio index (APRI) is a laboratory marker that has been shown to have some value but is inferior to liver biopsy. Ultrasound and magnetic resonance have been used for elasticity imaging. Magnetic resonance elastography, even though promising, has some disadvantages. Aside from the significant cost of the study, it cannot be performed in a liver with iron overload because of signal-to-noise limitations; has longer examination times compared to ultrasound elastography, and is subject to respiratory artifact<sup>[6]</sup>. Ultrasound elastography has been validated and has been shown in many studies to have similar sensitivity and specificity to liver biopsies<sup>[5,7]</sup>.

Ultrasound elastography measures the liver stiffness/elasticity by assessing at least 100 times the proportion of the liver that a biopsy does. Transient elastography (TE) has been validated in multiple studies<sup>[8]</sup> but shear wave elastography (SWE) may be preferred because unlike transient elastography, which consists of a vibrator producing shear waves, the latter can perform a conventional ultrasound at the same time. The technique is integrated into an ultrasound system. The principle behind the interpretation of shear wave elastography is that shear waves produced by a focused ultrasound beam are directly related to the stiffness of the liver from where they are generated<sup>[5,7,8]</sup>. SWE is also reportedly more accurate than TE in assessing significant fibrosis ( $\geq F2$ )<sup>[8,9]</sup>. The use of shear wave elastography in the diagnosis and staging of liver fibrosis has been increasing. Being a non-invasive technique proves advantageous because repeat measurements can be obtained in patients with chronic progressive liver diseases. However, this non-invasive procedure does have some pitfalls. It is subject to intra- and inter-observer variability, validated cut-offs have mainly only been demonstrated in hepatitis C; Acute hepatitis can have false positives. In patients with a high body mass index, erroneous values may be obtained. A very practical pitfall is confounding factors such as edema, inflammation, cholestasis and congestion. All these

must be put in context and a multidisciplinary clinical approach used in the interpretation of the results<sup>[5,7,8,10]</sup>.

A limitation of prior studies is the lack of integration of the accuracy and limitations of elastography. No prior study has combined elastography with the use of APRI and histology to guide management of liver fibrosis. This study addresses the gaps and makes practical inferences that focus on accurate early diagnosis and staging. The focus in our study is "interpretation within a clinical context". This multi-institutional study performed in Kenya aims to capture and highlight factors based on the disease burden in this region. Ultrasound elastography has only recently been made available in East Africa. The findings, therefore, could be of wider benefit because of the high burden of other etiologies of liver disease such as hepatitis B in the region. Most studies thus far have been carried out in the West with the disease burden focused on hepatitis C. In addition, the literature largely reports data from middle-high economic areas whereas adherence to clinical guidelines may not be as feasible in poor/resource challenged facilities.

## MATERIALS AND METHODS

### Objectives

The primary objective was to analyze the accuracy of shear wave elastography in comparison to liver biopsy in differentiating the various stages of liver fibrosis. The secondary objective was to evaluate whether the addition of the APRI score to SWE would improve the accuracy of this differentiation. With these, illustrate the role of the shear wave elastography, APRI score, and biopsy solely and or in combination in the diagnostic algorithm of accurate quantification of liver fibrosis. We also sought to assess the role of other covariates, namely, age, gender and steatosis, and their influence on the relative importance of SWE and the APRI score in predicting the extent of liver fibrosis.

### Design

Three hospitals were included in this prospective study: Aga Khan University (AKU) Hospital, Kenyatta Teaching and Referral Hospital and St Mary's Mission Hospital. Approval was obtained from the relevant Scientific and Ethics committees. All consecutive patients referred for an ultrasound guided liver biopsy at all three institutions were subject to recruitment based on the inclusion and exclusion criteria as well as informed written consent. The study included patients above eighteen years of age with chronic progressive diffuse liver disease. Patients were excluded from the study if they did not have any of the three diagnostic tests, *i.e.*, liver biopsy, APRI score or SWE.

Consecutive patients were recruited by the principle investigator in three ways: (1) referral for an ultrasound guided liver biopsy at the AKU Radiology Department; (2) referral from St Mary's Hospital with biopsy performed by the AKU Radiology department and pathological

analysis performed at AKU department; and (3) referral for a liver biopsy request to be analyzed at the Pathology department of Kenyatta National Hospital.

At recruitment, a study file was opened for each patient by the principle investigator at the AKU. Routine liver function tests, platelet counts, and demographic information related to confounding factors of chronic liver disease, including information on alcohol use, Human Immunodeficiency Virus status, viral load and CD4 levels, hepatitis B and C status was collected. Men who had been drinking more than 30 g of alcohol per day and women who had been drinking more than 20 g of alcohol per day were considered current drinkers. Patients who had stopped drinking completely for more than six months before the biopsy were considered ex-drinkers<sup>[11]</sup>.

At the AKU routine ultrasound of the liver was performed to qualitatively record presence (grade 0-3) or absence of steatosis using established criteria published by Lupşor-Platon *et al*<sup>[12]</sup>. Any other diffuse or focal lesions were documented followed by SWE. At AKU elastography measurements were taken from the right lobe<sup>[13]</sup> of the liver with the patients holding their breath. Measurements were considered successful using validated criteria established by Castéra *et al*<sup>[14]</sup>: "(1) 10 valid shots; (2) a ratio of valid shots to the total number of shots of 60% or higher; and (3) variability of measurements less than 30% of the median value of liver stiffness measurements". Philips iU22 ultrasound machine with its C5-1 curvilinear transducer was used. The units for SWE readouts (liver stiffness) were kilopascals (kPa). Four sonologists each with more than 5 years' experience in routine liver scanning and validated ultrasound elastography experience from uniform training performed each exam independently. The median stiffness (used to grade the fibrosis), average stiffness and standard deviation of measurements generated by the software were recorded and interpreted by the four sonologists independently<sup>[7,10]</sup>. Each patient had one liver biopsy specimen taken from the right lobe<sup>[13]</sup> after the ultrasound elastography which was graded histologically for fibrosis based on the Metavir classification system<sup>[15,16]</sup>. This was done by two experienced histopathologists at the AKU and KNH Pathology departments. Each specimen was evaluated by the two histopathologists from each respective pathology department. Discrepancies were resolved by consensus between the two. The histopathologists from the two sites were full-time faculty, certified by the Kenya Medical Practitioners and Dentists Board, practicing in University Hospitals each with greater than ten years' experience in liver biopsy assessment for fibrosis. In each patient the time interval between ultrasound, elastography and histology was not more than one month. The pathologists and sonologists were blinded to clinical data and elastography or histology grade.

Interpretation of liver fibrosis by shear wave elastography in kPa divided the entity into no fibrosis (F0), mild fibrosis (F1), severe fibrosis (F2), significant fibrosis (F3)

**Table 1** Summary illustrating sample size calculation above

AUROC	Total (n)	% Positive	# Positive	# Negative	SE	Confidence interval	
						Lower	Upper
0.8	110	30	33	77	0.050	0.701	0.899
0.8	130	30	39	91	0.046	0.709	0.891

AUROC: Area under the receiver operating characteristic.

**Figure 1** Elastography average vs histology fibrosis score (Box Plot).

and cirrhosis (F4). Automatic median value generated by the ultrasound software was used to establish the elastography grade as follows  $< 4.6 = F0$ ,  $4.6-5.6 = F1$ ,  $5.7-7.0 = F2$ ,  $7.1-12.0 = F3$  and  $> 12 = F4$ <sup>[10,17-19]</sup>. APRI score was calculated using a formula proposed by original study of Wai *et al.*<sup>[20]</sup>:  $APRI = [(AST \text{ level}/ULN)/platelet \text{ counts } (10^9/L)] \times 100$ . A score of  $< 0.5$  was graded as F0,  $0.5-1.5$  as F1-3 and  $> 1.5$  as F4. The corresponding histology grade was assessed<sup>[21,22]</sup>.

### Sample size estimates

The sample size was determined with the aim to keep the standard error of the AUROC at 0.05. This set the difference between the upper and lower 95%CI limits to 0.20 ( $\pm 2$  standard errors). From previous publications the range for the AUROC for significant fibrosis, as determined from non-invasive tests, is approximately 0.69 to 0.89; for cirrhosis the range is from 0.81 to 0.98. Assuming the AUROC to be approximately 0.8<sup>[20]</sup> the sample size of 110 patients would yield a standard error of 0.05 (Table 1).

Shear wave elastography has been shown to have a lower operator error technique than transient elastography (3%-16%)<sup>[23-25]</sup>. As a precautionary measure we raised the sample size from 110 to 130.

### Statistical analysis

The statistical review of the study was performed by a biomedical statistician. Logistic regression models with backward elimination, using SAS version 9.3, were utilized to assess the significance of SWE median,

the APRI score and the covariates age (categorized as below and above the median), gender and steatosis. Besides the *P*-values, the analysis provided the ORs and their respective 95%CI limits. The sensitivity and the specificity were computed based on the variables included in the model. This in turn enabled the ROCs and the AUROC to be determined. Summary statistics and correlation coefficients, where appropriate, were computed.

## RESULTS

### Demographics and baseline characteristics

One hundred and twenty-eight patients were recruited for the study. AKU, KNH and St. Mary's contributed 54 (42.2%), 53 (41.4%) and 21 (16.4%) patients, respectively. The most prevalent viral infection was hepatitis B that was noted in 30 (23.4%) patients. This was followed by human immunodeficiency virus (HIV) with 18 (14.1%) and hepatitis C with 13 (10.2%) patients (Appendix 1); fifteen patients had 2 or more infections. Sixty-three (49.2%) of the patients had a steatosis score of 0 and 61 (47.7%) of the patients had a histology fibrosis score of 0. Eighty-one (63.3%) patients fell in the histology fibrosis score subgroup F0-1; the remaining 47 (36.7%) fell in the F2-F4 subgroup. Fifty percent of the patients had an elastography score of F0 and 59 (46%) of the patients the APRI score of F0 (Appendix 2). The elastography median scores were the lowest among HIV subjects followed by those with hepatitis B and then a hepatitis C infection. The highest scores were from those with multiple viral infections. The APRI scores also follow the pattern described above for the elastography median scores (Appendix 3). There appears to be a good correlation between the elastography median scores and the histology fibrosis scores (Appendix 4). The elastography and APRI fibrosis score are statistically significantly correlated with the histology fibrosis scores (Appendix 5) (Figure 1 and Table 2).

### Logistics regression results

Table 3 summarizes some of the key results that stemmed from the analysis of the SWE median and APRI score data using logistic regression. Both variables show a high degree of statistical significance in their individual ability to distinguish between the lower stages of fibrosis compared to the higher stages. This is true across all possible partitions of the Metavir fibrosis scores. However, the AUROCs for SWE medians are much higher than

**Table 2** Summary of liver disease scores by histology fibrosis score (discrete variables) *n* (%)

those for APRI score.

The SWE median differentiates the Metavir fibrosis subgroups F0-1 and F2-4 with an AUROC of 0.908 compared to 0.780 for the APRI score. These results imply that the SWE on its own is a better predictor of the differentiating the subgroups than the APRI score. When we utilize both variables simultaneously, the increase in the AUROC attributed to the APRI score is less than 1.2% higher than that predicted by SWE median. This amounts to about 13% of the 9% not predicted correctly by the SWE median. The results for other partitions of the histology fibrosis scores mimic those described above with the AUROC for SWE median being around 0.9 and that of the APRI score being about 0.8.

Additional logistic regression models incorporated several other variables in the analysis to evaluate their impact on the AUROC. The variables considered, in addition to the SWE median and the APRI score were the covariates age (categorized as below and above the median), gender and steatosis score. The results of the logistic regression analysis (Table 4) with all of the aforementioned variables in the model showed that SWE and the steatosis score were the only two variables that

made significant contributions to the predictive power of the model.

Using the backward elimination method, all of the variables that were not making a significant contribution at the 0.1 level were dropped from the model. The results of these analysis (Table 5) show that for the primary objective of differentiating between F0-1 and F2-4 is accomplished quite well with an AUROC of 0.944; the two variables that made a significant contribution were SWE and steatosis. The steatosis score adds significantly to the prediction model that tries to identify the fibrosis group that a patient belongs to (Table 5); this is true in every case except for the F0-3 vs F4 partition. The APRI score on the other hand makes a significant contribution to only the partition F0-2 vs F3-4. Given that the APRI score appears in only one partition as an important predictor, an additional analysis was performed by dropping the APRI score from the model. This resulted in adding a few additional observations to the data set used for analysis since missing APRI scores had contributed to a slightly reduced sample size. In addition, the steatosis score was added to the F0-3 vs F4 model in order to have a unique set of predictors across

**Table 4** Prediction of histology fibrosis score (Grouping: F0-1 vs F2-4) using elastography median, aminotransferase platelet ratio index score, age category<sup>1</sup>, sex and steatosis maximum likelihood and odds ratio estimates

<sup>1</sup>NS: Not significant at the 0.1 level. SWE: Shear wave elastography; APRI: Aminotransferase platelet ratio index; AUROC: Area under the receiver operating characteristic.

all partitions. These results are presented in Table 6. The fact that the results from Tables 5 and 6 are very similar implies that the missing data points did not influence the outcome in any meaningful way.

The F0-2 vs F3-4 data shows that the AUROC obtained with the use of the SWE median and the steatosis score is 0.954 (Table 6). By adding the APRI score (Table 5) the AUROC increase of 0.008 or 0.8%. This represents a decrease of about 13% (0.008 of 0.046) in the error rate. On the other hand, adding steatosis to the model after including the SWE median and the APRI score, the AUROC increase from 0.931 (Table 3) to 0.962 (Table 5), an increase of 0.031 or 3.1%. This represents a decrease of about 44.9% (0.031 of 0.069) in the error rate.

## DISCUSSION

### Summary of findings

The infection with the highest prevalence was hepatitis B. There were also patients with HIV, hepatitis C and the co-infections in this cohort. While the prevalence of hepatitis B, C and HIV in Sub-Saharan Africa has not been conclusively established<sup>[26]</sup>, it has been postulated that hepatitis B is relatively more prevalent than hepatitis C as compared to the western world where hepatitis C is more prevalent<sup>[27]</sup>. Most studies on liver fibrosis quantification have been carried out in the western world therefore it is important to have the same studies carried out in Sub-Saharan Africa where the epidemiology of the viral infections is likely to be different. The elastography median scores were the lowest among HIV subjects

**Table 6** Elastography median and steatosis

OR: Odds ratio; AUROC: Area under the receiver operating characteristic.

followed by those with hepatitis B infection; the next highest score was for patients with a hepatitis C infection. The lowest score was from those with multiple infections. The APRI scores also follow the pattern described above for the elastography scores. This pattern corresponds with what has previously been described. Hepatitis C most likely has higher levels of quantified liver fibrosis because of the three viruses it has the most indolent and chronic clinical course. The mortality from these infections is correlated to chronic liver disease and not due to progression of the virus due to the success of antiretroviral therapy<sup>[27,28]</sup>.

Analysis categorized fibrosis as, F0 vs F1-4, F0-1 vs F2-4, F0-2 vs F3-4, F0-3 vs F4. The results focus on F0-1 vs F2-4 which is of most clinical significance (no and non-significant fibrosis vs significant fibrosis that demands intervention). There is a good correlation between the elastography median scores and the histology fibrosis scores. The OR of 3.0 implies that the elastography median scores are 3 times more likely to correctly identify a fibrosis score of F2-4 compared to F0-1. The upper and lower limits for the OR with 95%CI do not cross 1 which

**Figure 2** Prediction of histology fibrosis score (Grouping: F0-F1 vs F2-F4) using elastography median. ROC: Receiver operating characteristic.

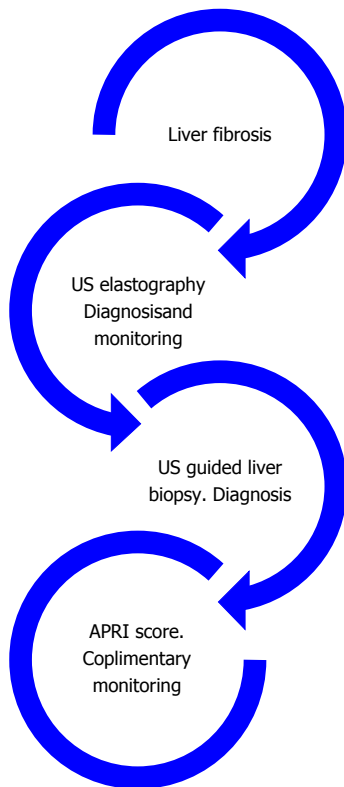

**Figure 3** Prediction of histology fibrosis score (Grouping: F0-1 vs F2-4) using elastography median, aminotransferase platelet ratio index score, age categor, sex and steatosis.

strengthens this result. However, the limits are wide 1.8-5. This may be due to the small sample size and because close to 50% of the sample at F0. If F0 were to be eliminated from the analysis this may reduce the limits with a questionable effect on clinical significance. The accuracy of the elastography median depends on the sensitivity and specificity. This is clear from the raw data used to generate the ROC curve. An elastography median of approximately 3.8 is the point at which you get the best sensitivity matched with specificity. The ROC curve for model, which depicts sensitivity and specificity, illustrates how for a very high sensitivity, specificity is low and as sensitivity reduces; one arrives at a point where specificity is acceptable clinically. That is, one can identify disease with a high sensitivity and be correct (specifically know that you are also picking the non-diseased). The AUROC for the elastography median was 0.91. The elastography and APRI fibrosis score are statistically significantly correlated with the histology fibrosis scores. However, APRI score in itself or when combined with elastography median score does not significantly increase the accuracy of elastography in the differentiation of non-significant vs significant fibrosis. APRI had an AUROC of 0.78. APRI and elastography median had an AUROC of 0.92. Therefore APRI does not have a statistically significant effect on the prediction of F0-1 from F2-4 when added to elastography. And when used alone it is significantly less accurate than elastography. However in patients with chronic progressive liver fibrosis who need repeated analysis to categorize and monitor the progress of liver fibrosis APRI does have a clinically significant role in the management algorithm of liver fibrosis.

Previous studies vary on the accuracy of elastography. The sensitivity, specificity and diagnostic accuracy of shear wave elastography in the determination of liver

stiffness compared with biopsy results is comparable to<sup>[8-10]</sup>. The accuracy of elastography mirrors those depicted by these studies albeit a slightly higher accuracy in this study. This may be due to the difference in grouping of the fibrosis scores for analysis. Also, if the F0 of this study are removed from the analyses this may lead to more similar figures since the F0 constitute approximately 50%. The diagnostic accuracy of shear wave elastography and APRI score in the determination of liver stiffness has not been reported before<sup>[8-10]</sup>.

Ordinal regression and backward elimination was used to analyze significance of HIV, hepatitis B, alcohol use, steatosis, age and gender. It showed that steatosis has a significant OR and *P*-value in the analysis for fibrosis. Ferraioli *et al*<sup>[10]</sup> showed that steatosis does not affect the performance of elastography. The challenge as stated in this paper is the confounding effect of various pathologies in the diagnosis and staging of liver fibrosis. This is particularly relevant in the generation and given the wide use of reference ranges for all modalities used in the diagnosis and staging of liver fibrosis. It is for this reason that to date several studies have used variable reference ranges for F0-F4<sup>[8,10,17-19]</sup>. Our results highlight the potential effect of the presence of steatosis (EF-S\_1\_10\_3\_Logistic\_All Variables\_F0-F1VsF2-F4 document) on the diagnosis and characterization of liver fibrosis. Of note from this result is the increase in the AUROC from 0.91 (Figure 2) to 0.95 (Figure 3) in the logistic regression backward elimination analysis that is attributable to the elastography median and steatosis each with a significant *P*-value and OR (Table 4). This is an area that needs further study, especially since steatosis was measured subjectively in this study. The data on HIV and alcohol use as variables were not adequately

**Figure 4** Link between diagnostic tests used in the evaluation of liver fibrosis. US: Ultrasound; APRI: Aminotransferase platelet ratio index.

powered to add to this analysis.

### Strengths

This study is timely because of the growing use of elastography in the developed world. In the developing world the use of this diagnostic tool needs to grow *via* an evidence based approach that is tailored to the local disease burden. Most research in the west has focused on hepatitis C and alcohol or nonalcoholic steatosis. The wider disease burden covered in this study is thus a more homogenous representation of chronic liver fibrosis pathology. The complimentary use of APRI score is especially relevant in resource limited setups.

### Theoretical and practical implications of these findings

This study brought to light theoretical implication of the need to standardize the diagnosis and accurate staging and follow-up of liver fibrosis. Figure 4 depicts the link between all tests used in the evaluation of liver fibrosis (Figure 4).

The use of all tests should be complimentary and histology has its place but the noninvasive tests may be more logical in the beginning and for progressive monitoring. Inference from the results generates a flowchart below describing a management algorithm (Figure 5).

### Inference from the results: Consider the following flowchart at diagnosis

Practical unique and reported challenges exist. Care needs to be taken in interpretation and training for elasto-

**Figure 5** Flow chart depicting use of diagnostic tests in liver fibrosis. Begin with US SWE result. US: Ultrasound; SWE: Shear wave elastography; APRI: Aminotransferase platelet ratio index.

graphy. Technical and interpretation skill for elastography specifically when choosing the ten values to include in the report; this includes excluding/ignoring far outliers, though these outliers may represent focal areas of different fibrotic stages! Use of the median to give a final conclusion of the ten chosen readings is appropriate especially in the setting of variable readings. But, care must be exercised. There should be a low threshold to recommend a biopsy (still the gold standard) to confirm the findings especially if the mean elastography reading is in keeping with a diagnosis of no fibrosis yet the standard deviation is high in the presence of individual readings of cirrhosis<sup>[5]</sup>. The challenge of the heterogeneously fibrotic liver or presence of lesions, *e.g.*, metastasis causing heterogeneity of the liver rendering fibrosis assessment questionable in terms of using just the median to conclude on the level of fibrosis especially when there is a big difference in the individual stiffness values must be remembered. These issues red flag the danger of not allowing room to vary an impression and advise further evaluation with an United States guided liver biopsy to correlate<sup>[5]</sup>. Indeed, one must also bear in mind that the suggestion to further evaluate with a liver biopsy is inherently flawed because of the attend pitfalls of the tool. Chronic progressive liver fibrosis needs accurate early diagnosis and interval monitoring. Elastography is a validated tool. APRI can be used as a complimentary tool though its effect is not of statistical significance but clinical significance. Biopsy remains the gold standard. We propose a flow chart at diagnosis. Further, the probability of a correct diagnosis is significantly enhanced with the addition of steatosis as a prognostic factor (Figure 5).

### Limitations and problems encountered in the method

The number of ultrasound guided liver biopsies for the assessment of liver fibrosis has continued to reduce because of the increasing use of elastography which is noninvasive and without the side effects associated with

liver biopsy. This diagnostic trend is reinforced by the continued validation of elastography<sup>[5,7,10,12]</sup>. Therefore during this study the recruitment rate was low. As such participants were recruited from three different sites to meet the sample size requirement to adequately power the results. The ultrasound and elastography were all performed at the same site (AKU). Biopsy results were analyzed by pathologists at two of the three sites (AKU and KNH). This may have potentially led to variable histological inter-observer variability. To counter this each sample was read by each pathologist at each respective site and discrepant values were resolved by consensus. However, major and minor discrepancy analyses of histology for inter-observer discrepancies were not assessed.

There are limitations associated with elastography, including the confounding effects of inflammatory activity, and to a lesser extent, steatosis<sup>[13]</sup>, on liver stiffness evaluation. There is also reduced accuracy observed in lower fibrosis stages (F0-F2). Furthermore, the incidences of failed and unreliable scans have been reported to be approximately 3% to 16% in transient elastography but less in shear wave elastography (figures not reported yet)<sup>[22]</sup>. The sample size was inflated by 5% to cater for this. A typical liver biopsy covers 1/10000<sup>th</sup> of the liver while elastography covers a larger area. Matching the two sites covered by the two exams may not have been 100%.

The information sort in the data collection form to analyze the secondary objectives was sensitive in nature including queries about alcohol use and HIV status. This precluded complete disclosure from participants and led to inadequate data on related parameters. This led to a reduction in the power of inferences regarding the role of alcohol and HIV.

### Suggestions for improvement and further work

This has been an East African experience: Unique challenges and similar differences to those published. More comprehensive analysis needs to be done to further reveal the extent of confounding factors affecting the use of elastography in the diagnosis and staging of liver fibrosis. The role of steatosis needs further objective assessment. Further work needs to be done to describe the in cooperation of magnetic resonance elastography in the diagnostic algorithm of liver fibrosis.

Our study validates the use of ultrasound shear wave elastography in the diagnosis and staging of fibrosis within the context of liver disease in a LMIC.

### ACKNOWLEDGMENTS

We would like to thank the Aga Khan United States Research funding body and research support team for funding this study and their non-wavering technical support. Many thanks to the Aga Khan Research team for support and to all patients and staff that were involved in this endeavor.

## COMMENTS

### Background

Chronic progressive liver diseases cause liver fibrosis whose end result is decompensated liver failure. Liver fibrosis that results from these diseases can be reversed if diagnosed early. The current gold standard in the diagnosis of liver fibrosis is a liver biopsy preferably ultrasound guided, which is an invasive procedure with limitations and risks. Recent research have validated the use of shear wave ultrasound based liver elastography which is a non-invasive imaging based tool that has a sensitivity and specificity that almost parallels histological diagnosis from a liver biopsy. The staging of liver fibrosis at diagnosis uses a Metavir scoring system that has been adapted by elastography. Aminotransferase to platelet ratio index is a liver function test that has some usefulness in the diagnosis of liver fibrosis. The combined use of histology, elastography and aminotransferase to platelet ratio index has not been elucidated.

### Research frontiers

Previous studies have shown that ultrasound based elastography can substitute liver biopsy in the accurate diagnosis of liver fibrosis.

### Innovations and breakthroughs

This is the first study to evaluate the combined role of ultrasound based elastography, histology and aminotransferase to platelet ratio index in a low to middle income country for the management of progressive liver fibrosis.

### Applications

The use of the three tests should be complimentary and histology has its place but the noninvasive tests may be more logical in the beginning and for progressive monitoring. More comprehensive analysis needs to be done to further reveal the extent of confounding factors affecting the use of elastography in the diagnosis and staging of liver fibrosis. Further work needs to be done to describe the in cooperation of magnetic resonance elastography in the diagnostic algorithm of liver fibrosis.

### Terminology

Elastography is radiological based software that can diagnose and quantify the degree of liver fibrosis. It is either ultrasound or magnetic resonance based. Ultrasound based elastography uses sound wave to assess for and quantify liver stiffness that is directly related to liver fibrosis. Aminotransferase to platelet ratio is a laboratory parameter derived from part of the routine liver function tests and platelet count.

### Peer-review

The authors have validated the use of ultrasound shear wave elastography in the diagnosis and staging of fibrosis within the context of liver disease in a low to middle income country. Practical management algorithms that in cooperate the use of ultrasound based elastography, histology and aminotransferase to platelet ratio index have been demonstrated. More comprehensive analysis needs to be done to further reveal the extent of confounding factors affecting the use of ultrasound or magnetic resonance based elastography.

### Abstract

#### AIM

To evaluate the long-term treatment outcomes of tenofovir therapy in patients in a real world Australian tertiary care setting.

#### METHODS

We performed a retrospective analysis of treatment outcomes among treatment-naïve and treatment-experienced patients receiving a minimum 3 mo tenofovir therapy through St Vincent's Hospital Melbourne, Australia. We included patients receiving tenofovir [tenofovir disoproxil fumarate (TDF)] monotherapy, as well as patients treated with TDF in combination with a second antiviral agent. Patients were excluded if they demonstrated human immune-deficiency virus/hepatitis C virus/hepatitis delta virus coinfection or were less than 18 years of age. We considered virological and biochemical

response, as well as safety outcomes. Virological response was determined by measurement of hepatitis B virus (HBV) DNA using sensitive assays; biochemical response was determined *via* serum liver function tests; histological response was determined from liver biopsy and fibroscan; safety analysis focused on glomerular renal function and bone mineral density. The primary efficacy endpoint was complete virological suppression over time, defined by HBV DNA < 20 IU/mL. Secondary efficacy endpoints included rates of biochemical response, and HB e antigen (HBeAg)/HB surface antigen loss and seroconversion over time.

## RESULTS

Ninety-two patients were identified who fulfilled the enrolment criteria. Median follow-up was 26 mo (range 3-114). Mean age was 46 (24-78) years, 64 (70%) were male and 77 (84%) were of Asian origin. 55 (60%) patients were treatment-naïve and 62 patients (67%) were HBeAg-negative. Complete virological suppression was achieved by 45/65 (71%) patients at 12 mo, 37/46 (80%) at 24 mo and 25/28 (89%) at 36 mo. Partial virological response (HBV DNA 20-2000 IU/mL) was achieved by 89/92 (96.7%) of patients. Multivariate analysis showed a significant relationship between virological suppression at end of follow-up and baseline HBV DNA level (OR = 0.897, 95%CI: 0.833-0.967,  $P = 0.0046$ ) and HBeAg positive status (OR = 0.373, 95%CI: 0.183-0.762,  $P = 0.0069$ ). There was no difference in response comparing treatment-naïve and treatment-experienced patients. Three episodes of virological breakthrough occurred in the setting of non-compliance. Tenofovir therapy was well tolerated.

## CONCLUSION

Tenofovir is an efficacious, safe and well-tolerated treatment in an Australian real-world tertiary care setting. Our data are similar to the reported experience from registration trials.

**Key words:** Tenofovir; Hepatitis B virus; Australia; Real-life; Virological suppression; Chronic hepatitis B

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Clinical trials have demonstrated that tenofovir is a safe and efficacious treatment for patients with chronic hepatitis B, with high rates of sustained virological suppression. There are limited data evaluating the safety and efficacy of tenofovir in real-world settings. The aim of this study was to evaluate the long-term treatment outcomes of tenofovir therapy in patients in an Australian tertiary care setting. We performed a retrospective analysis of treatment outcomes among treatment-naïve and treatment-experienced patients.

experience. *World J Hepatol* 2017; 9(1): 48-56 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i1/48.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i1.48>

## INTRODUCTION

Chronic hepatitis B (CHB) affects 240-400 million people around the world<sup>[1]</sup>. It is estimated that 218000 people in Australia live with CHB, a population prevalence of approximately 1%<sup>[2]</sup>. CHB is associated with the long-term complications of cirrhosis, liver failure and hepatocellular carcinoma (HCC), in 15%-40% of patients. CHB is one of the most common causes of HCC, the most rapidly rising cause of cancer deaths in Australia<sup>[3-5]</sup>.

The goal of treatment for CHB is to improve survival by preventing disease progression to cirrhosis, liver failure and HCC<sup>[6]</sup>. This can be achieved by long-term suppression of hepatitis B virus (HBV) DNA levels<sup>[7-10]</sup>. In long-term follow-up, sustained virological suppression has been associated with histological improvement and regression of cirrhosis, as well as reduced risk of hepatic decompensation and HCC<sup>[6,11-14]</sup>. Surrogate endpoints used in clinical trials include rates of biochemical [serum alanine aminotransferase (ALT) < upper limit of normal (ULN)], virological (undetectable HBV DNA level), serological [HB e antigen (HBeAg)/HB surface antigen (HBsAg) loss ± seroconversion] and histological (improvements in necro-inflammatory grade and fibrosis stage) response<sup>[13]</sup>. Current therapies approved for CHB include peginterferon-alpha, lamivudine (LMV), adefovir (ADV), telbivudine, entecavir (ETV) and tenofovir (TDF).

Tenofovir is a nucleotide analogue (NA) recommended as first-line treatment for CHB. Tenofovir was first developed as an antiviral for the treatment of human immune-deficiency virus (HIV). The safety and efficacy of TDF for the treatment of chronic HBV infection was confirmed in two phase-III clinical trials, enrolling patients with HBeAg-positive and HBeAg-negative CHB respectively. Rates of virological suppression were 76% and 93% at week 48 in HBeAg-positive and HBeAg-negative patients respectively<sup>[13]</sup>, and > 98% overall at week 240<sup>[15]</sup>. Among HBeAg-positive patients, rates of HBeAg seroconversion were 21% and 40%, and rates of HBsAg seroconversion were 3% and 7%, at weeks 48 and 240, respectively<sup>[15]</sup>. Genotypic resistance to TDF has not been described. TDF is effective for the treatment of both treatment-naïve and treatment-experienced patients. TDF has a reported good safety profile. Reversible renal toxicity has been reported in < 2% of patients in registration/post-registration studies<sup>[16]</sup>. Decreased bone mineral density has been reported in HIV-infected patients treated with TDF, but the effect in HBV-mono-infected patients remains unclear<sup>[17,18]</sup>.

There are limited data that describe the safety and efficacy of TDF in the "real world". The few studies that have been published describe populations in Europe and North America<sup>[19-21]</sup>. There have been no reports

of the experience with TDF in Australia. Such data are important. Australia is a multi-cultural country, and the CHB population is unique for the diversity of HBV genotypes, reflecting immigration patterns from Southern Europe, South-East Asia and Sub-Saharan Africa<sup>[2]</sup>. The rates of TDF response and resistance in Australia are unknown.

The aim of this study was to evaluate the efficacy and safety of long term TDF therapy in an Australian single-centre real-world cohort of CHB patients.

## MATERIALS AND METHODS

### Data collection

Data were collected retrospectively from a comprehensive clinical database of CHB patients receiving TDF through liver clinics at St Vincent's Hospital Melbourne (Australia) between 7 March 2006 and 18 February 2014.

### Selection criteria

All patients receiving TDF 300 mg daily therapy for HBV mono-infection through St Vincent's Hospital Melbourne were considered for analysis. Inclusion criteria included age > 18 years and treatment duration > 3 mo. Patients could be treatment-naïve or treatment-experienced. We included patients receiving TDF monotherapy, as well as patients treated with TDF in combination with a second antiviral agent. Patients were excluded in the setting of HIV, hepatitis C or hepatitis D co-infection.

### Prescription of TDF therapy

TDF was prescribed in accordance with the Australian Pharmaceutical Benefit Scheme. Patients were required to satisfy the following criteria: Non-cirrhotic patients must demonstrate documented chronic liver injury confirmed *via* liver function tests or liver biopsy and must demonstrate appropriate HBV DNA levels according to HBeAg status (HBeAg positive patients HBV DNA > 20000 IU/mL; HBeAg negative patients HBV DNA > 2000 IU/mL). Patients with cirrhosis are required to demonstrate detectable HBV DNA. Patients may be NA naïve or experienced (having failed previous therapy).

### HBV DNA assay

Prior to 2010, HBV DNA levels were measured using the versant HBV DNA 3.0 assay (bDNA) (Siemens Healthcare Diagnostics, Tarrytown, NY) with a lower limit of detection (LLD) of 351 IU/mL. From 2010, HBV DNA levels were measured using the Cobas Taqman assay (LLD = 20 IU/mL, Roche Molecular Systems, Pleasanton, CA, United States).

### Definitions of response

Complete virological suppression was defined as plasma HBV DNA level < 20 IU/mL. Partial virological suppression was defined as plasma HBV DNA level of  $\geq$  20 IU/mL and < 2000 IU/mL. Virological breakthrough (VBT) was

defined as an increase in viral load > 1 log<sub>10</sub> from nadir, or by a detectable HBV DNA level on two serial measures in a patient who had previously achieved an undetectable HBV DNA level. Biochemical response was defined as the normalisation of serum ALT to < 45 IU/L. Serological response was defined as the loss of detectable HBeAg and/or HBsAg from serum (HBeAg/HBsAg loss)  $\pm$  the development of antibodies against these antigens (HBeAg/HBsAg seroconversion).

### Clinical endpoints

The primary efficacy endpoint was complete virological suppression over time, defined by HBV DNA < 20 IU/mL. Secondary efficacy endpoints included rates of biochemical response, and HBeAg/HBsAg loss and seroconversion over time. We also measured rates of VBT and the occurrence of clinical events including hepatic decompensation and HCC. The assessment of safety was specifically focussed on renal function and, where available, bone mineral density.

### Statistical analysis

All statistical analyses were performed using SAS 9.4. For descriptive statistics, continuous variables were summarised as median (25<sup>th</sup>-75<sup>th</sup> centile). Categorical variables were described as frequency and percentage. Comparisons between groups for demographic, clinical and virological data were performed using the Wilcoxon signed pair test for continuous data and Fisher's exact test for categorical data. Significance was defined at *P*-value < 0.05. Kaplan Meier analysis was used to determine influences on the time to virological suppression. The associations between baseline HBeAg status, baseline HBV DNA, treatment experience, age, gender, baseline ALT, fibrosis stage and end of follow-up virological suppression were tested using Cox proportional hazards regression analysis and direct multivariate analysis. Ninety-two patients were included in the analysis of demographics and on-treatment safety and efficacy. Patients who had undetectable HBV DNA levels at time of commencement of TDF were excluded from the multivariable analysis (*n* = 18).

This study was approved by the Human Research Ethics Committee at St Vincent's Hospital Melbourne (QA: 009/14).

## RESULTS

### Study population

A total of 92 patients were identified. Patient characteristics are summarised in Table 1. The majority of patients were male (70%), of Asian ethnicity (84%) and had HBeAg-negative disease (69%). Fifty-five (60%) were treatment-naïve at the time TDF was commenced. Thirty-seven (40%) patients had been previously treated with NA therapy. Compared to treatment-naïve patients, treatment-experienced patients were more likely to have a lower serum HBV DNA level, and a normal serum ALT

"Treatment experience" refers to previous NA therapy. "Viraemia" refers to HBV DNA > 20 IU/mL. Liver biopsy was scored using the METAVIR scoring system. HBe: Hepatitis B "e"; HBV DNA: Hepatitis B viral deoxyribonucleic acid; ALT: Alanine aminotransferase; N/A: Not applicable.

at the time TDF therapy was commenced. Seventeen treatment-experienced patients had a baseline HBV DNA level less than the lower limit of detection, and had directly switched to TDF for convenience. Nity-seven percent of patients received TDF monotherapy. Median duration of follow-up was 24 mo (6-42 mo).

### Virological outcomes

Virological response to TDF is detailed in Table 2 and

Figure 1. Overall, 77 (83.7%) patients achieved complete virological suppression by the end-of-follow-up, with a median time to suppression of 6 mo (IQR = 3-12 mo). The rates of complete virological suppression were 71% (45/65) at 12 mo, 80% (37/46) at 24 mo and 89% (25/28) at 36 mo. Eighty-nine/ninety-two (96.7%) achieved a partial virological response (HBV DNA 20-2000 IU/mL).

**Treatment-naïve individuals:** Complete virological

**Table 2** Virological suppression at on-treatment time-points (*n* = 92)

Follow-up (mo)	0	6	12	18	24	30	36
Patients with viral load <i>n</i> (%)	92 (100)	74 (80.4)	65 (70.7)	58 (63)	46 (50)	30 (32.6)	28 (30.4)
Virological suppression <i>n</i> (%)	18 (19.6)	41 (55.4)	45 (69.2)	46 (79.3)	37 (80.4)	26 (86.7)	25 (89.3)

"Patients with viral load" refers to the number of patients at each time point who had an available HBV DNA reading. "Virological suppression" refers to the number of patients with HBV DNA < 20 IU/mL. HBV: Hepatitis B virus.

**Figure 1** Complete virological suppression and partial virological suppression at on treatment time points. The proportion of patients who achieve complete virological suppression (HBV DNA < 20 IU/mL) or partial virological suppression (HBV DNA 20-2000 IU/mL) while on tenofovir therapy. The number of patients followed up at each time point is recorded below the Time axis. HBV: Hepatitis B virus.

suppression was achieved in 43/55 (78%) of patients with a median time to suppression of 6 mo (IQR = 3-12 mo). Rates of complete virological suppression were 70% (29/44) at 12 mo, 87% (26/30) at 24 mo and 100% at 36 mo (18/18). This was maintained by 50/55 (91%) of patients throughout follow-up. While a total of five patients failed to maintain complete virological suppression, only three patients experienced VBT. This was associated with reported non-compliance. In the first patient, HBV DNA levels rose from undetectable viral load at 12 mo to 55 IU/mL at 18 mo and 23 IU/mL at 24 mo. In the second patient, HBV DNA levels rose from undetectable at 18 mo to 1940 IU/mL at 24 mo and 578 IU/mL at 30 mo. In the final patient, HBV DNA levels increased from undetectable at 24 mo to 46300 IU/mL at 42 mo and 29 IU/mL at 48 mo (results for the intervening 12 mo were unavailable). A transient low level viraemia not meeting the definition for VBT (single HBV DNA level of 23 IU/mL and 21 IU/mL, respectively, following achievement of complete virological suppression) was observed in two additional patients before returning to undetectable levels.

**Treatment-experienced individuals:** Viraemia was seen in 54% (20/37) of treatment-experienced individuals at the time TDF therapy was commenced. Complete virological suppression was achieved among 85% (17/20) of viraemic patients with a median time to

suppression of 6 mo (IQR = 3-18 mo). Rates of complete virological suppression were 64% (9/14) at 12 mo, 58% (7/12) at 24 mo and 63% (5/8) at 36 mo. While 3 patients showed persistent viraemia at 36 mo, all had an HBV DNA level < 2000 IU/mL and subsequently achieved complete virological suppression by 60 mo. This was maintained in 17/20 (85%) patients throughout follow-up. No patient met the strict definition for virological breakthrough. Two patients demonstrated a single instance of HBV DNA > 20 IU/mL (28 IU/mL and 27 IU/mL) before returning to undetectable levels, but did not meet the criteria for VBT. Among patients with an undetectable plasma HBV DNA level at baseline, 16/17 patients (94%) maintained complete virological suppression throughout follow-up. One patient experienced a single HBV DNA level of 40 IU/mL.

### Predictors of virological outcome

Survival analysis of the influence of treatment experience on complete virological suppression is presented in Figure 2. Cox proportional hazards analysis was carried out on viraemic patients at baseline with the final model including baseline HBV DNA, HBeAg status treatment experience, age and baseline ALT (Table 3). Multivariate analysis showed a significant relationship between virological suppression at end of follow-up and baseline HBV DNA (OR = 0.897, 95%CI: 0.833-0.967, *P* = 0.0046) and HBeAg status (HR = 0.373, 95%CI: 0.183-0.762, *P* = 0.0069).

### Serological outcomes

**HBeAg loss/seroconversion:** Among 30 HBeAg-positive patients at baseline, 5 (16.7%) underwent HBeAg loss and seroconversion. Median time to seroconversion was 30 mo (9-60 mo). Mean age was 38 years (24-48 mo) and median baseline HBV DNA was  $1.7 \times 10^7$  IU/mL. There was no significant difference in HBeAg seroconversion rates between treatment-naïve and treatment-experienced patients (*P* = 0.87). Two patients showed documented HBeAg seroreversion while on TDF treatment. One patient who was HBeAg-negative at baseline underwent HBeAg seroreversion at 24 mo of TDF therapy. HBeAg seroconversion then reoccurred at 36 mo and was sustained for the remainder of follow-up. The second case showed HBeAg loss without seroconversion at 12 mo, followed by seroreversion at 36 mo of treatment. This patient had only been on therapy for 36 mo at end of follow-up.

**HBsAg:** One treatment-naïve male underwent HBsAg loss and seroconversion following 12 mo of TDF therapy.

**Figure 2** Survival analysis of the influence of treatment experience on complete virological suppression. A: Time to virological suppression according to duration of treatment,  $n = 92$ ; B: Amongst treatment naïve patients  $n = 54$ ; C: Treatment experienced patients,  $n = 37$ ; D: Treatment experienced viraemic patients,  $n = 20$ . Number at risk describes the number of target group patients captured at each time period.

**Table 3** Cox regression model of predictors of end of follow-up virological suppression ( $n = 74^1$ )

Covariates	Multivariable	
	Hazard ratio (95%CI)	P value
Baseline HBV DNA ( $\log_{10}$ IU/mL)	0.897 (0.833-0.967)	0.0046
HBeAg status (HBeAg pos vs neg)	0.373 (0.183-0.762)	0.0069
Treatment experience (Naïve vs experienced)	1.189 (0.598-2.364)	0.6207
Age (yr)	1.018 (0.992-1.044)	0.1760
ALT ( $\log_{10}$ IU/mL)	1.093 (0.816-1.465)	0.5505

<sup>1</sup>Excludes patients who were not viraemic at baseline. HBV: Hepatitis B virus; ALT: Alanine aminotransferase.

This individual was 28 years of age and HBeAg-negative at the time TDF was started.

### Biochemical outcomes

Mean ALT at baseline was  $134 \pm 340$  U/mL and  $33 \pm 13$  U/mL at end of follow-up, with a mean change of  $-101.3 \pm 340.4$  U/mL. Treatment experienced patients had a lower mean baseline ALT than treatment naïve patients ( $52 \pm 70.2$  U/mL vs  $190 \pm 431.1$  U/mL,  $P = 0.02$ ). They consequently had a lower mean change in ALT at the end of follow-up ( $-21 \pm 68$  U/mL vs  $-155 \pm 432$  U/mL,  $P = 0.28$ ). Baseline serum ALT levels were within the

normal range in 42/92 (45.7%) patients. By the end of treatment, 76/92 (83%) patients were within the normal range. Of the 50 patients who were above the ULN at baseline, 38 (76%) achieved ALT normalisation by the end of follow-up.

### Clinical outcomes

Hepatocellular cancer was diagnosed in two patients within 12 mo of starting TDF treatment. Both patients were diagnosed with cirrhosis prior to commencing TDF and one patient died as a result of their malignancy. A third patient was diagnosed with HCC 12 mo after ceasing TDF. No episodes of hepatic decompensation were recorded in the study population.

### Treatment discontinuation and safety

Treatment was discontinued at the discretion of individual clinicians in 11 patients (12%). Treatment was discontinued as a result of a rise in serum creatinine levels in 3 patients (3%). All 3 patients had a peak serum creatinine  $< 1.5 \times$  ULN. Two patients had only been taking TDF for 3 mo, and both had previously been treated with long-term LMV plus ADV therapy. Creatinine returned to the normal range on switch to ETV in one patient and LMV plus ADV in the other. The clinical decision to return the latter patient to LMV plus

ADV was determined by the treating physician and is not a standard treatment recommendation. One treatment-naïve patient was noted to have a rising serum creatinine at month 42 of treatment (peak creatinine = 118  $\mu\text{mol/L}$ , ULN = 104). Serum phosphate levels were normal. Treatment was switched to ETV and creatinine returned to the normal range. Bone mineral density measurements were not routine and were only performed in a minority. There were 4 patients who were noted to have osteopenia or osteoporosis after treatment durations of 18–42 mo. Two of these patients were treatment naïve at the time TDF was started, one patient had previously been treated with adefovir for 5 years, and one patient had previously received LMV for 4 years. None of the 4 patients had a baseline bone mineral density measure available for comparison. Tenofovir was discontinued in another 4 patients after reports of non-specific adverse events including nausea, dizziness, fatigue, weight loss and myalgia.

## DISCUSSION

Tenofovir is a potent antiviral therapy for CHB. It has been associated with high rates of virological suppression in clinical trials and virological resistance is yet to be described in clinical practice<sup>[13]</sup>. Post-registration real-world studies provide confirmation of therapy efficacy outside of the selected clinical trial situation, and monitor for rare adverse events. This is the first real-life study of TDF in an Australian setting. It validates the efficacy and safety of TDF in NA-naïve and experienced patients with CHB.

Similarly to registration trials and real-life studies, the study population was predominantly male and HBeAg negative, with 75% over the age of 40. However, while registration trials studied predominantly Caucasian populations, this population was mostly of Asian origin. Other ethnic minorities were also represented, reflecting Australian migration patterns. HBV genotype data were available for a minority of patients (35/92). Genotypes C and B were the most common genotypes, with A and D also represented. Studies from Europe and Asia are dominated by genotype A/D (Europe) and genotype B/C (Asia), limiting cross genotype comparisons. The tenofovir registration studies included mainly Western genotype A/D individuals, as have most of the real world data<sup>[13,22,23]</sup>. While this study's patient size may be limited, the population studied here are unique for the breadth of ethnicity and HBV genotypes and comprise the first dataset described in an Australian population. Liver fibrosis ranged predominately between stages 1 and 2, with 10% of patients diagnosed with cirrhosis at baseline. Forty percent of the population were NA treatment-experienced.

The efficacy of TDF therapy in our cohort largely reflects the clinical trial experience. A daily dose of 300 mg of TDF was found to achieve at least partial virological suppression in 97% of patients and complete virological suppression in 84% of patients, demonstrating

robust efficacy. Complete virological suppression was sustained by 94% of patients over time. Patients with persistent viraemia had HBV DNA levels < 2080 IU/mL, except for two patients who had a viral load  $1.2\text{--}2.6 \times 10^5$  IU/mL after 3 mo on therapy. Virological breakthrough was only observed in one patient with documented non-compliance. The clinical variables that were independently associated with time to suppression were high HBV DNA level at baseline, and HBeAg seropositivity. Previous NA therapy was not associated with reduced response rate. HBeAg seroconversion was achieved in 17% of HBeAg positive patients, with median duration of follow-up of 24 mo. One patient underwent HBsAg loss and seroconversion after 12 mo of treatment. The efficacy data are therefore broadly consistent with the experience in the registration studies<sup>[13,22,24]</sup>.

Our findings are also in keeping with "real life" international studies. Pol *et al.*<sup>[23]</sup> reviewed safety and efficacy data from two real-life cohorts in the United Kingdom and Europe. The cohorts had a combined sample size of 362 NA-naïve patients with a median follow-up of 9–28 mo. Virological suppression was achieved in 80%–89% of patients with breakthrough identified in 2% of patients, without any corresponding resistance mutations. HBeAg seroconversion occurred in 7%–18% of patients and HBsAg loss occurred in 2% of the European cohort. Eighty-seven percent of patients achieved ALT normalisation by 30 wk<sup>[5]</sup>. Pan *et al.*<sup>[21]</sup> analysed the real-life safety and efficacy of TDF in 90 Asian-American patients over 48 wk. Ten percent of the population had a history of prior treatment with lamivudine or adefovir. Virological suppression was achieved in 82% of patients, 12% of patients underwent HBeAg seroconversion and 66% of patients showed ALT normalisation by the end of follow-up. No resistance to TDF was detected and the treatment was considered well-tolerated with few related adverse events. While our results reflect those of other "real life" data, few studies have included treatment-experienced patients and if so they compose only a small minority. This is an area for future focus considering clinical practice of switching patients over to TDF from older less effective NAs.

Therapy was ceased in 12% of patients at the discretion of individual clinicians due to concern about renal (3%) and bone impairment. Tenofovir was self-ceased by 4% of patients due to non-specific adverse events. It was not possible to establish causality for these events; all possible renal events were mild and reversible with discontinuation. No confirmed cases of proximal tubular dysfunction were observed. Isolated cases of osteomalacia and osteopenia concurrent with TDF therapy have also been reported in the HBV literature<sup>[25]</sup>; there are more numerous reports in the HIV literature. In our cohort, although cases of osteopaenia and osteoporosis were noted, the absence of baseline bone mineral density scans meant that causality could not be speculated. Chronic liver disease itself is a risk factor for osteoporosis. We now perform routine monitoring of renal function and fasting serum phosphate levels every

six months, as well as bone mineral densitometry at baseline and every 3 years to screen for osteoporosis. This approach needs prospective validation.

In conclusion, our Australian experience shows TDF to be an effective and safe therapy for patients with CHB. Rates of sustained virological suppression were very high. Elevated baseline HBV DNA level and HBeAg-positive disease were associated with slower time to suppression, but TDF resistance was not observed, and most patients achieved complete virological suppression with continued therapy. Tenofovir was generally well tolerated. This study supports the findings of other real-life experience into the efficacy and safety of TDF in the treatment of CHB.

## COMMENTS

### Background

Chronic hepatitis B (CHB) affects 240-400 million people around the world. It is estimated that 218000 people in Australia live with CHB, a population prevalence of approximately 1%. CHB is associated with the long-term complications of cirrhosis, liver failure and hepatocellular carcinoma (HCC), in 15%-40% of patients. CHB is one of the most common causes of HCC, the fastest increasing cause of cancer death in Australia.

### Research frontiers

Tenofovir is a nucleotide analogue recommended as first-line treatment for CHB. The safety and efficacy of tenofovir disoproxil fumarate (TDF) for the treatment of chronic HBV infection has been confirmed in two phase-III clinical trials. There are limited data that describe the safety and efficacy of TDF in the "real world". The few studies that have been published describe populations in Europe and North America. There have been no reports of the experience with TDF in Australia.

### Innovations and breakthroughs

Out of 92 patients, 89 (96.7%) achieved partial virological response and 77 (83.7%) achieved complete virological suppression by the end-of-follow-up. Predictors of virological suppression included lower baseline HBV DNA and HBeAg negative disease.

### Applications

The authors' Australian experience shows that TDF is an effective and safe therapy for patients with CHB. Rates of sustained virological suppression were very high and most patients achieved complete virological suppression with continued therapy. TDF resistance was not observed and treatment was generally well tolerated. This study supports the findings of other real-life experience into the efficacy and safety of TDF in the treatment of CHB.

### Terminology

The hepatitis B virus (HBV) is transmitted vertically, parenterally or *via* mucosal exposure to infected blood or bodily fluids. CHB is associated with long-term complications of cirrhosis, liver failure and hepatocellular carcinoma. They carry high rates of morbidity and mortality and affect 15%-40% of patients at some point in their life. Tenofovir disoproxil fumarate is a nucleotide analogue used in the treatment of CHB. Prior to its role in CHB, TDF was used in the treatment of HIV type 1 infection.

### Peer-review

This is a well-designed and well-written real life data study of tenofovir treatment for hepatitis B.

## Abstract

### AIM

To evaluate the therapeutic effects of ursodeoxycholic acid (UDCA) on autoimmune hepatitis (AIH).

### METHODS

A total 136 patients who were diagnosed with AIH were included in our study. All of the patients underwent a liver biopsy, and had at least a probable diagnosis on the basis of either the revised scoring system or the simplified scores. Initial treatment included UDCA monotherapy (Group U,  $n = 48$ ) and prednisolone (PSL) monotherapy (Group P,  $n = 88$ ). Group U was further classified into two subgroups according to the effect of UDCA: Patients who had achieved remission induction with UDCA monotherapy and showed no sign of relapse (Subgroup U1,  $n = 34$ ) and patients who additionally received PSL during follow-up (Subgroup U2,  $n = 14$ ). We compared the clinical and histological findings between each groups, and investigated factors

contributing to the response to UDCA monotherapy.

## RESULTS

In Group U, 34 patients (71%) achieved and maintained remission over 49 (range: 8-90) mo (Subgroup U1) and 14 patients (29%) additionally received PSL (Subgroup U2) during follow-up. Two patients in Subgroup U2 achieved remission induction once but additionally required PSL administration because of relapse (15 and 35 mo after the start of treatment). The remaining 12 patients in Subgroup U2 failed to achieve remission induction during follow-up, and PSL was added during 7 (range: 2-18) mo. Compared with Subgroup U2, Subgroup U1 had significantly lower alanine aminotransferase (ALT) levels at onset (124 IU/L *vs* 262 IU/L,  $P = 0.023$ ) and a significantly higher proportion of patients with mild inflammation (A1) on histological examination (70.6% *vs* 35.7%,  $P = 0.025$ ). When multivariate analysis was performed to identify factors contributing to the response to UDCA monotherapy, only a serum ALT level of 200 IU/L or lower was found to be associated with a significant difference ( $P = 0.013$ ).

## CONCLUSION

To prevent adverse events related to corticosteroids, UDCA monotherapy for AIH needs to be considered in patients with a serum ALT level of 200 IU/L or lower.

**Key words:** Autoimmune hepatitis; Japanese patients; Adverse events; Corticosteroids; Ursodeoxycholic acid

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Autoimmune hepatitis (AIH) is generally responsive to immunosuppressive treatment, and corticosteroids are commonly used for the initial and maintenance treatments. However, corticosteroid treatment must be discontinued in some patients because of several side effects. This study aimed to evaluate the therapeutic effects of ursodeoxycholic acid (UDCA), which has high tolerability and no severe side effects, on AIH. Our results suggest that to prevent adverse events related to corticosteroids, treatment with UDCA alone for AIH needs to be considered in selected patients, especially those with an alanine aminotransferase level of 200 IU/L or lower. This utility of UDCA must be confirmed in a prospective study.

Clinical usefulness of ursodeoxycholic acid for Japanese patients with autoimmune hepatitis. *World J Hepatol* 2017; 9(1): 57-63 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i1/57.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i1.57>

## INTRODUCTION

Autoimmune hepatitis (AIH) is an unresolving pro-

gressive liver disease that affects females preferentially and is characterized by interface hepatitis, hypergammaglobulinemia, circulating autoantibodies, and a favorable response to immunosuppression. The aim of treatment in AIH is to obtain complete remission of the disease and to prevent further progression of liver disease, which generally requires permanent maintenance therapy. Corticosteroids have been widely used as the first choice drug treatment of AIH<sup>[1,2]</sup>. However, long-term treatment with a generous corticosteroid dosage may induce predictable side effects, such as cosmetic changes (facial rounding, dorsal hump formation, striae, weight gain, acne, alopecia, and facial hirsutism) or even more dreadful complications, such as osteopenia, brittle diabetes, psychosis, pancreatitis, opportunistic infections, labile hypertension, and malignancy<sup>[3-7]</sup>. Consequently, corticosteroid treatment must be discontinued in 13% of patients. Of those withdrawn from therapy, most have intolerable cosmetic changes or obesity (47%), osteoporosis with vertebral compression (27%), and/or difficult-to-control diabetes (20%)<sup>[4,8]</sup>. Because AIH predominantly affects middle-aged women, the presence of cosmetic issues is one of the key factors for maintaining drug compliance. Cosmetic issues may lead to emotional problems that result in treatment failure and a poor prognosis. Thus, a strategy to reduce the adverse effects of corticosteroid treatment is needed.

Ursodeoxycholic acid (UDCA) has been widely used as the first choice for treating primary biliary cirrhosis (PBC) and has been established as clinically useful<sup>[9-11]</sup>. No severe side effects have been reported during UDCA therapy for PBC<sup>[12]</sup>. Although there are reports that UDCA is also useful for treating similar autoimmune liver diseases, its clinical value has not as yet been established<sup>[13-15]</sup>. In this study, patients with a confirmed diagnosis of AIH who started treatment with UDCA alone were analyzed, and the results are reported.

## MATERIALS AND METHODS

### Patients

The present study included 136 patients who were diagnosed with AIH between 1975 and 2011 at the Division of Gastroenterology and Hepatology, Department of Internal Medicine, The Jikei University Hospital (Tokyo, Japan). All of the patients had at least a probable diagnosis on the basis of either the revised scoring system, as proposed by the International Autoimmune Hepatitis Group in 1999<sup>[16]</sup>, or the simplified scores<sup>[17]</sup>. All of the patients underwent a liver biopsy. In this study, patients with no histological fibrosis (F0) were excluded. Chronic viral hepatitis B and C were excluded by serological testing in all of the patients. Patients with an overlapping syndrome or a coexistent liver disease (e.g., primary biliary cirrhosis, primary sclerosing cholangitis, nonalcoholic fatty liver disease, or alcohol-induced liver injury) were also excluded by medical history, serological data and histological finding. So, patients with positive antimitochondrial antibody were excluded. Of the 136

<sup>1</sup>Subgroup U1, normalized ALT and sustained remission; <sup>2</sup>Subgroup U2, non-normalized ALT or relapse. Continuous variables are expressed as median (range) values. The Mann-Whitney *U* test was used to evaluate differences in continuous variables between two groups. Dichotomous variables were compared by Pearson's  $\chi^2$  test. Values of  $P < 0.05$  were considered significant. ALT: Alanine aminotransferase; AIH: Autoimmune hepatitis; AST: Aspartate transaminase; HLA: Human leukocyte antigen; ANA: Antinuclear antibody; ALP: Alkaline phosphatase;  $\gamma$ -GTP:  $\gamma$ -glutamyltransferase; SMA: Smooth muscle antibody; T.Bil: Total bilirubin; IgG: Immunoglobulin G; ns: No significant difference.

induction with UDCA monotherapy and showed no sign of relapse, and Subgroup U2, consisting of patients who additionally received PSL during follow-up. Laboratory test results and histopathological findings at the time of diagnosis were compared between Subgroups U1 and U2 (Table 2).

This study complied with the standards of the Declaration of Helsinki and the current ethical guidelines, and was approved by the institutional ethics board. Written, informed consent for participation in this study was not obtained from the patients, because this study did not report on a clinical trial and the data were retrospective in nature and analyzed anonymously.

### Treatment

PSL was used as the standard initial treatment. Taking into account body weight, the initial dose was set between 30 and 40 mg/d, with subsequent reduction after improvement in liver function had been confirmed.

In mild clinical cases with both histological low-grade inflammatory activity and adequate residual capacity of

liver function, the initial treatment was UDCA alone. The initial dose of UDCA was set at 600 mg/d (10–13 mg/kg per day) in accordance with Japanese guideline for the treatment of PBC. The dosage was neither increased nor decreased during the treatment period. PSL was also administered, as described above, when an incomplete response to UDCA monotherapy or relapse was observed.

### Follow-up

Each patient underwent a comprehensive clinical review and physical examination at each follow-up visit. Conventional laboratory blood tests were performed every 1–3 mo.

### Criteria for the remission and relapse of AIH

Remission was defined as a normalization of serum ALT levels after the start of treatment. The judgement of remission for UDCA monotherapy was carried out within at least 18 mo after initiation of therapy. Relapse was defined as an increase in serum ALT levels to more than twice the upper normal limit following the normalization of serum ALT levels with medical treatment.

### Statistical analysis

Statistical analysis was performed using the SPSS statistical program (release 16.0.1 J, SPSS, Inc., Chicago, IL). Continuous variables are expressed as medians and ranges. The Mann-Whitney *U* test was used to evaluate differences in continuous variables between two groups. Dichotomous variables were compared by Pearson's  $\chi^2$  test. Multivariate analyses by logistic regression were used to identify independent factors contributing to the response to UDCA monotherapy. Values of  $P < 0.05$  were considered significant.

## RESULTS

### Comparison of clinical features among two groups classified according to initial treatment

As the initial treatment, of the 136 patients, 48 received UDCA monotherapy (Group U) and 88 received PSL monotherapy (Group P). There were no differences between Groups U and P in age, serum levels of alkaline phosphatase, the frequencies of positivity for antinuclear antibody or human leukocyte antigen DR4, and scores derived from either the old or the new scoring system. However, compared with Group P, Group U had significantly lower serum levels of aspartate transaminase (AST) (104 IU/L vs 303 IU/L,  $P < 0.001$ ), ALT (149 IU/L vs 431 IU/L,  $P < 0.001$ ), total bilirubin (0.8 mg/dL vs 1.3 mg/dL,  $P < 0.05$ ),  $\gamma$ -glutamyltransferase (82 U/L vs 182 U/L,  $P < 0.05$ ), and immunoglobulin G (1954 mg/dL vs 2336 mg/dL,  $P < 0.01$ ), and lower frequencies of male sex, acute presentation, and positivity for smooth muscle antibody at the onset. Additionally, Group U had a significantly higher proportion of patients with mild inflammation and fibrosis (A1 and F1) on histological examination (28.4% vs 60.4%,  $P < 0.01$ , and 48.9% vs

72.9%,  $P < 0.05$ ) (Table 1). Cumulative incidence of the normalization of serum ALT levels was 80% in Group P.

### UDCA monotherapy as initial treatment

The follow-up durations were 49 (range: 8–156) mo in Group U. In Group U, 34 patients (71%) achieved and maintained remission over 49 (range = 8–90) mo (Subgroup U1), and 14 patients (29%) additionally received PSL during follow-up (Subgroup U2). Two patients in Subgroup U2 achieved remission induction once but additionally required PSL administration because of relapse (15 and 35 mo after the start of treatment). The remaining 12 patients in Subgroup U2 failed to achieve remission induction during follow-up, and PSL was added during 7 (range: 2–18) mo.

### Comparison of clinical features among two subgroups classified according to the effect of UDCA

The rate of numbers was 73% in Subgroup U1 and 27% in Subgroup U2. Compared with Subgroup U2, Subgroup U1 had significantly lower ALT levels at onset (124 IU/L vs 262 IU/L,  $P = 0.023$ ) and a significantly higher proportion of patients with mild inflammation (A1) on histological examination (70.6% vs 35.7%,  $P = 0.025$ ) (Table 2). However, there were no differences between Subgroups U1 and U2 in other clinical features, as shown in Table 2.

### Predictive factors associated with normalized ALT and sustained remission with UDCA monotherapy in AIH patients

When multivariate analysis was performed to identify factors contributing to the response to UDCA monotherapy, a serum ALT level of 200 IU/L or lower was found to be associated with a significant difference (Table 3).

On subgroup analysis, remission was induced and maintained by UDCA in 85%, 83% and 92% of patients in Subgroups A, B, and C, respectively. In these subgroups, high rates of remission induction and successful maintenance were achieved by UDCA. On the other hand, the rates of remission induction and successful maintenance in Subgroups D, E and F were low, at 40%, 53%, and 50%, respectively (Figure 1).

## DISCUSSION

UDCA has been widely used as the first choice drug for the treatment of PBC<sup>[9–11]</sup>. This is because of its efficacy for cholestasis, exerted through its choleretic action which is well understood<sup>[19]</sup>. In addition to its choleretic action, UDCA reportedly has a protective action on hepatocytes and an immunomodulatory action<sup>[20]</sup>. In fact, it has also been reported that the administration of UDCA reduces elevated serum immunoglobulin levels in patients with PBC, which is one of the clinical characteristics of PBC<sup>[9,21]</sup>. *In vitro* studies have also shown that UDCA inhibits immunoglobulin production by peripheral lymphocytes in a concentration-dependent manner<sup>[22]</sup>. Although the

ALT: Alanine aminotransferase; AIH: Autoimmune hepatitis.

UDCA level required to inhibit immunoglobulin production is approximately 10 times the blood concentration after administration of UDCA at routine doses<sup>[22]</sup>, similarly high levels apparently exist in hepatocytes secreting bile, in other words, in the liver. Thus, UDCA may exert a liver-specific immunosuppressive action. This indicates that UDCA can be administered to achieve immunosuppression in patients with AIH. Miyake *et al.*<sup>[13]</sup> demonstrated in a small-scale study that UDCA is effective for AIH. Moreover, the administration of UDCA has also been shown to allow corticosteroid doses to be tapered<sup>[14]</sup>.

In this study, 71% of the UDCA group achieved and maintained the normalization of serum ALT levels with UDCA monotherapy. Especially, the present study also identified that in 85% of the patients with ALT levels of 200 IU/L or lower at the start of treatment, AIH remission could be induced and maintained by UDCA monotherapy. So, UDCA monotherapy will be effective in some Japanese AIH patients. However, in this study, patients treated with UDCA monotherapy had lower serum ALT levels and milder histological activity and fibrosis at presentation than those treated with PSL as shown in Table 1. Hence, it is necessary to consider that usefulness of UDCA was presented in mild AIH group. In the future, utility of UDCA must be confirmed in a prospective study.

On the other hand, among these mild AIH patients, the proportion indicated for UDCA monotherapy was low. On the bases of this finding, the patients in Group U can be considered to have no indications for treatment. In fact, 10-year survival in untreated patients with mild disease was reported to be 67%-90%<sup>[23,24]</sup>, and in an uncontrolled study, untreated asymptomatic patients had similar survival to those receiving immunosuppression<sup>[25]</sup>.

**Figure 1** Remission rate of each subgroup with ursodeoxycholic acid therapy. Remission was induced and maintained by ursodeoxycholic acid in 85%, 83% and 92% of patients in Subgroups A, B and C, respectively. On the other hand, the rates of remission induction and successful maintenance in Subgroups D, E, and F are low, at 40%, 53% and 50%, respectively. ALT: Alanine aminotransferase.

However, it also has to be acknowledged that untreated AIH has a fluctuating, unpredictable disease behavior, and a substantial proportion of asymptomatic patients become symptomatic during the course of their disease follow-up<sup>[25,26]</sup>, and progression towards end-stage liver disease with liver failure and development of HCC is possible<sup>[24]</sup>. Muratori *et al.*<sup>[27]</sup> also reported that patients with asymptomatic vs symptomatic AIH have similar courses of disease progression and responses to immuno-suppressive agents, and should therefore receive the same treatment. Additionally, to exclude patients with transient liver damage that may not have required treatment, patients with no histological fibrosis (F0) were not enrolled in the present study.

According to the AIH Guidelines issued by the American Association for the Study of Liver Diseases in 2010, no treatment is needed for patients with AST and ALT levels close to or below the standard levels<sup>[1]</sup>. The patients included in the present study did not meet these criteria, but largely met the indications for treatment. While the efficacy of corticosteroids for the treatment of AIH has been established, treatment with corticosteroids is currently the first choice only in patients with appropriate indications<sup>[1,2]</sup>. However, corticosteroids are associated with adverse events, such that there is often reluctance to administer these drugs. In patients with AIH in Japan, the age at onset and diagnosis has been increasing annually<sup>[28]</sup>. Particularly in elderly women, many of whom are postmenopausal, there is actually considerable concern regarding osteoporosis. Moreover, in the treatment of AIH, prevention of relapse is the most important issue, and maintenance therapy is thus important. However, because many patients are women, drug compliance can actually be poor due to cosmetic issues. In addition, it has also been pointed out that the incidence of other adverse events is high in elderly patients. The present study subjects had an age distribution between 17 and 74 years, demonstrating that elderly patients with AIH associated

with mild liver disorders could be treated with UDCA. Moreover, when the therapeutic effects of UDCA become inadequate, treatment can be continued by switching to corticosteroids, as shown in the present study. Furthermore, treatment with UDCA also has the benefit of eventually allowing the corticosteroid dose to be tapered<sup>[14]</sup>. A recent nationwide survey on AIH in Japan showed that UDCA monotherapy is administered as the initial treatment in 20% of patients<sup>[28]</sup>, so it is reasonable to assume that the treatment of AIH with UDCA is becoming clinically established. While Czaja *et al.*<sup>[15]</sup> found UDCA to be effective in a double-blind study, it is important to define criteria for UDCA treatment indications, as in the present study. Although the present study had a retrospective design, the results allow the conclusion to be drawn that UDCA use may be considered in patients with a serum ALT level of 200 IU/L at the time of diagnosis, especially in those who are elderly. Prospective studies on the long-term outcomes of patients receiving UDCA monotherapy are needed.

## COMMENTS

### Background

Autoimmune hepatitis (AIH) is an unresolving progressive liver disease that affects females preferentially and is characterized by interface hepatitis, hypergammaglobulinemia, circulating autoantibodies, and a favorable response to immunosuppression. The aim of treatment in AIH is to obtain complete remission of the disease and to prevent further progression of liver disease, which generally requires permanent maintenance therapy. Corticosteroids have been widely used as the first choice drug treatment of AIH. However, long-term treatment with a generous corticosteroid dosage may induce side effects. Ursodeoxycholic acid (UDCA) has been widely used as the first choice for treating primary biliary cirrhosis (PBC) and has been established as clinically useful. No severe side effects have been reported during UDCA therapy for PBC. Although there are reports that UDCA is also useful for treating similar autoimmune liver diseases, its clinical value has not as yet been established. In this study, patients with a confirmed diagnosis of AIH who started treatment with UDCA alone were analyzed.

### Research frontiers

There are few reports that UDCA monotherapy is effective for treating AIH. Moreover, the administration of UDCA has also been shown to allow corticosteroid doses to be tapered. However, its clinical value has not as yet been established.

### Innovations and breakthroughs

Few prior reports showed that UDCA is effective in some AIH patients. However, there is no report which showed independent predictive factors associated with normalized ALT and sustained remission of UDCA monotherapy in AIH patients. The present study showed that ALT levels of 200 IU/L or lower associated with to response to UDCA monotherapy. The results of the authors' study contribute to predict the therapeutic effect of UDCA for patients with AIH.

### Applications

This study suggests that that to prevent adverse events related to corticosteroids, treatment with UDCA alone for AIH needs to be considered in selected patients, especially those with an ALT level of 200 IU/L or lower.

### Terminology

UDCA: One of the secondary bile acids, which are metabolic byproducts of intestinal bacteria. It has been widely used as the first choice drug for the treatment of PBC. This is because of its efficacy for cholestasis, exerted through its choleretic action which is well understood. In addition to its choleretic

action, UDCA reportedly has a protective action on hepatocytes and an immunomodulatory action.

### Peer-review

This is a very interesting cut off point for future prospective studies to confirm these retrospective results.

### Abstract

#### AIM

To investigate shear wave (SW) propagation velocity in patients with untreated hepatitis C and patients with sustained virological response (SVR).

#### METHODS

A total of 136 hepatitis C patients [85 patients who had not received antiviral therapy (naïve group) and 51 patients who had received antiviral therapy and subsequently achieved SVR of at least 24 wk (SVR group)] and 58 healthy volunteers and outpatients without liver disease (control group) underwent evaluation of liver stiffness by SW elastography (SWE). Various parameters were evaluated in the chronic hepatitis C patients at the time of SWE.

#### RESULTS

SW propagation velocity ( $V_s$ ) was  $1.23 \pm 0.14$  m/s in the control group,  $1.56 \pm 0.32$  m/s in the SVR group, and  $1.69 \pm 0.31$  m/s in the naïve group. Significant differences were seen between the control group and the SVR group ( $P = 0.0000$ ) and between the SVR group and the naïve group ( $P = 0.01417$ ). All four fibrosis markers were higher in the naïve group than in the SVR group. In the naïve group,  $V_s$  was positively correlated with alanine aminotransferase (ALT) ( $r = 0.5372$ ),  $\alpha$  fetoprotein (AFP) ( $r = 0.4389$ ), type IV collagen ( $r = 0.5883$ ), procollagen III peptide (P-III-P) ( $r = 0.4140$ ), hyaluronic acid ( $r = 0.4551$ ), and Mac-2 binding protein glycosylation isomer (M2BPGi) ( $r = 0.6092$ ) and negatively correlated with albumin ( $r = -0.4289$ ), platelets ( $r = -0.5372$ ), and prothrombin

activity ( $r = -0.5235$ ). On multiple regression analysis, Vs was the most strongly correlated with ALT (standard partial regression  $\beta = 0.4039$ ,  $P = 0.00000$ ). In the SVR group, Vs was positively correlated with AFP ( $r = 0.6977$ ), type IV collagen ( $r = 0.5228$ ), P-III-P ( $r = 0.5812$ ), hyaluronic acid ( $r = 0.5189$ ), and M2BPGi ( $r = 0.6251$ ) and negatively correlated with albumin ( $r = -0.4283$ ), platelets ( $r = -0.4842$ ), and prothrombin activity ( $r = -0.4771$ ). On multiple regression analysis, Vs was strongly correlated with AFP (standard partial regression  $\beta = 0.5953$ ,  $P = 0.00000$ ) and M2BPGi (standard partial regression  $\beta = 0.2969$ ,  $P = 0.03363$ ).

### CONCLUSION

In hepatitis C patients, liver stiffness is higher in treatment-naïve patients than in those showing SVR. SWE may be a predictor of hepatocarcinogenesis in SVR patients.

**Key words:** Hepatocarcinogenesis; Sustained virological response; Antiviral therapy; Shear wave elastography; Hepatitis C

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This study is the first to compare liver stiffness in a group of hepatitis C patients in whom the virus was eliminated with antiviral therapy and a group of untreated hepatitis C patients using shear wave elastography. The liver stiffness value was higher in the untreated group than in the group in which the virus had been eliminated, which is thought to be due hepatitis activity. This study also suggests the possibility that liver stiffness measurements with shear wave elastography can be used as predictors of hepatocarcinogenesis in patients in whom the virus has been eliminated.

Shear wave elastography in hepatitis C patients before and after antiviral therapy. *World J Hepatol* 2017; 9(1): 64-68 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i1/64.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i1.64>

### INTRODUCTION

Shear wave elastography (SWE) is a new technology that gauges liver stiffness by measuring the propagation velocity of shear waves generated in liver tissue. At the same time, images are observed in real time using a normal B-mode ultrasound probe. The velocity of laterally propagated shear waves (lateral waves) is measured. SWE is useful for a diagnosis of breast tumor<sup>[1]</sup>, thyroid tumor<sup>[2]</sup>, muscle stiffness<sup>[3]</sup> as well as liver stiffness. SWE resembles acoustic radiation force impulse<sup>[4]</sup>, but it is new another technology.

Liver stiffness measurements with SWE are reported to be useful in diagnosing fibrosis in hepatitis C<sup>[5]</sup>. In

studies using transient elastography, liver stiffness was affected not only by liver fibrosis but also by necroinflammatory activity<sup>[6,7]</sup>. Therefore, the meaning of liver stiffness is predicted to differ in untreated patients with hepatitis activity and patients whose hepatitis has subsided with antiviral therapy.

The purpose of this study was to investigate the significance of SW propagation velocity in patients with untreated hepatitis C and patients with sustained virological response.

### MATERIALS AND METHODS

#### Patients

This prospective study was reviewed and approved by the Ethics Committee of Dokkyo Medical University Koshigaya Hospital, and written, informed consent was obtained from all participants and healthy volunteers. This study conformed to the ethical guidelines of the 2008 Declaration of Helsinki.

The subjects were 136 chronic hepatitis C patients who were diagnosed in the Department of Gastroenterology of Dokkyo Medical University Koshigaya Hospital from April to October, 2015. The 136 patients included 85 patients in a naïve group who had not received antiviral therapy and 51 patients who had received antiviral therapy, either interferon-based therapy or direct-acting antiviral agent therapy (daclatasvir/asunaprevir), and subsequently achieved sustained virological response (SVR) of at least 24 wk (SVR group). Patients with decompensated liver cirrhosis, hepatocellular carcinoma, autoimmune disease, collagen disease, or chronic heart disease were excluded. Patients with a history of drinking  $\geq 20$  g alcohol per day and those diagnosed with obvious fatty liver on abdominal ultrasound were also excluded.

To obtain a standard liver stiffness value, SWE was performed in a total of 58 people including healthy volunteers and outpatients without liver disease (control group).

#### Measurement of SWE

Measurement of liver stiffness by shear wave elastography was performed using a LOGIQ E9 (GE Healthcare, Milwaukee, WI). The right lobe of the liver was visualized through an intercostal space while the patient was lying in a supine position with the right arm in maximum abduction. Measurements were taken while subjects held their breath during spontaneous breathing. The visual depth of the system was fixed at 8 cm, and the region of interest was 1-2 cm below the surface of the liver. The system was adjusted so that sample volume depth was 4 cm or less. Liver stiffness was automatically calculated by the apparatus, and the results are expressed as the velocity of shear wave velocity (Vs) (m/s). Measurements were performed by two investigators (Suda T and Tamano M) who have measurement experience of SWE more than 100 patients. They shot 10 to 12 times on liver segment 5, and the result was considered reliable only when 10

**Figure 1** Velocity based on shear wave elastography is shown for each group. Vs is  $1.23 \pm 0.14$  m/s in the control group,  $1.56 \pm 0.32$  m/s in the sustained virological response (SVR) group, and  $1.69 \pm 0.31$  m/s in the naïve group. Significant differences are seen between the control group and the SVR group ( $P = 0.0000$ ) and between the SVR group and the naïve group ( $P = 0.01417$ ). Vs: Velocity.

successful shots and a measurement success rate > 80% were obtained.

### Clinical parameters

The following clinical parameters were determined in chronic hepatitis C patients at the time SWE was performed: Age; aspartate aminotransferase (AST); alanine aminotransferase (ALT); total bilirubin, serum albumin; white blood cell (WBC) count; platelet count; prothrombin activity;  $\alpha$  fetoprotein (AFP); hyaluronic acid; type IV collagen; procollagen III peptide (P-III-P); Mac-2 binding protein glycosylation isomer (M2BPGi) measurements; and the Fib-4 index.

### Statistical analysis

Continuous data for Vs and other clinical parameters are expressed as means  $\pm$  SD. The Mann-Whitney *U* test was used for between-group comparisons. Correlations between Vs and other parameters were assessed using Spearman's rank correlation coefficient and multiple regression analysis. Values of  $P < 0.05$  were regarded as statistically significant.

## RESULTS

Figure 1 shows Vs (m/s) measured by SWE in each group. Vs was  $1.23 \pm 0.14$  m/s in the control group,  $1.56 \pm 0.32$  m/s in the SVR group, and  $1.69 \pm 0.31$  m/s in the naïve group. Significant differences were seen between the control group and the SVR group ( $P = 0.0000$ ) and between the SVR group and the naïve group ( $P = 0.01417$ ).

Table 1 shows the characteristics of the naïve group and the SVR group. Compared with the SVR group, the naïve group had significantly higher AST and ALT values ( $P = 0.00001$ ) and a significantly lower serum albumin value ( $P = 0.01049$ ). No significant differences were seen between the two groups in total bilirubin, WBC, platelet count, or prothrombin activity. AFP was significantly higher in the naïve group than in the SVR

**Table 1** Clinical characteristics in the Naïve and sustained virological response group

Characteristics	Naïve group ( <i>n</i> = 85)	SVR group ( <i>n</i> = 51)	<i>P</i> value
Age (yr)	$63.5 \pm 13.7$	$64.9 \pm 10.2$	0.9726
Sex (male/female)	43/42	27/24	0.79039
AST (IU/L)	$55.4 \pm 38.7$	$29.2 \pm 16.8$	0.00001
ALT (IU/L)	$61.9 \pm 50.1$	$23.9 \pm 18.0$	0.00001
Total bilirubin (mg/dL)	$0.89 \pm 0.36$	$0.95 \pm 0.33$	0.14736
Serum albumin (g/dL)	$4.10 \pm 0.46$	$4.32 \pm 0.44$	0.01049
WBC ( $\times 10^3/\text{mm}^3$ )	$5.21 \pm 1.83$	$5.24 \pm 1.56$	0.79015
Hb (g/dL)	$13.9 \pm 1.6$	$14.1 \pm 1.5$	0.47879
Platelet ( $\times 10^4/\text{mm}^3$ )	$14.5 \pm 6.4$	$14.5 \pm 5.7$	0.89078
Prothrombin activity (%)	$97.5 \pm 12.1$	$96.9 \pm 13.1$	0.98341
AFP (g/dL)	$9.6 \pm 10.6$	$5.1 \pm 3.3$	0.00773
Type IV collagen (ng/mL)	$180.5 \pm 71.8$	$179.2 \pm 71.6$	0.62913
P-III-P (U/mL)	$0.92 \pm 0.27$	$0.81 \pm 0.31$	0.00215
Hyaluronic acid (ng/mL)	$191.5 \pm 290.3$	$102.1 \pm 93.5$	0.24908
M2BPGi (COI)	$3.67 \pm 4.41$	$2.03 \pm 2.49$	0.00546
FIB-4 index	$4.44 \pm 4.21$	$3.39 \pm 2.63$	0.37443

AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; WBC: White blood cell; P-III-P: Procollagen III peptide; M2BP: Mac-2 binding protein; COI: Cut-off index.

group ( $P = 0.00773$ ). All four fibrosis markers were higher in the naïve group than in the SVR group. No significant differences were seen in type IV collagen or hyaluronic acid, but significant differences were seen in P-III-P ( $P = 0.00215$ ) and M2BPGi ( $P = 0.00546$ ). The FIB-4 index tended to be higher in the naïve group than in the SVR group, but the difference was not significant ( $P = 0.37443$ ).

### Correlation between Vs and each parameter in the naïve group (*n* = 85)

Vs was positively correlated with ALT ( $r = 0.5372$ ), AFP ( $r = 0.4389$ ), type IV collagen ( $r = 0.5883$ ), P-III-P ( $r = 0.4140$ ), hyaluronic acid ( $r = 0.4551$ ), and M2BPGi ( $r = 0.6092$ ). Vs was negatively correlated with albumin ( $r = -0.4289$ ), platelets ( $r = -0.5372$ ), and prothrombin activity ( $r = -0.5235$ ). A multiple regression analysis was performed with the five parameters of ALT, platelets, prothrombin activity, type IV collagen, and M2BPGi that had correlation coefficients ( $r$ )  $\geq 0.5$ , and the results showed that Vs was the most strongly correlated with ALT in the naïve group (standard partial regression std  $\beta = 0.4039$ ,  $P = 0.00000$ ) (Table 2).

### Correlation between Vs and each parameter in the SVR group (*n* = 51)

Vs was positively correlated with AFP ( $r = 0.6977$ ), type IV collagen ( $r = 0.5228$ ), P-III-P ( $r = 0.5812$ ), hyaluronic acid ( $r = 0.5189$ ), and M2BPGi ( $r = 0.6251$ ). Vs was negatively correlated with albumin ( $r = -0.4283$ ), platelets ( $r = -0.4842$ ), and prothrombin activity ( $r = -0.4771$ ). A multiple regression analysis was performed with the five parameters of AFP, type IV collagen, P-III-P, hyaluronic acid, and M2BPGi that had correlation coefficients ( $r$ )  $\geq 0.5$ , and the results showed that Vs was strongly correlated with two parameters, AFP

(standard partial regression  $\text{std } \beta = 0.5953$ ,  $P = 0.00000$ ) and M2BPGi (standard partial regression  $\text{std } \beta = 0.2969$ ,  $P = 0.03363$ ) (Table 3).

## DISCUSSION

The extent of hepatic fibrosis has classically been evaluated by histological procedures. However, the accuracy of this evaluation of hepatic fibrosis is limited by both sampling variability and inter-observer variability between pathologists<sup>[8,9]</sup>. In addition, liver biopsy is associated with patient discomfort and a risk of serious complications<sup>[10]</sup>.

Transient elastography (TE) has attracted attention as a noninvasive, objective diagnostic tool, and liver stiffness measured by TE is reported to be useful in diagnosing fibrosis in hepatitis C<sup>[11]</sup>. TE is useful in diagnosing non-alcoholic fatty liver disease<sup>[12]</sup> and in predicting carcinoma development in viral hepatitis patients<sup>[13]</sup>. However, TE is a test that is done blindly using a special probe in the right hepatic lobe confirmed with B mode, as a result of which measurement results are imprecise if vessels or other structures are present in the measured region. SWE is built into ultrasonic diagnostic equipment, and reliable measurements are possible in a short time under observation with normal B mode<sup>[14]</sup>.

The results of SWE measurements are expressed as the SW propagation velocity Vs (m/s). In this investigation, the Vs was  $1.23 \pm 0.14$  m/s in healthy livers,  $1.69 \pm 0.31$  m/s in the naïve group, and  $1.56 \pm 0.32$  m/s in the SVR group. The naïve group had a significantly higher Vs than the SVR group, suggesting that Vs decreases with virus elimination in hepatitis C patients. In this study, however, the naïve group and SVR group were different populations, and Vs measurements over time in the same population will be needed to accurately compare Vs before and after treatment.

Vs is determined not only by tissue elasticity (fibrosis), but it is also affected by viscosity. Thus, in cases of active hepatitis, propagation is expected to become faster due to increased tissue viscosity from increased exudate into the interstitium and cell infiltration, and in acute hepatitis that trend is marked<sup>[15,16]</sup>. In the naïve group, Vs was most strongly correlated with ALT. This is thought to be because the naïve group included many patients with active hepatitis with high ALT levels. Good positive correlations were seen between Vs and the liver fibrosis markers of hyaluronic acid, type IV collagen, P-III-P, and M2BPGi in the naïve group. Thus, in the naïve group, Vs is thought to reflect both hepatic activity (viscosity) and

**Table 3 Multiple regression analysis in the sustained virological response group**

	Coefficient (β)	SE (β)	Std β	t-value	df	P value
AFP	0.05564	0.0098	0.5953	5.6797	28	0.00000

AFP: α feto protein; P-III-P: Procollagen III peptide; M2BP: Mac-2 binding protein.

fibrosis (elasticity).

In the SVR group, hepatitis had subsided for six months or more, and, in fact, the correlation between Vs and ALT in the SVR group in this study was very low. Therefore, Vs in the SVR group is presumed to almost purely reflect liver fibrosis (elasticity), and thus it is thought to have better correlations with fibrosis markers. Among the four different fibrosis markers, M2BPGi had the strongest positive correlation with Vs. M2BPGi is a new liver fibrosis marker that quantitatively measures changes in the carbohydrate structure of Mac-2 binding protein<sup>[17]</sup>, and it is also considered useful in predicting carcinogenesis in hepatitis C patients<sup>[18-20]</sup>.

In hepatitis C patients, AFP is a useful indicator of hepatocarcinogenesis following interferon therapy<sup>[21]</sup>. Although AFP had positive correlations in both the naïve group and the SVR group, a stronger correlation was seen in the SVR group. In the naïve group, AFP reflects inflammation and necrosis of hepatocytes and the accompanying hepatocyte regeneration. In the SVR group, on the other hand, AFP has a strong element as a surrogate marker of hepatocellular carcinoma, as mentioned previously. A very interesting finding in the SVR group in the present study was the strong correlations between Vs and AFP and between Vs and M2BPGi, which suggest the possibility that liver stiffness measurements with SWE may be used as predictors of hepatocarcinogenesis in hepatitis C patients following SVR.

In hepatitis C patients, liver stiffness with SWE was higher in the naïve group than in the SVR group, presumably due to hepatitis activity. In the SVR group, liver stiffness measurements with SWE may be a predictor of hepatocarcinogenesis.

## COMMENTS

### Background

Shear wave elastography (SWE) is a new technology that gauges liver stiffness by measuring the propagation velocity of shear waves generated in liver tissue. At the same time, images are observed in real time using a normal B-mode ultrasound probe. The velocity of laterally propagated shear waves (lateral waves) is measured.

### Research frontiers

The results of SWE measurements are expressed as the SW propagation velocity Vs (m/s). In this investigation, the Vs was  $1.23 \pm 0.14$  m/s in healthy livers,  $1.69 \pm 0.31$  m/s in the naïve group, and  $1.56 \pm 0.32$  m/s in the SVR group. The naïve group had a significantly higher Vs than the SVR group, suggesting that Vs decreases with virus elimination in hepatitis C patients. In this study, however,

the naïve group and sustained virological response (SVR) group were different populations, and Vs measurements over time in the same population will be needed to accurately compare Vs before and after treatment.

### Innovations and breakthroughs

A very interesting finding in the SVR group in the present study was the strong correlations between Vs and  $\alpha$  fetoprotein and between Vs and Mac-2 binding protein glycosylation isomer, which suggest the possibility that liver stiffness measurements with SWE may be used as predictors of hepatocarcinogenesis in hepatitis C patients following SVR.

### Applications

In the SVR group, liver stiffness measurements with SWE may be a predictor of hepatocarcinogenesis.

### Peer-review

This manuscript by Suda *et al* points to assess the changes of shear wave velocity in patients with untreated chronic hepatitis C and patients who received antiviral therapy and obtained SVR. The authors found significant differences between shear wave velocity between patients with SVR and those untreated.

## Contents

*World Journal of Hepatology*  
Volume 9 Number 2 January 18, 2017

### ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Dr. Ren-Qian Zhong, MD, PhD, Director, Professor, Department of Laboratory Medicine, Shanghai Changzheng Hospital, Second Military Medical University, Shanghai 200003, China

### AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### INDEXING/ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

In the last decades the prevalence of non-alcoholic fatty liver disease (NAFLD) has increased as a consequence of the childhood obesity world epidemic. The liver damage occurring in NAFLD ranges from simple steatosis to steatohepatitis, fibrosis and cirrhosis. Recent findings reported that fatty liver disease is related to early atherosclerosis and cardiac dysfunction even in the pediatric population. Moreover, some authors have shown an association between liver steatosis and cardiac abnormalities, including rise in left ventricular mass, systolic and diastolic dysfunction and epicardial adipose tissue thickness. In this editorial, we provide a brief overview of the current knowledge concerning the association between NAFLD and cardiac dysfunction.

**Key words:** Cardiac dysfunction; Non-alcoholic fatty liver disease atherosclerosis; Children; Cardiovascular risk

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Recently, growing scientific evidences suggest that obese children with non-alcoholic fatty liver disease are more predisposed to cardiovascular disease. Interestingly, this association seems to be independent from adiposity. In fact, based on recent findings, it has been proposed that liver steatosis plays an independent role in determining early atherosclerosis and cardiac dysfunction.

Di Sessa A, Umano GR, Miraglia del Giudice E, Santoro N. From the liver to the heart: Cardiac dysfunction in obese children with non-alcoholic fatty liver disease. *World J Hepatol* 2017; 9(2):

## INTRODUCTION

Currently, non-alcoholic fatty liver disease (NAFLD) represents the major cause of chronic liver disease in childhood and is considered a multisystem disease that affects many extra-hepatic organs<sup>[1]</sup>. Experimental evidence suggests that children with NAFLD have a higher risk of developing end stage liver disease than the general population of United States of same age and gender<sup>[2]</sup>. Moreover, NAFLD has emerged as an independent risk factor for cardiovascular diseases (CVD)<sup>[3,4]</sup>, including coronary artery disease and cardiac dysfunction<sup>[5-8]</sup>.

The molecular mechanisms linking NAFLD to cardiovascular complications are still poorly understood<sup>[6,8]</sup>. Children with NAFLD display increased free fatty acids that may lead to myocardial lipid accumulation with consequent impairments in myocardial substrate metabolism and efficiency and, finally, cardiac dysfunction<sup>[7,8]</sup>. Moreover, the presence of a low-grade inflammatory state in these patients contributes to the release of several mediators that amplify this condition<sup>[6,8]</sup>. Therefore, it has been hypothesized that intra-hepatic fat might exert a key pathogenetic role in developing cardio-metabolic complications (Figure 1).

In the last 20 years, NAFLD has become the most common liver disease in pediatrics<sup>[1]</sup>, as result of the increased prevalence of early onset obesity<sup>[2-4]</sup>. Although NAFLD develops in the context of insulin resistance related to obesity, it is possible that a parental effect exists. As suggested by experimental studies in rats, in fact, paternal and maternal obesity during preconception could lead to obesity, glucose metabolism abnormalities and liver steatosis in the offspring<sup>[5]</sup>.

## ATHEROSCLEROSIS

NAFLD represents an independent risk factor for CVD as it is associated with dyslipidemia, insulin resistance and alterations of cardiac function independent of the degree of obesity<sup>[3,4]</sup>.

Recent studies<sup>[2,3,6]</sup> have shown that atherosclerosis and alterations of cardiac function may occur already during childhood, as demonstrated by the presence of early onset subclinical atherosclerosis as measured by impaired flow-mediated vasodilation and increased carotid artery intimal medial thickness as well as by the presence of abnormalities in myocardial structure and function in obese children and adolescents<sup>[3,4]</sup> (Table 1).

Despite this evidence, the relationship between NAFLD and cardiovascular alterations is still poorly understood. Moreover, it is unclear whether there is a causal relationship between intra-hepatic fat accumulation and alterations of cardiac dynamics or whether the

two phenomena are just independent complications of obesity.

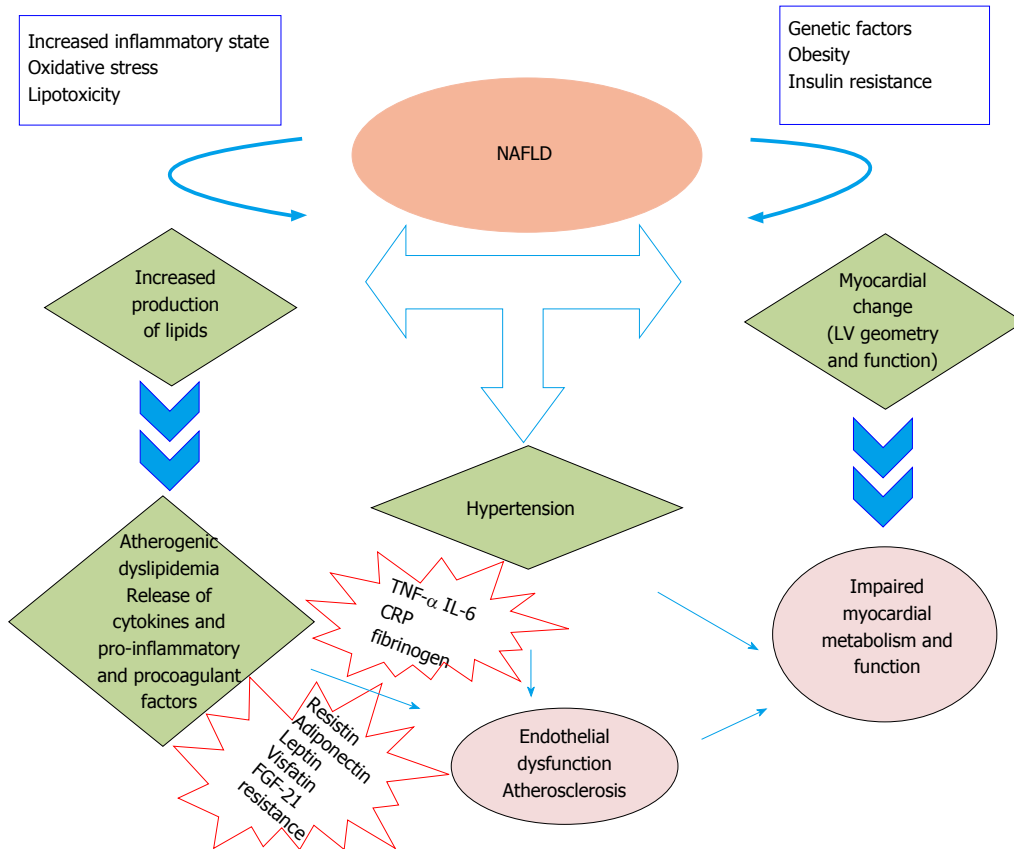

It is possible that intra-hepatic fat accumulation may be a pathogenic determinant of CVD. In fact, NAFLD can lead to atherosclerosis by causing an abundant secretion from the liver of lipoproteins [large very low density lipoproteins (VLDL)]<sup>[7]</sup>, which, in obese individuals with NAFLD, are abundant in oxidized fatty acids<sup>[8,9]</sup>. The higher concentration of large VLDL results in a high concentration in plasma of very small LDL, which in turn are a major contributor to the atherosclerotic plaque<sup>[7]</sup>, and their accumulation within the plaque would ultimately lead to ischemic events. NAFLD *per se*, in fact, is a hyperlipidemic state in which adipose tissue insulin resistance<sup>[10]</sup> and enhanced hepatic *de novo* lipogenesis<sup>[11]</sup> lead to an abnormal accumulation of fat in the liver, turning the hepatocytes in a fat producing factory.

It is important to remember that myocardial atherogenesis occurs very early in life. Seminal studies in the Bogalusa cohort showed that atherosclerosis often begins in pediatric age<sup>[12]</sup>, as demonstrated by the fact that fatty streaks are detected already in the aorta and the coronary arteries of children<sup>[6,13]</sup>. Since NAFLD can begin during childhood in obese children, it is reasonable to think that it can be an important determinant of these early events observed already in the pediatric population.

## CARDIAC ABNORMALITIES

While, the association between NAFLD and atherosclerosis could be easily explained by the abundance of circulating lipids present in obese children with NAFLD, it is more difficult to explain the relationship between NAFLD and cardiac function and geometry<sup>[14,15]</sup>. It has been reported that adolescents with NAFLD show an impaired systolic and diastolic function and an increased left ventricular mass compared to both healthy controls and age and gender matched obese adolescents without NAFLD<sup>[14,15]</sup> (Table 1).

To explain this observation several pathogenic mechanisms have been hypothesized, including the role of the liver as a generator of circulating mediators that could be involved in the cardiac remodeling<sup>[3,11,16,17]</sup>. In fact, the presence of a low-grade inflammatory state in patients obese patients with NAFLD and insulin resistance contributes to release of several cytokines and adipokines (e.g., IL-6, TNF-alpha, visfatin, FGF-21, adiponectin, resistin, leptin) that amplify this condition and worsen the metabolic phenotype<sup>[3,11,17]</sup>. Whether the trigger for this condition, usually referred to as "sterile inflammation", is NAFLD or insulin resistance *per se* is unclear, but a large body of evidence suggests that inflammatory cytokines may be the link among fatty liver, insulin resistance and myocardial changes<sup>[3,17]</sup>. In fact, adiponectin, a strong insulin sensitizer, seems to be

**Figure 1** The multifactorial mechanisms leading nonalcoholic fatty liver disease patients to unfavorable cardiac outcomes. CRP: C-reactive protein; IL-6: Interleukin-6; TNF- $\alpha$ : Tumor necrosis factor- $\alpha$ ; FGF-21: Fibroblast growth factor-21; NAFLD: Nonalcoholic fatty liver disease; LV: Left ventricular.

decreased in patients with NAFLD and some studies have suggested that low adiponectin levels may affect cardiac function and atherogenic risk. In contrast, patients with NAFLD experience also an increased production of pro-inflammatory and pro-atherogenic cytokines (IL-6, IL-12, TNF- $\alpha$ ), which in turn worsens insulin resistance, mostly through the down-regulation of insulin-receptor-substrate and by affecting gluconeogenesis<sup>[3,17]</sup>, these compounds could also affect the cardiac morphology and dynamics. More importantly, some data suggest that fibroblast growth factor 21 (FGF-21), a protein synthesized and secreted by the liver in high amounts in obese subjects with fatty liver, might play a role in cardiac hypertrophy<sup>[16]</sup>. Some investigators have speculated that FGF-21 resistance occurring in NAFLD could lead to cardiac damage in NAFLD patients<sup>[16]</sup>.

On the other hand, given that NAFLD is associated with high systolic blood pressure<sup>[18]</sup> it could be also argued that changes in myocardial structure might be the consequence of high blood pressure<sup>[18]</sup>. Against the latter hypothesis, there is the evidence that changes in cardiac morphology observed in children with NAFLD do not resemble the cardiac adaptation consequence of high blood pressure<sup>[19]</sup>. In fact, hypertension increases left ventricular (LV) mass and changes heart morphology as a result of overload. Recent findings reported that

obese children both with and without NAFLD showed no differences in LV mass and posterior wall thickness, while children with NAFLD were more likely to present low LV strain rate - a load - independent parameter that expresses LV elastance and deformation - than those without NAFLD. Therefore, the authors suggested that NAFLD affects myocardial fiber organization leading to systolic and diastolic dysfunction<sup>[19]</sup>.

## CONCLUSION

Besides the large amount of literature suggesting an association between NAFLD and CVD, the pathophysiologic mechanisms underlying these associations are far from being clear, therefore, in the future more studies should be focused on this area of research to unravel those mechanisms and to develop novel therapeutic strategies.

Moreover, we need to establish also whether NAFLD could be considered a marker of subclinical atherosclerosis as well as a cardiovascular risk factor even at a very early age. In fact, because of its strong relationship with CVD, NAFLD diagnosis could represent a red flag for the presence of high cardiovascular risk. In this scenario the prevention and treatment of NAFLD may play a crucial role in avoiding not only end-stage liver disease but also CVD.

**Table 1** Principal features and findings of the studies regarding the association between non-alcoholic fatty liver diseases and cardiac dysfunction

Ref.	Study design and methods	Population (n)	Main findings
Bonci <i>et al</i> <sup>[4]</sup>	Systematic review and meta-analysis Systematic literature search for papers from January 2000 to September 2014	12 observational studies: 9 studies based on adult population and 3 studies performed in pediatric population were selected	Children with NAFLD were not different from those without for LV mass Both children with and without NAFLD presented an increased LV mass compared to controls However children with NAFLD presented higher E/e' ratio rather those without NAFLD
D'Adamo <i>et al</i> <sup>[7]</sup>	Cross-sectional study NAFLD diagnosis performed by MRI Evaluation of VAT Lipoprotein particle characterized by MRS	Mean age 14.6 yr Obese African American (33) Obese Hispanic (33)	In multiple regression analyses liver fat accumulation resulted independently and significantly related to large VLDL concentrations
Sert <i>et al</i> <sup>[14]</sup>	Cross-sectional study NAFLD diagnosis performed by ultrasound and elevated serum alanine aminotransferase Pulsed and tissue doppler Echocardiography	Mean age 13.3 yr Healthy (68) Obese with NAFLD and elevated ALT (97)	NAFLD children showed increased CIMT and abnormalities of both LV structure and function LV CIMT and LV mass were positively related to HOMA-IR in obese children with NAFLD
Alp <i>et al</i> <sup>[15]</sup>	Cross-sectional study NAFLD diagnosis performed by liver biopsy Echocardiography	Obese without NAFLD and low ALT (83) Mean age 12 yr Healthy (150) Obese with NAFLD at United States (93)	NAFLD group had increased epicardial fat thickness, end-systolic thickness of the interventricular septum, and larger LV mass, as well as LV systolic and diastolic dysfunction
Pacifico <i>et al</i> <sup>[18]</sup>	Tissue doppler Echocardiography Cross-sectional study NAFLD diagnosis performed by MRI	Obese without NAFLD at United States (307) Mean age 12.5 yr Healthy (18)	Children with NAFLD presented signs of left ventricular dysfunction compared to children without NAFLD Subjects with a more severe NASH had a worse cardiac dysfunction
Singh <i>et al</i> <sup>[19]</sup>	Liver biopsy for NASH in 41 subjects Echocardiography Cross-sectional study NAFLD diagnosis performed by MRS Echocardiography	Obese with NAFLD at MRI (54) Obese without NAFLD at MRI (54) Mean age 15 yr Lean (14) Obese with Intrahepatic triglyceride content (15) Obese with increased Intrahepatic triglyceride content (15)	Obese adolescents with NAFLD show a worse systolic and diastolic functions rather than lean and obese adolescents without NAFLD independent from anthropometric parameters and blood pressure

MRI: Magnetic resonance imaging; NAFLD: Nonalcoholic fatty liver disease; MRS: Magnetic resonance spectrometry; VAT: Visceral adipose tissue; NASH: Non-alcoholic steatohepatitis; LV: Left ventricular; ALT: Alanine transaminase; CIMT: Carotis intima media thickness; VLDL: Very low density lipoproteins.

### Abstract

Over the last decade, the role of renin-angiotensin system (RAS) on the development of obesity and its comorbidities has been extensively addressed. Both

circulating and local RAS components are up-regulated in obesity and involved in non-alcoholic fatty liver disease onset. Pharmacological manipulations of RAS are viable strategies to tackle metabolic impairments caused by the excessive body fat mass. Renin inhibitors rescue insulin resistance, but do not have marked effects on hepatic steatosis. However, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers (ARB) yield beneficial hepatic remodeling. ARBs elicit body mass loss and normalize insulin levels, tackling insulin resistance. Also, this drug class increases adiponectin levels, besides countering interleukin-6, tumoral necrosis factor-alpha, and transforming growth factor-beta 1. The latter is essential to prevent from liver fibrosis. When conjugated with peroxisome proliferator-activated receptor (PPAR)-alpha activation, ARB fully rescues fatty liver. These effects might be orchestrated by an indirect up-regulation of MAS receptor due to angiotensin II receptor type 1 (AT1R) blockade. These associations of ARB with PPAR activation and ACE2-angiotensin (ANG) (1-7)-MAS receptor axis deserve a better understanding. This editorial provides a brief overview of the current knowledge regarding AT1R blockade effects on sensitivity to insulin and hepatic structural alterations as well as the intersections of AT1R blockade with peroxisome proliferator-activated receptor activation and ACE2-ANG (1-7) - MAS receptor axis.

**Key words:** Non-alcoholic fatty liver disease; Insulin resistance; Angiotensin receptor blockers; MAS receptor; Renin-angiotensin system

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Intrahepatic renin-angiotensin system activation contributes to insulin resistance and non-alcoholic fatty liver disease onset. ANG II interaction with angiotensin II receptor type 1 (AT1R) mediates pro-inflammatory and pro-fibrogenic responses, besides enhancing the oxidative stress, which makes the liver more prone to

noxious liver diseases. AT1R blockers mitigate insulin resistance and fatty liver by enhancing beta-oxidation, reducing lipogenesis and controlling inflammation. The impact of the AT1R blockade on liver ACE2-angiotensin (1-7)-MAS receptor axis remains to be fully unraveled.

## INTRODUCTION

Liver injuries can result from virus infection, alcohol and/or drugs abuse, and autoimmune diseases<sup>[1]</sup>. However, the increase in high-energy dense food availability combined with a sedentary lifestyle brought up unprecedented obesity rates, with the consequent increase in its comorbidities (hypertension, type 2 diabetes, and dyslipidemias) prevalences<sup>[2]</sup>. The metabolic disturbances caused by obesity also impair liver structure and physiology, with increasing prevalence of non-alcoholic fatty liver disease (NAFLD) and greater susceptibility to more harmful types of liver diseases such as non-alcoholic steatohepatitis (NASH) and liver fibrosis<sup>[3,4]</sup>.

Insulin resistance (IR) plays a central role in NAFLD pathogenesis<sup>[5]</sup>. Also, the low-grade inflammation observed in obese subjects and the increased adipocyte lipolysis are key factors for a more pronounced lipid droplet deposition within the hepatocytes<sup>[6]</sup>. Briefly, IR has opposite effects on adipose tissue and liver. On one hand, resistance to insulin action elicits enhanced lipolysis rate in the white adipose tissue as an attempt to compensate for the lack of glucose to be used as fuel by the adipocytes. Hence, increased free fatty acids (FFAs) are delivered to the liver<sup>[3,7]</sup>. On the other hand, insulin resistance impairs beta-oxidation within hepatocytes by reducing the expression of carnitine palmitoyltransferase 1 in the hepatic mitochondrion, besides reducing very low-density lipoprotein (VLDL) secretion. These conditions lead to unbalanced hepatic lipid metabolism as FFAs inflow surpasses fatty acid oxidation and lipoprotein exportation<sup>[8,9]</sup>. Therefore, excessive fatty acids are converted into triglycerides through the up-regulated lipogenic pathways, which accumulate as lipid droplets within hepatic parenchyma, characterizing the NAFLD<sup>[10]</sup>.

Considering that NAFLD is currently considered as the hepatic manifestation of the metabolic syndrome and that this condition, despite benign at first, can initiate a harmful spectrum of liver diseases, treatments should target hepatic alterations, but also alleviate others comorbidities such as hypertension, inflammation, and insulin resistance<sup>[11,12]</sup>. Recently, the activation of a local renin-angiotensin system (RAS) in the liver has been linked to NAFLD onset and progression towards liver fibrosis<sup>[13]</sup>. In

this way, the RAS emerges as a potential target to tackle hepatic alterations stemmed from obesity and other metabolic constraints imposed by increased body fat mass<sup>[14]</sup>.

## CIRCULATING RAS

From a classical view, the circulating RAS is implicated in the systemic hemodynamic regulation. Briefly, under a reduced renal perfusion, renin is secreted by the juxtaglomerular apparatus. This enzyme converts angiotensinogen (produced by the liver) in angiotensin 1 (ANG I), which is converted into angiotensin 2 (ANG II) by the angiotensin-converting enzyme (ACE). ANG II has countless physiological effects such as the stimulation of aldosterone release, which promptly reestablishes the hemodynamic control by enhancing water and sodium retention in the kidneys<sup>[15,16]</sup>.

ANG II exerts its main effects by interacting with two main receptors: Angiotensin II receptor type 1 (AT1R) or angiotensin II receptor type 2 (AT2R). AT1R has an important role in tissue repair and cell proliferation. However, when overexpressed, mediates pro-inflammatory and pro-atherogenic effects. Conversely, AT2R has anti-inflammatory effects, mainly by down-regulating tumoral necrosis factor-alpha (TNF-alpha) and nuclear factor-kappa B (NF-KB) pathways and by exerting anti-fibrogenic properties, besides reducing oxidative stress and cell proliferation<sup>[17,18]</sup>. Bearing this in mind, the angiotensin receptor blockers (ARBs) represents an evolution of the ACE inhibitors as they block exclusively the actions mediate by the interaction of ANG II with the AT1R<sup>[19,20]</sup>. Thus, important physiological effects stemmed from ANG II interaction with AT2R are maintained, leading to reduced atherogenesis, greater cardiac and endocrine pancreas functions, reduced glomerulosclerosis and fatty liver<sup>[21,22]</sup>.

Recently, with the discovery of ACE2, another branch of RAS has been described. ACE2 converts ANG II to ANG (1-7) and cleaves ANG I into ANG (1-9), which is also converted to ANG (1-7) by ACE. ANG (1-7) exerts its physiological effects through the MAS receptor. It can be argued that [ACE2-ANG (1-7)-MAS axis] counters the (ACE - ANG II - AT1R axis) effects. So, ACE2/ACE balance is an important target to tackle metabolic diseases<sup>[23-25]</sup>.

## LOCAL RAS: HEPATIC EFFECTS

Lately, apart from this circulating RAS, many local RAS have been described in organs such as heart, pancreas, adipose tissue, skeletal muscle, and liver<sup>[17,26,27]</sup>. Animal models of obesity show raised circulating renin, angiotensinogen, and ANG II<sup>[28]</sup>, besides higher expression of ACE and AT1R in the pancreas, which inhibit important steps of the insulin signaling cascade and contribute to IR and type 2 diabetes onset<sup>[29,30]</sup>. Intrahepatic activation of RAS favors NAFLD onset as it elicits greater triglycerides accumulation due to impaired beta-oxidation in conjunction with a significant fall in VLDL secretion.

These conditions comply with the increase of *de novo* lipogenesis (the formation of fatty acids from excessive dietary carbohydrate)<sup>[27,31]</sup>. Concomitantly, the increased production of reactive oxygen species by mitochondria and the raised expression of pro-inflammatory cytokines contribute to the progression to NASH<sup>[22]</sup>. These effects are mainly mediated by higher expression of ACE, ANG II, and AT1R concomitant to reduced ACE2 tissue expression in the hepatocytes of obese mice<sup>[32]</sup>.

Moreover, ANG II activates hepatic stellate cells (HSCs). Enhanced transforming growth factor-beta 1 (TGF-beta1) underlies this event, which implies a higher susceptibility to hepatic fibrosis, once HSCs acquire a myofibroblast phenotype<sup>[33,34]</sup>. These harmful effects of ANG II on liver structure and function are mediated predominantly by its interaction with the AT1R and results in collagen synthesis, pro-inflammatory cytokines release, stimulation of cell migration and proliferation<sup>[27,35]</sup>. These events altogether contribute to the second hit proposed by the two-hit theory, where inflammation and fibrogenesis play a decisive role in NAFLD progression to NASH<sup>[36]</sup>.

Obese mice show higher hepatic steatosis rate coupled with insulin resistance, a pro-inflammatory adipokine profile, reduced hepatic beta-oxidation of fatty acids and enhanced lipogenesis<sup>[37]</sup>. Recently, it has been shown that a mouse model of NAFLD, even without obesity, presents with enhanced ACE/AT1R expression locally in the liver<sup>[38]</sup>. Rats with liver fibrosis present with favored ACE-ANG II-AT1R axis over ACE2-ANG (1-7)-MAS receptor axis, confirming that AT1R is involved with NAFLD progression to NASH and fibrosis<sup>[24,25]</sup>. These observations suggest that the local expression of AT1R is related to NASH onset and AT1R blockade, with the consequent ACE2 induction, emerging as a potential approach to prevent liver fibrosis and chronic inflammation.

## BLOCKADE OF AT1 RECEPTOR EFFECTS ON INSULIN RESISTANCE AND FATTY LIVER

The impact of pharmacological manipulations of the RAS system on insulin resistance and liver structure is a new field of study. Evidence from animal studies shows that aliskiren (a direct renin inhibitor) rescued insulin resistance and hepatic steatosis, though its effects are not more advantageous than ARBs<sup>[39,40]</sup>.

Angiotensin-converting enzyme inhibitors (ACEi) inhibit ANG I to ANG II conversion and, therefore, enhances the availability of bradykinin<sup>[41]</sup>. This peptide yields cardiovascular protection by stimulating the release of important vasodilators such as nitric oxide and prostacyclin<sup>[42]</sup>. Bradykinin reduces the hepatic expression of glucose-6-phosphatase and phosphoenolpyruvate carboxykinase, inhibiting hepatic gluconeogenesis. Furthermore, isolated myocytes and adipocytes treated with bradykinin exhibited improved glucose uptake due to greater glucose transporter 4 translocation to the cell membrane<sup>[43]</sup>. These events show that by enhancing bradykinin availability,

ACEi are able to mitigate insulin resistance and counter NAFLD. Even though ACEi represent a potent approach as it combines benefits from bradykinin and ANG II inhibition, ARBs preserve AT2R-mediated benefits and favor ACE2-ANG (1-7)-MAS receptor axis. These properties make ARBs an attractive option to treat metabolic impairments.

Olmesartan, a pure ARB, reduced body mass and hepatic triglyceride content, besides recovering the expression of hepatic antioxidant enzymes and sensitivity to insulin in rats<sup>[44,45]</sup>. The recovery of uncoupling protein 2 expression is put forward as the main mechanism that enhances hepatic lipid metabolism and antioxidant capacity after the blockade of AT1R<sup>[44]</sup>. Amelioration of IR after olmesartan treatment is also perceived in humans<sup>[46]</sup>.

Irbesartan, another ARB, and an ACEi (perindopril) prevented obese Zucker rats from developing fatty liver in a recent study. Both treatments elicited a marked reduction in hepatic steatosis percentage, with no difference with the lean control group<sup>[47]</sup>. A remarkable reduction in hepatic expression of TNF-alpha, interleukine-6, and TGF-beta1 is produced by enhanced ACE2-ANG (1-7)-MAS receptor, leading to the alleviation of hepatic IR and, consequently, reducing fatty liver<sup>[25]</sup>. Furthermore, low TGF-beta1 expression complies with the marked reduction in liver fibrosis in obese animals treated with irbesartan<sup>[44]</sup>. In agreement to this, losartan, an ARB, led to anti-proliferative and anti-fibrogenic effects in ANG II stimulated HSCs *in vitro*. Once again, a marked reduction in TGF-beta1 expression and AT1R down-regulation explain these findings<sup>[48]</sup>.

It was recently proposed a synergistic action between hepatic cholesterol metabolism and intrahepatic RAS activation in the physiopathology of NAFLD. In this context, chronic local RAS activation in the liver augments the extracellular matrix synthesis and disrupts LDL metabolism by impairing LDL receptor functioning. These alterations seem to rely on AT1R activation by ANG II. In agreement to this, telmisartan, an ARB that is also a partial peroxisome proliferator-activated receptor (PPAR)-gamma agonist, prevented from lipid deposition and overrode the translocation of SCAP/SREBP-2 complex from the endoplasmic reticulum to Golgi, blocking LDL receptor gene transcription in HepG2 cells<sup>[31]</sup>.

Animal studies show that telmisartan rescues the sensitivity to insulin, markedly reduces hepatic steatosis and augments the numerical density of mitochondria per area of hepatic tissue in diet-induced obese mice<sup>[49]</sup>. These events rely on PPAR-alpha activation in the liver coupled with dual AT1R blockade/partial PPAR-gamma agonist properties, which determine enhanced adiponectin levels, favored beta-oxidation over lipogenesis and reduced HSCs activity<sup>[49,50]</sup>.

Also, telmisartan limits hepatic fibrosis by enhancing mRNA levels of ACE2 and MAS receptor concomitant to reducing ACE, AT1R, collagen type II and TGF-beta1, besides blocking HSCs activation in bile duct-ligated rats<sup>[51]</sup>. However, some effects are stemmed from the partial PPAR-gamma agonist property, such as IR alleviation,

**Figure 1 Overview of angiotensin receptor blockers actions on the liver.** ARBs reduce hepatic steatosis through favored beta-oxidation and reduced insulin resistance. Concomitantly, it indirectly enhances Mas receptor activity, eliciting hepatoprotective effects by low TGF-beta1 expression, which limits hepatic stellate cells activation and prevents liver fibrosis. ARBs: Angiotensin receptor blockers; TGF-beta1: Transforming growth factor-beta 1.

reduced oxidative stress, and hepatic lipid deposition<sup>[52]</sup>.

It is likely that the favored activity of the ACE2-ANG (1-7)-MAS receptor action under the AT1R blockade mediates the beneficial findings<sup>[25]</sup>. With regard to this, the infusion of ANG (1-7) in bile duct-ligated rats elicited fibrosis attenuation by the suppression of HSCs activity, while the use of MAS receptor antagonist confirmed these findings as the animals presented with a maximization of liver fibrosis, supported by higher expression of collagen and TGF-beta1<sup>[53]</sup>. Figure 1 illustrates the main pathways related to ARBs effects on the liver.

## CONCLUSION

Increasing rates of obesity and NAFLD have drawn the attention of the scientific community to strategies to treat these metabolic diseases. Local RAS is up-regulated in the liver from obese individuals and in lean individuals with fatty liver. Among the pharmacological manipulations of RAS, AT1R blockade is considered the best approach as it favors AT2R effects and seems to activate indirectly the ACE2-ANG (1-7)-MAS receptor axis, with additional beneficial effects. The combination of AT1R blockers with oral ANG (1,7) treatment seems to be a promising approach to treating NAFLD and NASH and prevent liver fibrosis.

### Abstract

Many patients with hepatocellular carcinoma (HCC) are diagnosed in an advanced stage, so they cannot be offered the option of curative treatments. The results of systemic chemotherapy are unsatisfactory and this has led to molecular targeted approaches.

HCC develops in chronically damaged tissue due to cirrhosis in most patients. Several different cell types and molecules constitute a unique microenvironment in the liver, which has significant implications in tumor development and invasion. This, together with genome instability, contributes to a significant heterogeneity which is further enhanced by the molecular differences of the underlying causes. New classifications based on genetic characteristics of the tissue microenvironment have been proposed and key carcinogenic signaling pathways have been described. Tumor and adjacent tissue profiling seem biologically promising, but have not yet been translated into clinical settings. The encouraging first results with molecular - genetic signatures should be validated and clinically applicable. A more personalized approach to modern management of HCC is urgently needed.

**Key words:** Systemic; Chemotherapy; Hepatocellular carcinoma; Prognosis

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The complete failure of chemotherapy in previous years gradually shifted hepatocellular carcinoma (HCC) treatment to the molecular targeted therapies. The initial-albeit limited - effectiveness of the currently approved systemic therapy, sorafenib, is due to the successful combination of targeting cancer cells and their microenvironment. Trials on drugs other than sorafenib, alone or in combination with drugs or transcatheter arterial chemoembolization were disappointing. Recently, genomic based analyses in HCC patients have proposed subclasses, based on molecular characteristics and a proliferative or non-proliferative genotypes. Combined targeted therapies, driven by specific molecular signatures for treatment selection and monitoring, potentially with immunotherapy, could be a future personalized approach.

## INTRODUCTION

Hepatocellular carcinoma (HCC) represents globally the fifth most common cancer and is considered the third most frequent cause of cancer related death<sup>[1]</sup>. In recent years there has been a significant progress in clarifying pathogenesis, etiology, and risk factors for hepatocarcinogenesis. Understanding the importance of underlying cirrhosis in the majority of HCCs led to more integrated approach, as in the majority of cases we have to deal with two diseases, cirrhosis and cancer.

The adoption of the barcelona-clinic liver cancer (BCLC) classification<sup>[2,3]</sup> offered the opportunity to better categorize HCC patients and select the best treatment option according to tumor stage, degree of liver function impairment and patient characteristics. The outcomes for surgical resection have improved and specific factors, as tumor and liver function characteristics, are being taken into account before the patient is referred for an operation<sup>[4]</sup>. Moreover, the widespread application of the Milan criteria in the field of transplantation, has changed the transplant procedure from an experimental approach to a standard of care therapy for HCC, which can treat at the same time the tumor and the underlying pre-neoplastic process (namely cirrhosis)<sup>[5]</sup>.

Despite screening patients at risk<sup>[6]</sup>, adopting regular surveillance rules and the impressive improvements in imaging, still many patients with HCCs are diagnosed in an advanced stage, thus being ineligible for radical treatments [transplantation, resection or Radiofrequency ablation (RFA)] or even for ablative techniques [transcatheter arterial chemoembolization (TACE)] that can also provide survival benefit<sup>[7]</sup>.

Patients with advanced HCC, especially if complicated with advanced cirrhosis, have a dismal prognosis. Several therapeutic efforts on this group of patients gave disappointing results in the past. The complete failure of systemic chemotherapy in previous years gradually shifted HCC treatment to the molecular targeted therapies. The first successful trials of sorafenib<sup>[8,9]</sup> provided a meaningful survival benefit in patients with advanced HCC, leaving at the same time many unresolved issues. This review attempts to present the effort of the scientific research to address the problem of HCC in multiple levels and to critically evaluate the inadequacies of the current trials of systemic treatments.

## THE STORY OF NEAR-FAILED SYSTEMIC TREATMENTS

Initial approaches with systemic therapy were ineffective,

as HCC is refractory to conventional chemotherapy and poorly tolerable in the context of liver cirrhosis due to altered drug metabolism and toxicity. Initial evidence for some efficacy of the anti-estrogen agent Tamoxifen in small trials were not confirmed in larger clinical trials and the drug has been abandoned<sup>[10]</sup>.

More interesting data came in to light with clinical studies of Somatostatin and its long acting analogues for advanced HCC with very promising initial results<sup>[11,12]</sup>, given the antiproliferative activity of the hormone and the positivity of HCC in somatostatin receptors in roughly 40% of the tumors<sup>[13]</sup>. Further publications have documented that somatostatin leads to apoptosis and has antineoplastic properties. Nevertheless, randomized trials - mainly from western countries - did not identify a clear survival benefit and this treatment is no longer recommended. There has been criticism for the methodology of these trials and the heterogeneity of selected patient population<sup>[14]</sup>.

Sorafenib, the only currently approved systemic treatment, that demonstrated statistically significant improvement in overall survival and prolonged time to progression in two large randomized controlled trials (Sharp and Asian Pacific)<sup>[8,15]</sup>. The efficacy of Sorafenib has been attributed to blockade of multiple kinases, most of them involved in the VEGF, PDGF, c-Kit and B-Raf and p38 signaling pathways<sup>[16]</sup>. Despite the low response rates and the associated toxicity, the drug showed survival benefit in Child's A patients with a good performance status.

The safety and efficacy of this treatment was further investigated in the Gideon trial (global phase IV, ongoing), focusing on patients with Child's B that were under represented in the registration trials. The interim analysis showed better outcomes for patients on the full dose (800 mg) as compared to the reduced (400 mg) dose, without significant differences in safety profile<sup>[17,18]</sup>. However, the median life expectancy of patients under Sorafenib treatment is generally less than one year, and this clearly needs to be improved. For the time being there are no validated factors to predict effectiveness or the possibility of adverse effects<sup>[19]</sup>.

More issues are still open, as what to do when the patient fails to respond or is intolerant to Sorafenib, or if Sorafenib could have a role as adjuvant treatment to other modalities like TACE. More data are expected and towards this direction is a recent study showed that tumor associated neutrophils (TAN) mediate the intratumoral infiltration of macrophages and Tregs by secreting the chemotactic C-C motif ligands CCL2 and CCL17. Thus neovascularization is being stimulated, and HCC growth and metastasis are promoted, all contributing to resistance to Sorafenib<sup>[20]</sup>. Thus, TAN infiltration is proposed as a potential biomarker.

Sunitinib, a potent multi-targeted receptor tyrosine kinase inhibitor of VEGFR, PDGFR, and c-KIT, reached to phase III study as compared to Sorafenib. The trial was terminated prematurely due to higher incidence of side effects in the sunitinib arm, besides demonstrating no superiority over sorafenib<sup>[21]</sup>.

Brivanib is a potent and selective inhibitor of VEGFR and FGFR and pre-clinical studies have shown *in vivo* antitumor activity<sup>[22]</sup>. Three phase III studies have been conducted, yielding negative results. The BRISK-FL study tested the efficacy of Brivanib vs Sorafenib, in patients with advanced HCC without prior systemic treatment<sup>[23]</sup>. The BRISK-PS study tested Brivanib vs placebo in patients that failed or were intolerant to Sorafenib<sup>[24]</sup>. In both studies Brivanib failed to improve OS but it did improve time to tumor progression (TTP), indicating some anti-tumor activity. Due to these results, a phase III trial in which Brivanib was used as an adjuvant to TACE was terminated prematurely<sup>[25]</sup>.

Linifanib is a multi-targeted receptor tyrosine kinase inhibitor effective on VEGFR and PDGFR. A phase III trial with 1035 patients comparing Sorafenib with Linifanib, showed similar overall survival in advanced HCC with a more favorable safety profile for Sorafenib; predefined superiority and non-inferiority overall survival boundaries were not met by Linifanib, which was more toxic than Sorafenib<sup>[26]</sup>.

Erlotinib is an orally active inhibitor of epidermal growth factor receptor (EGFR) tyrosine kinase. A phase III randomized trial (SEARCH) with 720 HCC patients (Child A cirrhosis) were assigned to Sorafenib/Erlotinib or Sorafenib/placebo<sup>[27]</sup>. The median OS and TTP were similar in both groups, thus adding Erlotinib to Sorafenib did not improve survival, but increased toxicity instead.

Dovotinib, a VEGFR, PDGFR, FGFR inhibitor was compared head to head with Sorafenib, in a randomized study in the Asian-Pacific in patients with advanced HCC. Although Dovotinib was well tolerated, it failed to show greater efficacy than sorafenib, and thus there will be no phase III trial<sup>[28]</sup>.

In patients who stopped Sorafenib due to disease progression or intolerance, a randomized phase III trial assessed Ramucirumab, a recombinant monoclonal IgG1 and VEGFR-2 blocking antibody (REACH). Despite acceptable safety profile, the study drug did not reach statistically significant survival benefit vs placebo<sup>[29]</sup>. However, a sub-population with  $\alpha$ FP > 400 ng/mL might have benefited from this 2<sup>nd</sup> line treatment and this is explored in an ongoing trial. Recently Codrituzumab, a humanized monoclonal antibody against Glypican-3 which is expressed in HCC, was studied vs placebo in a phase II randomized trial without showing any clinical benefit<sup>[30]</sup>.

Tivantinib is an oral selective small MET tyrosine kinase inhibitor with antitumor activity in MET-high patients. A phase II randomized placebo-controlled study in patients with advanced HCC, Child's A score and intolerant or progressing under the first line treatment, showed some promising results on time to progression, but with notable neutropenia in some patients<sup>[31]</sup>. A phase III study in patients with advanced HCC expressing high levels of c-MET after Sorafenib failure is underway.

Mammalian target of rapamycin (mTOR) regulates cell growth, metabolism and aging in response to nutrients, cellular energy state and growth factors<sup>[32]</sup>. It is

frequently up-regulated in cancer, including HCC, and is associated with poor differentiation and bad prognosis. Blocking this pathway appears an attractive option for HCC treatment. It is well known from the research on transplantation - given its immunosuppressive properties - that mTOR inhibitors (Sirolimus) are associated with better clinical outcomes in patients transplanted for HCC<sup>[33,34]</sup>.

Preliminary data in the non-transplant setting with Sirolimus and Everolimus treatment in HCC patients were encouraging. In the EVOLVE-1 phase III study, patients with advanced HCC and failure/intolerance to Sorafenib, randomized to Everolimus or placebo<sup>[35]</sup>. Everolimus did not improve OS with no difference to TTP vs placebo. Moreover, Everolimus led to hepatitis B virus (HBV) reactivation in 37% of the cases despite preventive antiviral therapies. A recent phase II randomized trial of the combination of Everolimus with Sorafenib vs Sorafenib alone, in patients with advanced HCC with Child's score  $\leq 7$ , showed that the combination was not more beneficial; in contrast it was more toxic<sup>[36]</sup>.

TACE is the treatment of choice for intermediate stage HCC. However, following TACE the hypoxic micro-environment promotes up-regulation of proangiogenic factors as VEGF and PDGF. This is the theoretical basis for the combination of TACE with drugs that inhibit angiogenesis, as Sorafenib and Brivanib. A recent review and meta-analysis reported that this combined approach may bring benefit to unresectable HCC in terms of TTP but not OS<sup>[37]</sup>. Recent studies (START, SOCRATES) that investigated the efficacy and safety of Sorafenib as an adjuvant to TACE displayed good tolerability and interesting response rate<sup>[38,39]</sup>. Clearly a better defined population of advanced HCC -that might have the maximal benefit from this approach- should be tested in clinical trial. Unfortunately, the recently published SPACE trial<sup>[40]</sup> showed that despite the combination of DC beads TACE with Sorafenib was feasible, this combination did not actually improve time to tumor progression in intermediate HCC.

Beyond TACE, efficacy and safety of Sorafenib was studied in a randomized phase III trial vs placebo, in patients with HCC after resection or local ablation (STORM trial)<sup>[41]</sup>. The recurrence free survival was identical in the two arms, whereas side effects were significantly more frequent in patients receiving Sorafenib in whom dose modification was necessary in 90% of the cases.

The combination of Sorafenib with other cytotoxic agents was tested to improve the disappointing results of conventional chemotherapy. In a phase II trial<sup>[42]</sup> the combination of Sorafenib/Doxorubicin was compared to Doxorubicin alone in Child-A cirrhotic patients with advanced HCC. The trial showed that the combination was better than doxorubicin alone as regards time to progression and overall survival. Whether there is benefit of the combination or this is an effect of sorafenib itself, will be clarified in an on-going phase III trial.

The efficacy and safety of GEMOX (Gemcitabin/Oxaliplatin) plus sorafenib, followed by sorafenib mono-

**Table 1 Randomized Phase III trials in advanced hepatocellular carcinoma**

Drug	<i>n</i> (patients)	OS (mo) SOR/Exp arm	HR
First line completed (Sorafenib standard)			
Brivanib	1155	9.9/9.5	1.06
Sunitinib	1074	10.2/7.9	1.3
Sorafenib/Erlotinib	720	8.5/9.5	0.92
Linifanib	1035	9.8/9.1	1.04
Second line completed (placebo standard)			
Brivanib	395	8.2/9.4	0.89
Everolimus	546	7.3/7.6	1.05
Ramucirumab	565	7.6/9.2	0.86

OS: Overall survival; SOR: Sorafenib arm.

therapy was examined in a small trial with 49 patients diagnosed with advanced HCC<sup>[43]</sup>. This approach was found effective (overall survival 15.7 mo) with manageable toxicity, and these results should be validated in a larger controlled trial. The data of a subsequent phase II randomized study on this combination, as well as the results of a single arm phase II study combining sorafenib with oxaliplatin/capecitabine, showed modest synergistic effect<sup>[44]</sup>. Further combinations that were tested, such as sorafenib with EGFR inhibitors or with mTOR inhibitors, both failed to show any meaningful antitumor activity.

Finally, the combination of Sorafenib with Octreotide was tested in a phase II study, recruiting 50 patients with advanced HCC and Child-Pugh score A or B<sup>[45]</sup>. The combination was well tolerated and displayed TTP 7 mo and median overall survival 12 mo. Nevertheless these results have not been confirmed in a larger phase III study as yet. We believe that this combination could provide an option for patients with inadequate response or intolerance to sorafenib (Figure 1).

The apparent failure of phase III trials beyond sorafenib, was disappointing but not discouraging for the scientific community (Table 1). Factors contributing to this failure and were related to drug toxicity (especially in cirrhotic patients), lack of significant antitumoural potency, lack of our understanding on diverse mechanisms of tumor progression and metastasis or biomarkers predictive of the efficacy of therapy<sup>[16]</sup>. Study design was another weak point for some trials. Trials in patients with advanced HCC should also pay attention to specific factors as portal vein invasion, the extrahepatic metastases, and the degree of liver impairment.

## EXPLORING THE ETIOPATHOGENESIS

### *Molecular and phenotypic diversity of HCC - Oncogenic pathways*

Beyond the success and wide adoption of the BCLC system on staging and prognosis of HCC<sup>[46]</sup>, recently new molecular classifications based on genetic characteristics of the tissue microenvironment have been proposed. However, HCC is a heterogeneous disease and each tumor is a result of unique combination of several genomic defects that lead to a significant diversity in the pathways

of carcinogenesis. It is documented that several differences exist not only amongst different patients, but also between different tumor nodules in the same liver, and even differences in the same nodule.

Cancer cells and stem cells have similar capacity as regards self-renewal, indefinite division, and generation of heterogeneous cell population. The concept of cancer stem cell, referring to a subset of cells bearing stem cell characteristics that is indispensable for tumour development and perpetuation, has been recently adopted<sup>[47]</sup>. Cancer stem cells are now considered an important target for the eradication of HCC. Furthermore, a 20%-40% of HCC subtypes show progenitor signature suggesting that these tumours derive from liver progenitor cell. These subtypes are highly aggressive and correlate with early recurrence after treatment and metastatic potential, thus correlated to worse prognosis. CD133 antigen (prominin-1) has been identified as a cancer stem cell marker in various cancers, including HCC. Patients with increased CD133 levels have shorter overall survival and higher recurrence rates compared to those with low expression. Recent data showed that IL-6/STAT3 signalling induced CD133 expression, through function co-operation with NF- $\kappa$ B and hypoxia-inducible factor 1 alpha (HIF-1 $\alpha$ ) during hepatocarcinogenesis<sup>[48]</sup> (Figure 2A).

Recently genomic based analyses in HCC patients have identified subclasses, based on molecular characteristics and proliferative and non-proliferative genotypes have been proposed<sup>[49]</sup>. The proliferative subclass - which is associated with a poor outcome - has been linked to the activation of RAS, mTOR, and/or IGF signaling. This has been further categorized into two phenotypic groups: The Wnt/TGF- $\beta$  group (activation of these pathways) and the progenitor cell group. In the former, the activation of the Wnt and the TGF- $\beta$  was the predominant feature, while the latter was enriched in progenitor cell, epithelial cell adhesion molecule and cytoskeletal markers and was associated with increased  $\alpha$ -fetoprotein at early stages<sup>[50]</sup>. On the other hand, the non-proliferative subclass was a heterogeneous one, with patients sharing only  $\beta$ -catenin in their molecular profiles<sup>[51]</sup>. The prognostic implications of these subclasses have been studied but there is no consensus on it and there is no translational clinical research has been done yet.

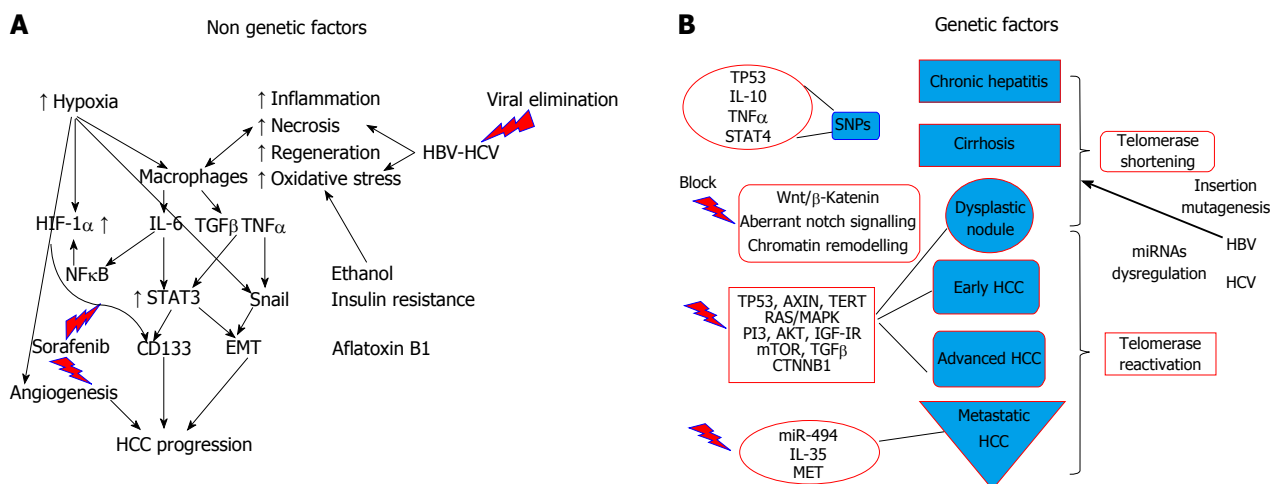

The paradigm from the management of other cancers such as colorectal cancer and non-small lung cell carcinoma, where mutations of K-Ras and EGFR drive the therapeutic choices, supports this new approach<sup>[52]</sup>. Unfortunately, HCC is still away from this path despite the success of sorafenib, a multi kinase inhibitor, which seems a proof towards the right direction. A key point may be that in HCC an average of 30-40 mutations were estimated per tumor, with 5-8 of them being the driver mutations<sup>[49]</sup> affecting cellular homeostasis and involved in the development of malignant phenotype.

A recent elegant study performing exome sequencing analysis of 243 surgically resected HCCs revealed mutational signatures associated with specific risk factors, as combined tobacco and alcohol use, or aflatoxin

**Figure 1** Serial computed tomography scans of a hepatocellular carcinoma patient with multiple co-morbidities precluding radical treatment, surviving 7 years with sequential approach in systemic treatment (Octreotide long acting release, followed by sorafenib). Despite an increase in tumor size, it is evident the central necrosis related to Sorafenib treatment (which was commenced when it became available).

**Figure 2** Interplay between genetic and non-genetic factors in the pathogenesis of hepatocellular carcinoma. Potential treatment targets. Hepatocellular carcinoma (HCC) is a complex entity with multifactorial pathogenesis. Control of non-genetic factors (A) (e.g., viral elimination, inhibition of CD133 positive cancer cell overexpression) may lead to alteration of the progress from cirrhosis to HCC. On the other hand, the various genetic irregularities (B) may lead to different HCC profiles with respect to invasiveness (miR-494) or response to treatment. New targeted treatments are also directed against Wnt/β-katenin. HBV: Hepatitis B virus; HCV: Hepatitis C virus; HIF-1α: Hypoxia-inducible factor 1 alpha; TNF: Tumor necrosis factor; IL-6: Interleukin-6; NFκB: Nuclear factor-kappa B.

B1. The researchers identified 161 putative driver genes associated with 11 recurrent pathways<sup>[53]</sup>. Moreover, a molecular 5 gene score (based on combined expression level of HN1, RAN, RAMP3, KRT19, and TAF9) was studied in surgical resected samples of 314 HCC, and was found significantly associated with outcomes<sup>[54]</sup>. Also recent data show that it is possible to modulate gene expression profiles (interfering with histone acetylation)

and thus increase the sensitivity to chemotherapeutic agents<sup>[55]</sup>.

Activation of telomerase is the earliest and most frequent alteration in the process of HCC development (mutations in TERT promoter in 60% - most frequently mutated gene - associated with increased telomerase expression)<sup>[56]</sup>. Genes as *TP53* and *CTNNB1* are also frequently mutated in HCC, whereas inactivating muta-

tions in TP53 are commonly found (especially with HBV etiology). Recently identified alterations in genes encoding metabolic enzymes, chromatin remodelers and a high rate of mTOR pathway activations could offer potential therapeutic targets<sup>[57]</sup>. Members of the Wnt pathway (crucial for hepatocarcinogenesis) are involved in the process of cell differentiation, which is frequently altered in cancer cells, whereas failure to control oxidative stress can favor additional DNA mutations and cellular damage.

Key carcinogenic signaling pathways have been described for HCC: Wnt/ $\beta$ -catenin [that can be triggered *via* both catenin  $\beta$ 1 (CTNNB1)-dependent and CTNNB1 independent pathways]<sup>[58]</sup>, a proliferation and hepatoblastoma-like pathway<sup>[59]</sup>. Nevertheless, their molecular signature is broad and for the time being this knowledge is unlikely to have clinical application. Notch signaling is important for normal liver development and aberrant Notch signaling is related to hepatocarcinogenesis (Figure 2B). Chromatin remodeling is important for the maintenance of DNA integrity, which is in turn crucial for cellular homeostasis. Aberrant chromatin remodeling has been implicated with HCC pathogenesis<sup>[57]</sup> as well as genes that are involved in oxidative stress (which induces mutations).

In respect to the receptor signaling pathways, RAS/MAPK pathway is activated in all patients with advanced HCC and in a large proportion of those with an early stage HCC<sup>[60]</sup>. PI3/AKT/mTOR and MAPK pathways related to proliferation, apoptosis and survival, as well as pro inflammatory cytokines (IL1, TNF $\alpha$ ) and growth factors, such as TGF $\beta$  (tumor stroma, progression, metastasis), are potential future clinical targets in HCC therapeutics (Figure 2B).

Very recently, IL-35 expression was found to correlate with HCC aggressiveness, conferring the rationale for another novel therapeutic target<sup>[61]</sup>. IFG-1R signalling is activated in a proportion of patients with HCC and its targeting had demonstrated antitumor activity in experimental models; however a phase II trial with an anti-IFG-1R monoclonal antibody did not show clinical benefit in unselected patients<sup>[62]</sup>. Finally, dysregulation of MET receptor and its ligand HGF, are crucial for hepatocyte regeneration after liver injury and are common events in HCC patients<sup>[49]</sup>. Activation of MET is found in half of advanced HCCs, and this pathway is currently tested in clinical trials. A MET inhibitor, cabozantinib, was found to suppress tumour growth and metastasis in a phase II study<sup>[63]</sup> and is further tested in a phase III second line clinical trial (in patients with high MET expression, treated with tivantinib).

### **Tissue microenvironment and the role of cirrhosis**

**Scientific basis:** Chronic liver injury triggers a sequence of cell death, inflammation, compensatory regeneration and genetic damage, which drives the development of HCC. In the majority of cases, HCC develops in chronically damaged tissue due to cirrhosis-irrespective of etiology - whereas the other malignancies develop on

an otherwise healthy tissue. This, together with genome instability, contributes to a significant heterogeneity which is further enhanced by the molecular differences of the underlying causes, *i.e.*, viral, alcohol, metabolic<sup>[52]</sup>. Moreover, epithelial plasticity is an important parameter in HCC, as strong inducers of epithelial to mesenchymal transition like TGF $\beta$  are able to co-ordinate both fibrogenesis and carcinogenesis, showing rising cytokine levels in cirrhosis as well as late stage HCC<sup>[64]</sup>.

Several different cell types and molecules constitute a microenvironment in the liver, which has significant implications in tumor development and invasion. Myeloid cells, including macrophages and neutrophils are the most abundant cells in the tumor microenvironment<sup>[65]</sup>. Tumor-associated macrophages acquire protumorigenic properties in primary and metastatic sites and support cancer development and progression, by stimulating cell proliferation and survival, angiogenesis, invasive behavior and suppression of cytotoxic T lymphocytes responses<sup>[66]</sup>. Tumor-associated neutrophils exhibit both antitumoral and protumoral functions. Dendritic cells, the main type of antigen presenting cells, play an important role in T cell priming. The generation and protective antitumour immunity depends on dendritic cell maturation and antigen presentation<sup>[67]</sup>.

It is generally accepted that dysregulated microenvironment affects tumorigenesis, based on the concept that chronic inflammation is associated with cancer<sup>[68]</sup>. Moreover, the stromal microenvironment has been recognized as a crucial element for cancer metastasis in general. A reasonable hypothesis is that an altered liver microenvironment, through reprogramming of the inflammatory milieu, may contribute to hepatocarcinogenesis, taking in account that HCC is an inflammation-associated cancer<sup>[69]</sup>. This microenvironment plays a major role in anti-tumor immunity.

**Therapeutic implications:** The effectiveness of the currently approved systemic therapy, sorafenib, is due to the successful combination of targeting cancer cells and their microenvironment, as a result of multiple kinases inhibition. Between sorafenib targets, an increasing amount of evidence has suggested that HSC are key regulators of hepatocarcinogenesis through a variety of mechanisms, including direct effects on malignant hepatocytes, and indirect *via* modulation of the peritumoral stroma and immune responses<sup>[70]</sup>. Moreover, activated stellate cells produce extracellular matrix.

Laminin-332 is produced and excreted by these cells in HCC but not in the surrounding non-neoplastic liver; this stimulates chemotaxis and migration of HCC cells in experimental models and promotes proliferation as well<sup>[52]</sup>. An association between Ln-332 and Keratin -19 has been documented, the latter being a marker of cholangiocytes<sup>[71]</sup>.

VEGF not only regulates tumor angiogenesis but also has important immunomodulatory functions. It inhibits dendritic cell maturation *in vitro* and *in vivo*, through activation of NF $\kappa$ B. Additionally VEGF may regulate T-cell

differentiation and its cytotoxic function and can enhance expression of immune checkpoint molecules<sup>[72]</sup>. This provides the rational of combining anti-VEGF therapy with checkpoint inhibitors.

Another area of active research is on the effect of mTOR inhibitors on advanced HCC in the non-transplant setting. Recent data showed that mTOR inhibition improves FGFR targeting<sup>[73]</sup> and reduces the activity level of Golgi protein 73, which is a serum marker for HCC<sup>[74]</sup>. However, the first results of trials with mTOR inhibitors were less than encouraging. Despite potential applications, the role of the whole tissue micro-environment is difficult to be reduced to the effect of just one molecule or protein.

### Immunity and implications

**Scientific basis:** Inflammation affects every single step of tumourigenesis from initiation, to tumor promotion and metastatic progress. Cancer development and its response to treatment are significantly influenced by innate and adaptive immunity, which either promote or attenuate tumourigenesis<sup>[66]</sup>. Various types of immune and inflammatory cells are present within tumours; these affect malignant cells through production of cytokines, chemokines, growth factors, prostaglandins and reactive oxygen and nitrogen species<sup>[68]</sup>.

The liver has been considered as an immunologically advantaged organ. A profound clinical paradigm is the development of tolerance in the context of transplantation. It is equipped with several myeloid and non-myeloid cell populations which affect both innate and adaptive responses in physiological conditions as well as in the context of defense against tumors<sup>[75]</sup>.

Kupffer cells represent the largest macrophage population in the human body and together with sinusoidal endothelial and hepatic stellate cells, play a critical role in physiology and disease. Local immunosuppression by these cells is induced by pro-inflammatory cytokines<sup>[69]</sup> whereas different immune cell subtypes have been related to antitumor immunity in HCC. Kupffer cells in analogy to the two subtypes of macrophages are now characterized as M1 and M2 types. In the case of HCC M2 cells are detrimental and M1 demonstrate anti-tumoral activity, contrary to the opposite effects of those cell subpopulations have in inflammation.

Among immunosuppressive cell populations, myeloid derived suppressor cells and T regulatory cells have the key role in cancer immunosurveillance<sup>[76]</sup>. A prominent humoral cytokine profile occurs in metastatic liver milieu and a shift towards anti-inflammatory/ immunosuppressive responses is significant for HCC metastases<sup>[77]</sup>.

**Therapeutic implications:** The liver is a privileged organ with respect to immune function and possesses a unique form of immune regulation: Tolerance is induced to avoid chronic inflammation caused by antigens coming from the portal vein blood. This may hampers an effective immune response against cancer cells<sup>[78]</sup>. Moreover this

is a challenge on the use of conventional immunotherapy is challenged. Immunotherapy trials have so far given suboptimal results. On the other hand, spontaneous immune responses as well as tumor regression have been reported in relation to systemic inflammatory responses<sup>[79]</sup>. This could as well be a result of M1 effect as previously mentioned.

Adaptive immune responses are well described in various conventional HCC treatments and are related to their effects. This has been extensively investigated in patients undergoing ablative therapies (TACE, RFA), and provide the theoretical basis for combined approaches. This applies to cytotoxic agents as well, and experience with sorafenib in experimental and clinical level is a paradigm.

While growing tumors acquire mutations, some of which create neoantigens that influence the response of patients to immune checkpoint inhibitors<sup>[80]</sup>. There are other studies supporting that cancers with high rate of somatic mutations respond best to immune check point blockade by triggering tumor rejection *via* activation of cytotoxic T-lymphocytes, a recent approach with acknowledged success in recent years in melanoma and non-small cell lung cancer<sup>[81]</sup>.

Preclinical and clinical studies have shown potential benefit of modulating immunogenicity of HCC and relevant approaches are currently being tested<sup>[82]</sup>. The rational to target immune-checkpoints is based on data that HCCs may evade the immune system by expressing molecules as PD-1, CTLA-4, TIM-3, LAG-3 and many more. Despite the fact that the blockade of PD-1 and CTLA-4 is already providing encouraging results in initial trials, overall the therapeutic relevance of blocking these agents is unclear<sup>[72]</sup>.

## CONCLUSION

HCC is one of the most lethal cancers and management still deems ineffective. Apart from the problems in prevention or early diagnosis, there are no persuasive answers for those (many) patients with advanced neoplasms. Systemic treatment was disappointing in the past, somehow improved with Sorafenib but with many weaknesses and grey zones, whereas the trials of new compounds beyond Sorafenib provided suboptimal results.

The complexity and heterogeneity of HCC pathogenesis is disregarded in treatment decisions. Is a personalized approach feasible with the limitations of current knowledge? Tumor and adjacent tissue profiling seems biologically significant, but not yet translated into the clinical setting. The role of liquid biopsy, *i.e.*, detection of circulating tumor cells, a hot topic in tumor biology is also inadequately explored in the case of HCC.

Nevertheless, encouraging first results with molecular - genetic signatures are promising towards -at least- prognosis. Additionally, miRNAs which are important regulators of gene expression, have been associated

with the occurrence of HCC. In addition, miRNAs are of potential value not only in diagnosis but also in the management of HCC.

Clinical scoring systems incorporating molecular profile characteristics, may better stratify patients at risk for HCC but further prospective validation is needed. The ideal future approach would be combined targeted therapies - driven by specific molecular signatures for the selection and the monitoring during treatment-potentially incorporating immunotherapeutic modalities, such as vaccination and/or check-point blockade.

## ACKNOWLEDGMENTS

We would like to thank Professor George Germanidis and Dr. Ioannis Drygiannakis, for reading and providing valuable comments on this paper, and Dr. Maria Daskalogiannaki for providing the computed tomography scans.

### Abstract

#### AIM

To investigate predictors for fibrosis specifically in a high risk population of morbidly obese patients, including detailed evaluation of lifestyle.

#### METHODS

We conducted a cross-sectional study among morbidly obese patients attending the bariatric clinic at the Tel-Aviv Medical Center between the years 2013-2014 with body mass index (BMI) above 40 or above 35 with co-morbidity. Patients with serum hepatitis B surface antigen or anti-hepatitis C virus antibodies, genetic liver diseases, autoimmune disease or high alcohol intake ( $\geq 30$  g/d in men or  $\geq 20$  g/d in women) were excluded from the study. Liver fibrosis was estimated by transient elastography (FibroScan®), using the "XL" probe. We collected data on age and gender, education, smoking status and amount, medical history, nutrition and lifestyle habits. All these data were collected using structured and validated questionnaires. Fasting blood test were available for a subsample.

#### RESULTS

Fibroscan was performed on a total of 91 patients, of which 77 had a valid examination according to the

accepted criteria. Of those, 21% had significant fibrosis (F2) and 39% had advanced or severe fibrosis (F3 or F4). In multivariate analysis, male gender and BMI had a positive association with advanced fibrosis; the OR for fibrosis  $F \geq 2$  was 7.93 (95%CI: 2.36-26.64,  $P = 0.001$ ) for male gender and 1.33 (1.11-1.60 kg/m<sup>2</sup>,  $P = 0.002$ ) for BMI. The OR for fibrosis  $F \geq 3$  was 2.92 (1.08-7.91,  $P = 0.035$ ) for male gender and 1.17 (1.03-1.33,  $P = 0.018$ ) for BMI. Subjects were categorized to subgroups based on the combination of male gender and BMI of 40 and above. A significant dose response association with stiffness level was noted across these categories, with the highest stiffness among men with a higher BMI ( $P = 0.001$ ). In addition, a significant positive correlation between pack-years cigarette smoking and liver stiffness was demonstrated among men ( $r = 0.54$ ,  $P = 0.012$ ).

## CONCLUSION

In the morbidly obese population, a higher BMI, male gender and degree of smoking in men bears a greater risk for advanced nonalcoholic fatty liver disease.

**Key words:** Non-alcoholic fatty liver disease; Morbid obesity; Fibrosis; Fibroscan; Diet

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The presented results indicate that male gender and a higher body mass index (BMI) are risk factors for advanced fibrosis in morbidly obese patients. There is also a positive correlation between cigarette smoking and liver stiffness in men. Our study highlights the fact that even in the upper BMI ranges, higher BMI bears greater risk for advanced disease. Therefore, in the morbidly obese population it may seem useful to emphasize the importance of weight reduction, even within the range of obesity.

Zelber-Sagi S, Shoham D, Zvibel I, Abu-Abeid S, Shibolet O, Fishman S. Predictors for advanced fibrosis in morbidly obese non-alcoholic fatty liver patients. *World J Hepatol* 2017; 9(2): 91-98 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i2/91.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i2.91>

## INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is the most common liver disease in the developed<sup>[1]</sup> and developing countries<sup>[2,3]</sup> with estimated prevalence of 20%-40%, and is predicted to become the leading indication for liver transplantation in the United States<sup>[4]</sup>. NAFLD is tightly associated with the metabolic syndrome and its complications. Obesity is the most important risk factor for NAFLD, which affects as much as 74% of obese individuals<sup>[5]</sup>. Two large electronic databases have demonstrated a clear association between a higher body mass index (BMI), diabetes and male gender and the risk for

NAFLD<sup>[6]</sup>. Furthermore, among morbidly obese patients, who are candidates for bariatric surgeries, the prevalence is even higher and reaches 96%<sup>[7-10]</sup>.

NAFLD encompasses a wide spectrum of histological and clinical manifestations, ranging from simple steatosis to steatohepatitis, fibrosis and cirrhosis<sup>[11]</sup>. It is estimated that approximately 6%-13% of patients with simple steatosis progress to steatohepatitis, of which approximately 10%-29% reach liver cirrhosis within 10 years<sup>[12]</sup>. Moreover, non-alcoholic steatohepatitis cirrhosis is a known risk factor for hepatocellular carcinoma<sup>[4]</sup>. Given the relative high prevalence of severe fibrosis (12%) in morbidly obese patients<sup>[7-10]</sup>, this population is especially prone to a detrimental course. Therefore, it is of utmost importance to identify those patients with high likelihood for advanced fibrosis who may later develop cirrhosis and hepatocellular carcinoma.

Several studies have aimed to find predictors and risk factors for advanced fibrosis, although most of them did not focus on morbidly obese population. In a study of 103 NAFLD patients who underwent serial liver biopsies to follow fibrosis progression rate<sup>[13]</sup>, only type-2 diabetes mellitus (T2DM), BMI and initial stage of fibrosis were associated with a higher rate of disease progression. Of note, in this study only 68% of patients were obese. Sub-analysis of 3041 subjects from the Rotterdam study<sup>[14]</sup> revealed that liver stiffness above 8 kilopascals (kPa), as measured by FibroScan, was strongly associated with steatosis and T2DM. In this cohort the average BMI was 27, thus not representing a morbidly obese population. With respect to lifestyle and other co-morbidities, smoking and obstructive sleep-apnea were demonstrated to be positively associated with liver fibrosis<sup>[15,16]</sup>. Once again, most of the patients were not morbidly obese with an average BMI of 34 and 28 respectively.

Given the scarce data regarding risk factors for advanced fibrosis in morbidly obese population, the aim of the present study was to investigate predictors for fibrosis, specifically in this high risk population, including detailed evaluation of lifestyle. To non-invasively assess liver fibrosis we used transient elastography (FibroScan®), which is a validated tool to determine liver stiffness<sup>[17]</sup>, and was demonstrated to be one of the most accurate tests for the non-invasive evaluation of liver fibrosis in NAFLD with a clinical prognostic value<sup>[18]</sup>.

## MATERIALS AND METHODS

We conducted a cross-sectional study among morbidly obese patients attending the bariatric clinic at the Tel-Aviv Medical Center between the years 2013-2014 with BMI above 40 or above 35 plus at least one co-morbidity (*i.e.*, hypertension, type 2 diabetes, cardiovascular disease, lung disease and respiratory disorders), according to the Israeli Health Ministry indications published on 2013 ([http://www.health.gov.il/hozer/mr33\\_2013.pdf](http://www.health.gov.il/hozer/mr33_2013.pdf)). Patients with serum HBsAg or anti-hepatitis C virus antibodies, genetic liver diseases, autoimmune disease or high alcohol intake ( $\geq 30$  g/d in men or  $\geq$

20 g/d in women)<sup>[19,20]</sup> were excluded from the study. All procedures performed in this study were approved by the institutional research committee of the Tel-Aviv Medical Center and in accordance with the ethical standards of the 1964 Helsinki Declaration and its later amendments or comparable ethical standards. Informed consent was obtained from all participants included in the study.

### Liver stiffness measurement

Liver stiffness measurement (LSM) was measured using the "XL" probe. LSM were considered representative only if they had at least 10 valid acquisitions with a success rate > 60%<sup>[21]</sup>. All measurements were taken by the same operator (experience, > 10000 measurements) which was blinded to other parameters of the patients. As previously described<sup>[22]</sup>, the examination was performed with the patient lying down in the dorsal decubitus position with the right arm in maximal abduction. The tip of the probe transducer was placed on the skin, between the ribs at the level of the right lobe of the liver. The results were expressed in kPa and each LSM corresponds to the median of 10 validated measurements. The cut-off values for fibrosis stage were according to the suggested best cutoffs to distinguish between fibrosis levels among NAFLD patients<sup>[23,24]</sup>: < 7.1; F0-F1: 7.1-9.5 kPa; F2: 9.6-11.5; F3: > 11.5; and F4: Significant fibrosis was defined as  $F \geq 2$ , and advanced fibrosis was defined as  $F \geq 3$ <sup>[25-27]</sup>.

### Demographic, health and lifestyle data

We collected data on age and gender, education, smoking status and amount, medical history including diabetes and medical treatment, nutrition, lifestyle habits and health status. All these data were collected using a structured and uniform questionnaire completed by all

participants, tailored for the current study based on validated questionnaires used in national Israeli surveys<sup>[28]</sup>. Fasting blood test were available for a subsample of 40-48 patients.

### Statistical analysis

Statistical analyses were performed using SPSS version 22 (SPSS Inc., Chicago, IL, United States) software. Continuous variables are presented as means  $\pm$  SD. To test differences in continuous variables between the two groups the independent samples *t*-test or the Mann-Whitney *U* test were performed. Associations between nominal variables were performed with the Pearson  $\chi^2$  test. The Pearson correlation was used for the evaluation of the correlation between liver stiffness and other measurements. A multivariate logistic regression analysis was performed to test the adjusted association between significant liver stiffness and potential predictors. Using a receiver operating characteristic curve, the best BMI cutoff point to predict significant fibrosis was 40, which represents grade-3 obesity. To test the combined effect of male gender and BMI of 40 and above (high BMI), we created a new variable with three categories: Lower BMI plus female gender, either male gender or high BMI, both male gender and high BMI. One way ANOVA of variance was used to test the difference in the distribution of liver stiffness between the categories with a *P* for trend test. Pearson  $\chi^2$  test was used to test the association between these categories and the categories of fibrosis severity with a *P* for trend test. *P* < 0.05 was considered statistically significant for all analyses.

## RESULTS

### Description of the study population

A total of 201 consecutive patients were recruited, of which 91 agreed to undergo Fibroscan exam, and 77 patients had a valid examination according to the accepted criteria<sup>[21]</sup>. As depicted in Table 1, the average BMI was 41.71  $\pm$  4.68 kg/m<sup>2</sup>, with a range between 32.25 to 56.36 kg/m<sup>2</sup>, 48 had a BMI of 40 and above. Alcohol consumption was very low and no patient had to be excluded due to excessive consumption. The available blood tests indicated impaired fasting glucose and mildly elevated triglycerides and ALT levels. Most patients (60%) had some level of fibrosis (F2 and above) according to the Fibroscan examination. Of note, 39% of the patients had advanced or severe fibrosis (F3 or F4), 21% had significant fibrosis (F2) and only 40% of the patients had minimal or no fibrosis (F0-F1) (Figure 1).

### Comparison between subjects with significant or advanced fibrosis and subjects with minimal or no fibrosis

Male gender was significantly more prevalent in subjects with fibrosis level of F2 and above or F3 and above, as compared to subjects with minimal or no fibrosis (63% vs 22.6%, *P* < 0.001 and 63.3% vs 36.2%, *P* = 0.020, respectively) (Tables 2 and 3). In addition, BMI was

**Table 2** Comparison between subjects with fibrosis degree  $F < 2$  and subjects with significant fibrosis degree  $F \geq 2$  (mean  $\pm$  SD, unless otherwise stated)

**Figure 1** Distribution of liver stiffness levels according to Fibroscan.

significantly higher in subjects with fibrosis level of F2 and above or F3 and above as compared to subjects with minimal or no fibrosis (42.99  $\pm$  5.11  $\text{kg}/\text{m}^2$  vs 39.82  $\pm$  3.16  $\text{kg}/\text{m}^2$ ,  $P < 0.001$  and 42.32  $\pm$  5.3  $\text{kg}/\text{m}^2$  vs 40.68  $\pm$  3.96  $\text{kg}/\text{m}^2$ ,  $P = 0.023$ , respectively) (Tables 2 and 3). No other significant differences were noted between groups in nutritional, physical activity and biochemical parameters (Tables 2 and 3). Of note, there was no correlation between ALT and fibrosis (correlation  $r = 0.17$ ,  $P = 0.253$ ).

#### Multivariate analysis for the prediction of significant or advanced fibrosis

In multivariate analysis, including age, gender and BMI, the positive association between male gender (OR =

7.93, 95%CI: 2.36-26.64,  $P = 0.001$ ) and BMI (OR = 1.33, 95%CI: 1.11-1.60,  $P = 0.002$ ) and fibrosis  $F \geq 2$  was maintained. Similarly, the positive association between male gender (OR = 2.92, 95%CI: 1.08-7.91,  $P = 0.035$ ) and BMI (OR = 1.17, 95%CI: 1.03-1.33,  $P = 0.018$ ) and fibrosis  $F \geq 3$  was maintained (Table 4).

#### The dose response association of the combined categories of BMI of 40 and above (grade 3 obesity) and male gender with fibrosis level

Subjects were categorized to subgroups based on the combination of gender and BMI of 40 and above: Subgroup (1) women and BMI below 40; subgroup (2) either men or BMI of 40 and above; subgroup (3) both men and BMI of 40 and above. A significant dose response association was noted across these categories for stiffness as a continuous variable ( $P$  for trend = 0.001) (Figure 2A), for the rate of subjects with  $F \geq 2$  ( $P$  for trend < 0.001) (Figure 2B) and for the rate of subjects with  $F \geq 3$  ( $P$  for trend = 0.011) (Figure 2C). The highest stiffness or prevalence of significant/advanced fibrosis was among men with a higher BMI.

#### Cigarette smoking and fibrosis level

Twenty one of the men and 16 of the women were current or past smokers. Among them, there was a significant positive correlation between cigarette smoking measured by pack-years (number of packs multiplied with the number of years of smoking) and liver stiffness ( $r = 0.37$ ,  $P = 0.025$ ). However, stratification by gender

**Table 3** Comparison between subjects with fibrosis degree  $F < 3$  and subjects with advanced fibrosis degree  $F \geq 3$  (mean  $\pm$  SD, unless otherwise stated)

Variable	$F < 3$ ( $n = 47$ )	$F \geq 3$ ( $n = 30$ )	$P$

**Table 4** Multivariate analysis for the prediction of significant or advanced fibrosis

Variable	Model 1: $F \geq 2$		Model 2: $F \geq 3$	
	OR (95%CI)	$P$	OR (95%CI)	$P$
Age (yr)	1.03 (0.99-1.08)	0.153	1.03 (0.98-1.07)	0.246
Gender (male)	7.93 (2.36-26.64)	0.001	2.92 (1.08-7.91)	0.035
BMI (kg/m <sup>2</sup> )	1.33 (1.11-1.60)	0.002	1.17 (1.03-1.33)	0.018

The models are adjusted for all variables listed in the model. BMI: Body mass index.

revealed that this association existed among men ( $r = 0.54$ ,  $P = 0.012$ ) (Figure 3), but not among women ( $r = -0.10$ ,  $P = 0.716$ ).

## DISCUSSION

The presented results indicate that male gender and a higher BMI are risk factors for advanced fibrosis in morbidly obese patients. Notably, there is also a positive correlation between cigarette smoking measured by pack-years and liver stiffness in men. Our data corroborate previous publications<sup>[5,7-10]</sup>, demonstrating high rate of NAFLD with significant percent of severe (F4) fibrosis in morbidly obese patients, which in our population reached approximately 25% of the patients. Given the magnitude of the disease in the morbidly obese patients, only few attempts have been performed to stratify the risk for advanced fibrosis in this unique

population, mostly among patients undergoing bariatric surgery. Ong *et al.*<sup>[29]</sup> have found in 212 consecutive morbidly obese patients in whom liver biopsy was taken during bariatric surgery, that waist to hip ratio and AST levels were independently associated with severe fibrosis. In our cohort, liver enzymes were not predictive of advanced fibrosis. In another study<sup>[7]</sup> which obtained liver biopsy from 181 patients undergoing bariatric surgery, only age was significantly associated with advanced disease (moderate and severe fibrosis), in contrast to our results which did not show such an association (Tables 2 and 3). In line with our results, Dixon *et al.*<sup>[8]</sup> have found in 105 consecutive biopsied bariatric patients that advanced fibrosis was associated with male gender and not with the presence of T2DM. In contrast, Beymer *et al.*<sup>[9]</sup> has found T2DM as the only predictor to advanced fibrosis. This discrepancy may be explained by systemic insulin resistance characterizing most of the patients in the aforementioned cohorts who have not developed overt diabetes yet. This assumption is supported by the higher C-peptide level found in patients with advanced fibrosis in Dixon's cohort<sup>[8]</sup>. Interestingly, a recent cohort analyzing 134 South Indian patients have found arterial hypertension as a sole independent risk factor for fibrosis<sup>[30]</sup>.

In our study we have extended the search for advanced liver fibrosis predictors toward diet elements, eating behavior and lifestyle variables, all of which have shown an association with obesity in general<sup>[31]</sup> and some of them with NAFLD in particular<sup>[32]</sup>. Whereas the

**Figure 2** Dose response relationship of the combined categories of body mass index of 40 and above (grade 3 obesity) and male gender with fibrosis level. Women + BMI < 40;  $n = 14$ , men or BMI  $\geq 40$ ;  $n = 42$ , men + BMI  $\geq 40$ ;  $n = 21$ . BMI: Body mass index.

association between active and passive smoking and NAFLD has been already demonstrated<sup>[33]</sup>, we succeeded to show a significant positive correlation between cigarette smoking measured by pack-years and liver stiffness in men (Figure 2). Our findings are corroborated by the data of the Multicenter Nonalcoholic Steatohepatitis Clinical Research Network generated from 1081 patients<sup>[16]</sup>, in which multivariate analysis has demonstrated 1.6 fold increased odds for advanced fibrosis among those with a smoking history of  $\geq 10$  pack-years. Among non-diabetics, a history of  $\geq 10$  pack-years was associated with even a higher chance of 2.5 fold for advanced fibrosis. Multiple mechanisms may be involved in smoking injury,

**Figure 3** Correlation between pack-years and liver stiffness among ever smoking men ( $n = 21$ ).

such as insulin resistance, oxidative stress and hypoxia<sup>[16]</sup>. Further studies are needed to confirm this finding among morbid obese patients and to elucidate this phenomenon.

We failed to find an association between liver stiffness and dietary parameters or eating patterns in this study. This lack of association may stem from potential sources of bias that need to be considered. First, recall and reporting bias may exist, especially on lifestyle habits and partially because of social desirability among obese population<sup>[34]</sup>. The bias was minimized by the use of structured and validated questionnaires. Also, no information about the purpose and the hypotheses of the study was provided to the participants in order to minimize the report bias. In addition, the interview was performed before receiving the results of the Fibroscan and thus the information bias is expected to be non-differential. Second, a measurement of liver stiffness is not the gold standard for the assessment of liver fibrosis. However, the Fibroscan test with the XL transducer is adjusted for patients with obesity and morbid obesity and compared with the standard transducer leads to lower rates of test failure (1.1% vs 16%) and an established validity<sup>[17,21]</sup>. However, among obese subjects, unreliable results may still be observed with the XL probe<sup>[35]</sup>. Nevertheless, despite this disadvantage, Fibroscan was demonstrated to be one of the most accurate tests for the non-invasive diagnosis of liver fibrosis in NAFLD<sup>[18]</sup>.

In conclusion, our study highlights the fact in even in the upper BMI ranges, higher BMI bears greater risk for advanced disease. In addition, male gender may a risk factor for advanced disease in the morbidly obese population. The suggested association with the degree of smoking in men will have to be confirmed in further studies with a larger sample size.

## ACKNOWLEDGMENTS

We would like to thank Ms. Stella Levit for performing the Fibroscan examinations.

## COMMENTS

### Background

Given the high prevalence of severe fibrosis (12%) in morbidly obese patients,

this population is especially prone to a detrimental course of nonalcoholic fatty liver disease (NAFLD). Therefore, it is of utmost importance to identify those patients with high likelihood for advanced fibrosis who may later develop cirrhosis and hepatocellular carcinoma.

### Research frontiers

The presented results indicate that male gender and a higher body mass index (BMI) are risk factors for advanced fibrosis in morbidly obese patients. There is also a positive correlation between cigarette smoking and liver stiffness in men.

### Innovations and breakthroughs

Their study highlights the fact in even in the upper BMI ranges, higher BMI bears greater risk for advanced disease. In addition, male gender may be a risk factor for advanced disease in the morbidly obese population.

### Applications

This study may indicate that weight reduction, even a modest one within the morbid obesity range, may be helpful in prevention of advanced fibrosis in morbid obese patients. Men may need more closer monitoring of fibrosis, and if supported by larger studies, may be advised to undergo smoking cessation.

### Terminology

NAFLD encompasses a wide spectrum of histological and clinical manifestations, ranging from simple steatosis to steatohepatitis, fibrosis and cirrhosis.

### Peer-review

This is an interesting and well-organized study. The results are clearly presented.

## Abstract

### AIM

To determine the impact of transjugular intrahepatic porto-systemic shunt (TIPS) on post liver transplantation (LT) outcomes.

### METHODS

Utilizing the United Network for Organ Sharing (UNOS) database, we compared patients who underwent LT from 2002 to 2013 who had undergone TIPS to those without TIPS for the management of ascites while on the LT waitlist. The impact of TIPS on 30-d mortality, length of stay (LOS), and need for re-LT were studied. For evaluation of mean differences between baseline

characteristics for patients with and without TIPS, we used unpaired *t*-tests for continuous measures and  $\chi^2$  tests for categorical measures. We estimated the impact of TIPS on each of the outcome measures. Multivariate analyses were conducted on the study population to explore the effect of TIPS on 30-d mortality post-LT, need for re-LT and LOS. All covariates were included in logistic regression analysis.

## RESULTS

We included adult patients (age  $\geq 18$  years) who underwent LT from May 2002 to September 2013. Only those undergoing TIPS after listing and before liver transplant were included in the TIPS group. We excluded patients with variceal bleeding within two weeks of listing for LT and those listed for acute liver failure or hepatocellular carcinoma. Of 114770 LT in the UNOS database, 32783 (28.5%) met inclusion criteria. Of these 1366 (4.2%) had TIPS between the time of listing and LT. We found that TIPS increased the days on waitlist ( $408 \pm 553$  d) as compared to those without TIPS ( $183 \pm 330$  d),  $P < 0.001$ . Multivariate analysis showed that TIPS had no effect on 30-d post LT mortality (OR = 1.26; 95%CI: 0.91-1.76) and re-LT (OR = 0.61; 95%CI: 0.36-1.05). Pre-transplant hepatic encephalopathy added 3.46 d (95%CI: 2.37-4.55,  $P < 0.001$ ), followed by 2.16 d (95%CI: 0.92-3.38,  $P = 0.001$ ) by TIPS to LOS.

## CONCLUSION

TIPS did increase time on waitlist for LT. More importantly, TIPS was not associated with 30-d mortality and re-LT, but it did lengthen hospital LOS after transplantation.

**Key words:** Transjugular intrahepatic porto-systemic shunt; Shunt; Liver; Transplantation; Ascites; Model for end-stage liver disease; Mortality; Transjugular

**Core tip:** The study was completed to determine the impact of transjugular intrahepatic porto-systemic shunt (TIPS) on post liver transplantation (LT) outcomes. Utilizing the United Network for Organ Sharing database, we compared patients who underwent LT from 2002 to 2013 who had undergone TIPS to those without TIPS for the management of ascites while on the LT waitlist. The impact of TIPS on 30-d mortality, length of stay (LOS), and need for re-LT were studied. TIPS was not commonly used in patients with ascites on the waitlist but did increase time on waitlist for LT. More importantly, TIPS was not associated with 30-d mortality and re-LT, but it did increase hospital LOS after transplantation.

for Organ Sharing database. *World J Hepatol* 2017; 9(2): 99-105 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i2/99.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i2.99>

## INTRODUCTION

Transjugular intrahepatic portosystemic shunts (TIPS) play an important role in the treatment of recurrent esophageal varices, bleeding gastric varices and refractory ascites. Multiple randomized trials and meta-analyses have reported the superiority of TIPS over large volume paracentesis in controlling refractory ascites with no effect on long-term survival<sup>[1-8]</sup>. One study compared 149 patients with refractory ascites allocated to TIPS and 156 to paracentesis with significant improvement in the TIPS population regarding transplant-free survival of cirrhotic patients with refractory ascites<sup>[6]</sup>.

A few single-center studies have reported the impact of TIPS on liver transplant metrics<sup>[9-11]</sup>. When comparing TIPS vs non-TIPS patients, studies revealed comparable transfusion requirements and operative time between the two cohorts and also demonstrated operative mortality and early graft function not to be influenced by TIPS placement<sup>[9,10]</sup>. In fact, TIPS may offer an advantage in reducing ascites at the time of transplantation, which in turn may expedite the transplant time<sup>[11]</sup>.

Other single center studies explored the impact of TIPS on post-transplant survival and found no significant difference<sup>[12-14]</sup>. Guerrini *et al*<sup>[15]</sup>, however, found that patients who underwent TIPS pre-liver transplantation (pre-LT) had a lower risk of mortality at 1 year after LT. These potential advantages associated with the use of TIPS, however, are balanced by technical complications associated with it at time of LT<sup>[16]</sup>.

Previously, most single center studies and meta-analyses evaluating the utility of TIPS in the context of LT have explored the survival at 1 year or longer<sup>[12-14]</sup>. It appears that TIPS may improve portal hypertension related issues in immediate post-transplant setting by reducing the flow of blood in the collateral circulation, thus improving portal supply to the graft<sup>[15]</sup>. Keeping in mind the mechanism by which TIPS may be helpful or disadvantageous, it's prudent to study short-term outcomes such as 30-d mortality and re-LT.

We utilized the United Network for Organ Sharing (UNOS) database to determine if TIPS had an influence on short-term outcomes of LT. We hypothesized that TIPS is not associated with an increase in 30-d post LT mortality and rate of re-LT.

## MATERIALS AND METHODS

### Data collection

A retrospective cohort study was performed on adult LT candidates who were registered in the Organ Procurement and Transplant Network (OPTN) Standard Transplant Analysis and Research Database (Reference:

**Figure 1** Flow diagram of inclusion criteria. TIPS: Transjugular intrahepatic porto-systemic shunt; ALF: Acute liver failure.

UNOS/Organ Procurement and Transplantation Network Standard Transplant Analysis and Research Database. Available from: <https://optn.transplant.hrsa.gov/data/about-data/>, Accessed September 6, 2013). The study was approved by the Nationwide Children's Hospital Institutional Review Board with a waiver of individual consent (IRB14-00716). The UNOS/OPTN liver database was queried for all patients with cirrhosis listed from May 2002 to September 2013. Each first-time LT candidate listed was tracked until death. All patients with TIPS for ascites who ultimately underwent LT were included in this sample.

The data available from the UNOS Registry included status of TIPS in patients with ascites. Other variables included in analysis were gender, age, diabetes mellitus, body mass index (BMI) at listing, cold ischemia time (CIT), waitlist hepatic encephalopathy, etiology of liver disease (alcoholic vs other), model for end-stage liver disease (MELD) score at listing, MELD score at LT; biochemical tests including serum creatinine, bilirubin, albumin, and international normalized ratio (INR). We studied various outcomes including mortality at 30-d, need for re-LT and hospital length of stay (LOS) during admission for LT.

### Study sample

We included adult patients (age  $\geq 18$  years) who underwent LT from May 2002 to September 2013 [*i.e.*, after the inception of the MELD score and use of expanded-polytetrafluoroethylene (ePTFE) covered TIPS]. Only those undergoing TIPS after listing and before liver transplant were included in the TIPS group. We excluded patients with variceal bleeding within two weeks of listing (in order to exclude TIPS for variceal bleed) for LT and those listed for acute liver failure or hepatocellular carcinoma. After application of exclusion criteria (Figure 1) the analytic sample consisted of 32783/114770 (28.5%) patients with ascites who underwent LT and had a known

TIPS status. Among these 32783 patients with ascites, 1366 patients underwent TIPS while 31417 patients did not undergo TIPS.

### Statistical analysis

All values were expressed as means  $\pm$  SD for continuous measures, and counts and percentages for categorical variables. For all analyses, a  $P$ -value  $< 0.05$  was considered statistically significant. For evaluation of mean differences between baseline characteristics for patients with and without TIPS, we used unpaired  $t$ -tests for continuous measures and  $\chi^2$  tests for categorical measures. We estimated the impact of TIPS on each of the outcome measures. Multivariate analyses were conducted on the study population to explore the effect of TIPS on 30-d mortality post-LT, need for re-LT and LOS. All covariates were included in logistic regression analysis. All analyses were performed using Stata/MP, version 13.1 (College Station, TX: StataCorp LP). The statistical review of this study was performed by a biomedical statistician.

## RESULTS

### Study population

After applying the inclusion/exclusion criteria a total of 32783 patients with ascites from database were selected. A total of 1366 (4.2%) underwent TIPS for management of refractory ascites while awaiting LT (Figure 1). Those without TIPS ( $n = 31417$ ) were selected as a control group for comparison.

Demographics such as gender, age and BMI were comparable in the two groups; albumin and CIT were also equally distributed (Table 1). Patients with TIPS on waitlist had a lower mean MELD score at time of listing ( $16.6 \pm 6.7$ ) as compared to those without TIPS ( $19.7 \pm 8.9$ ), ( $P < 0.001$ ). Plausibly, TIPS group had a lower creatinine, bilirubin and INR. Interestingly, the MELD score at transplantation was higher in the TIPS group ( $23.2 \pm 9.2$ ) as compared to without TIPS group ( $22.6 \pm 9.8$ ) ( $P = 0.03$ ). Plausibly, there were less patients with severe hepatic encephalopathy (HE) in the TIPS group ( $n = 68$ ; 4.9%) as compared to without TIPS ( $n = 2218$ ; 7%) ( $P = 0.01$ ).

On univariate analysis (Table 2), we found that TIPS increases the days on LT waitlist ( $408 \pm 553$  d) as compared to those without TIPS ( $183 \pm 330$  d), ( $P < 0.001$ ). TIPS group had comparable 30-d post LT mortality as compared to non-TIPS group (46; 3.51% vs 915; 3.05%;  $P = 0.34$ ). There was also a comparable re-LT rate at 30 d (15; 1.1% vs 560; 1.78%;  $P = 0.06$ ) and hospital LOS (17.58 vs 16.62;  $P = 0.12$ ) between the two groups.

### Thirty-days post LT mortality predictors

On logistic regression, TIPS had no effect on 30-d post LT mortality (OR = 1.26; 95%CI: 0.91-1.75). However, the significant predictors of mortality at 30-d were advanced age (OR = 1.02; 95%CI: 1.01-1.03,  $P < 0.001$ ),

**Table 1** Demographics and clinical variables categorized by transjugular intrahepatic porto-systemic shunt status

Variables	TIPS on waitlist ( <i>n</i> = 1366; % or mean $\pm$ SD)	Non TIPS on waitlist ( <i>n</i> = 31417; % or mean $\pm$ SD)	<i>P</i> -values
Male candidate	943 (69)	21374 (68)	0.43
Candidate race			< 0.001
White	1072 (78.4)	23063 (73.4)	
Black	75 (5.4)	2865 (9.1)

low serum albumin (OR = 0.88; 95%CI: 0.79-0.98, *P* = 0.029), and increasing CIT (OR = 1.04; 95%CI: 1.02-1.05, *P* < 0.001). Another predictor of 30-d mortality was bilirubin (OR = 1.014; 95%CI: 1.004-1.024; *P* = 0.008 (Table 3).

### TIPS and re-LT at 30 d

On logistic regression, TIPS was not associated with re-LT at 30 d (OR = 0.61; 95%CI: 0.36-1.05). Predictors of re-LT at 30 d included advanced age (OR = 0.97; 95%CI: 0.96-0.98; *P* < 0.001), creatinine (OR = 0.87; 95%CI: 0.77-0.99; *P* = 0.032) and CIT (OR = 1.05; 95%CI: 1.03-1.07; *P* < 0.001) (Table 4).

TIPS: Transjugular intrahepatic porto-systemic shunt; ALD: Alcoholic liver disease; MELD: Model for end-stage liver disease; INR: International normalized ratio; BMI: Body mass index.

### TIPS and LOS

Advanced HE (grade 3-4) on waitlist contributed most days to LOS ( $\beta$  = 3.46; 95%CI: 2.37-4.55, *P* < 0.001), followed by TIPS ( $\beta$  = 2.16; 95%CI: 0.92-3.38, *P* = 0.001). Other factors that contributed to LOS were black race ( $\beta$  = -1.58; 95%CI: -2.46 to -0.69, *P* < 0.001) and advanced age ( $\beta$  = 0.09; 95%CI: 0.06-0.11, *P* < 0.001). High MELD score, INR, albumin, BMI and CIT also significantly contributed to LOS after LT (Table 5).

## DISCUSSION

The most important finding of the current study is that TIPS for the treatment of ascites in the MELD era for LT is not associated with heightened 30-d mortality or the need for re-transplantation. However, hospital LOS was increased in patients with TIPS which may point to post-operative morbidity. TIPS was found to increase time on waitlist in patients with ascites.

Our findings of safety of TIPS in terms of short term mortality and need for re-LT is in line with multiple other studies, as these also did not find any difference in operative time, transfusion and LOS<sup>[9,12,14,17]</sup>. One of the largest retrospective studies of 207 patients explored the impact of TIPS on post-transplant survival and graft loss and found no significant difference<sup>[12]</sup>. In fact, a recent study went even further to find lower risk of mortality in TIPS group at 1 year after LT<sup>[15]</sup>.

Our study holds many advantages to prior studies including the use of a national database and large sample size. Furthermore, our study had increased homogeneity as it was limited to those undergoing TIPS for refractory

**Table 4** Multivariable logistic regression analysis to assess the impact of transjugular intrahepatic porto-systemic shunt on retransplantation

ascites and was limited to a study period in the post-MELD era and with more homogeneity in shunt type (*i.e.*, ePTFE covered).

Existing literature on LOS is variable with certain studies describing intra-operative complications in patients who have undergone TIPS<sup>[16]</sup>. On the other hand, additional studies have not found TIPS to affect the LOS in post LT setting<sup>[14,18]</sup>. It has been shown in our study that advanced HE (grade 3-4) on waitlist cirrhotics contributes the most to LOS adding 3.5 d followed by TIPS insertion which prolonged stay by an average of 2.16 d. This finding is remarkable given encephalopathy is a known complication of TIPS<sup>[7,8]</sup>. We can hypothesize that TIPS insertion may contribute to ongoing encephalopathy and therefore increase length of hospital stay.

Among other predictors of increased LOS were advanced age, high MELD score and CIT. All these factors are recognized predictors of increased LOS and reported in literature<sup>[19,20]</sup>. Of note, the TIPS group in our study began with a lower MELD score at the time of listing but had higher MELD scores at the time of LT. This finding suggests patients undergoing TIPS were able to survive longer on the wait list with continued progression of liver disease at the time of LT. More advanced disease among TIPS patients would explain increased LOS post-LT.

We found that increased time on the waitlist in the TIPS group was consistent with findings from single center studies<sup>[18]</sup>. Several randomized controlled trials and a meta-analysis of individual patient data also found TIPS superior to repeated paracentesis in increasing time on waitlist and therefore transplant free survival<sup>[2,5,6]</sup>. The increased time on LT wait list may be explained by

decreased portal hypertension produced by the TIPS and mortality associated with complications of portal hypertension. One study found that TIPS lowered mortality rate while on waitlist and decreased need for transplantation<sup>[21]</sup>. Hence, it is possible TIPS can be utilized as a bridge to transplant and even to improve waitlist survival of listed patients.

Our findings demonstrate the challenge of using TIPS in patients who need to undergo LT. Following TIPS placement, this patient population has an increased wait time for LT, yet suffers comparable immediate post procedural mortality as their non-TIPS counterparts. This longer time on the waitlist may allow for other decompensated non-TIPS patients with higher MELD scores to undergo LT first. Thus, it appears that a disparity is created where the patient population requiring more advanced treatment of ascites (*i.e.*, TIPS) have increased time on waitlist through improvement of the MELD score and therefore experience a delay in transplantation. Based on our findings, we propose an idea to potentially provide special circumstances to patients requiring TIPS on the waitlist for LT as their outcomes after transplantation are not influenced by placement of the shunt. An example of special circumstances could be exceptional MELD points to avoid further delay in LT.

Limitations of our study are mainly related to availability of variables in the UNOS database. This database only lists TIPS status at the time of LT recipient registration and does not provide information on control and recurrence of tense ascites, post TIPS encephalopathy, intra- and post-LT information such as operative time and blood

product transfusion requirements. Waitlist mortality, intensive care unit stay, and complications of TIPS placement such as TIPS migration and endovascular stenting were also not available to us. Due to these database limitations we cannot directly measure the number of patients on waitlist undergoing TIPS or the waitlist mortality. As a result, days on waitlist had to be used as a surrogate measure for waitlist mortality and transplant free survival.

In conclusion, we found that TIPS had no effect on the 30-d mortality after LT and the need for re-LT. TIPS increased time on LT waitlist while also increasing length of hospital stay post-LT. It was found that TIPS is not a commonly used intervention for the management of ascites in patients on the waitlist for LT. With TIPS not influencing 30-d mortality and need for re-LT, it appears that more patients may benefit from its use. However, one of the downsides of using TIPS could be a potential delay in LT due to improvement in MELD score. These important factors must be considered and discussed with patients before pursuing TIPS procedure.

## COMMENTS

### Background

Prior studies exploring the role of transjugular intrahepatic porto-systemic shunt (TIPS) with regards to cirrhotic patients being evaluated for liver transplant were limited by small sample sizes, single center studies, and heterogeneous study groups that resulted in poor generalizability. Further, these studies were completed prior to advent of expanded-polytetrafluoroethylene covered stents and introduction of model for end-stage liver disease allocation system. Here the authors would like to utilize the United Network for Organ Sharing (UNOS) database to address the effect of TIPS on waitlist times, liver transplantation (LT) morbidity and mortality, and hospital length of stay.

### Research frontiers

Since its inception, TIPS has been touted as a potential bridge to LT by possibly improving transplant free survival. Studies such as that performed by Berry *et al* have recently used the UNOS data base to confirm TIPS' role in improving transplant free survival and support the notion that TIPS is a bridge to LT.

### Innovations and breakthroughs

To our knowledge no study has utilized the UNOS database in exploring post-LT outcomes in the TIPS population. The study confirmed findings of prior single center studies that TIPS does not significantly affect post-LT outcomes. Of note, their large study group size adds power and improves generalizability of these findings. Short term outcomes were their primary focus given the concern for potential for intra-operative LT complications in patients who have undergone TIPS.

### Applications

The authors' findings support prior single center and more recent meta-analyses and database reviews in confirming increased transplant free survival while not affecting post-LT outcomes. The study supports the notion that TIPS can be utilized as a bridge to transplantation. Prospective studies will be necessary to further elucidate the influence of TIPS on LT outcomes and the potential detriments resulting from prolonged waitlist times.

### Terminology

CIT: Cold ischemia time; ePTFE: Expanded-polytetrafluoroethylene; HE: Hepatic encephalopathy; LOS: Length of hospital stay; LT: Liver transplantation; LVP: Large volume paracentesis; MELD: Model for end-stage liver disease; TIPS: Transjugular intrahepatic porto-systemic shunt; UNOS: United Network

for Organ Sharing.

### Peer-review

The paper is well written and the design is good.

### Abstract

#### AIM

To examine patient-centered outcomes with vasopressin (AVP) use in patients with cirrhosis with catecholamine-refractory septic shock.

#### METHODS

We conducted a single center, retrospective cohort study enrolling adult patients with cirrhosis treated for catecholamine-resistant septic shock in the intensive care unit (ICU) from March 2011 through December 2013. Other etiologies of shock were excluded. Multivariable regression models were constructed for seven and 28-d mortality comparing AVP as a second-line therapy to a group of all other vasoactive agents.

#### RESULTS

Forty-five consecutive patients with cirrhosis were treated for catecholamine-resistant septic shock; 21 received AVP while the remaining 24 received another agent [phenylephrine (10), dopamine (6), norepinephrine (4), dobutamine (2), milrinone (2)]. In general,

no significant differences in baseline demographics, etiology of cirrhosis, laboratory values, vital signs or ICU mortality/severity of illness scores were observed with the exception of higher MELD scores in the AVP group (32.4, 95%CI: 28.6-36.2 *vs* 27.1, 95%CI: 23.6-30.6,  $P = 0.041$ ). No statistically significant difference was observed in unadjusted 7-d (52.4% AVP *vs* 58.3% and  $P = 0.408$ ) or 28-d mortality (81.0% AVP *vs* 87.5% non-AVP,  $P = 0.371$ ). Corticosteroid administration was associated with lower 28-d mortality (HR = 0.37, 95%CI: 0.16-0.86,  $P = 0.021$ ) independent of AVP use.

### CONCLUSION

AVP is similar in terms of patient centered outcomes of seven and 28-d mortality, in comparison to all other vasopressors when used as a second line vasoactive agent in catecholamine resistant septic shock. Large-scale prospective study would help to refine current consensus standards and provide further support to our findings.

**Key words:** Portal hypertension; Vasopressor; Liver; Intensive care unit; Hepatology

**Core tip:** Although the management of septic shock has evolved dramatically in recent decades, data regarding optimal vasopressor therapy in critically-ill patients with cirrhosis is less robust and is based largely on consensus expert opinion. We found no difference in 7-d or 28-d mortality with vasopressin use when compared to all other vasoactive agents as a second line agent in catecholamine-resistant septic shock. Further large-scale studies are needed to refine current consensus standards and provide further support to our findings.

Myc LA, Stine JG, Chakrapani R, Kadl A, Argo CK. Vasopressin use in critically ill cirrhosis patients with catecholamine-resistant septic shock: The CVICU cohort. *World J Hepatol* 2017; 9(2): 106-113 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i2/106.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i2.106>

### INTRODUCTION

The management of septic shock has evolved since the inception of the Surviving Sepsis Campaign and the adoption of early goal-directed therapy, with short-term mortality rates improving markedly over the past decade<sup>[1]</sup>. Improved outcomes appear to have extended to special populations as well, including patients with cirrhosis of the liver, a population in which sepsis has traditionally been characterized by extremely high mortality rates of nearly 100% in some studies, well above those of the general population which approximate 40% at 28-d<sup>[2-4]</sup>. Concurrent with the development of bundled care protocols, the incorporation of arginine

vasopressin (AVP) into the management of septic shock has generated significant clinical and research interest. Based on reports of inappropriately low levels of circulating AVP coupled with apparent AVP-hypersensitivity in patients with cirrhosis and septic shock, exogenous AVP was seen as potentially restorative of both vascular tone and catecholamine-sensitivity in septic states<sup>[5-7]</sup>.

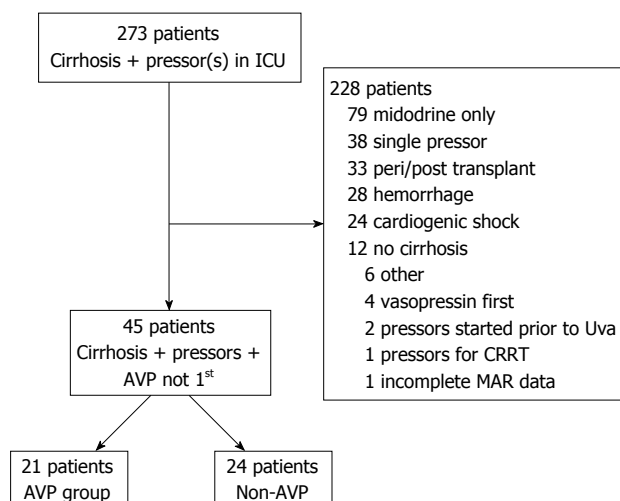

Current recommendations for AVP use in managing septic shock largely derive from the published results of the Vasopressin and Septic Shock Trial (VASST) which reported no significant difference in 28-d mortality in patients with septic shock treated with vasopressin *vs* norepinephrine<sup>[4]</sup>. Nevertheless, the authors did report improved 28-d mortality in a pre-specified subgroup of patients with less severe septic shock as well as decreased norepinephrine requirements in patients receiving AVP, leading to the adoption of exogenous AVP use as an ungraded recommendation into the Surviving Sepsis Guidelines.

Appreciating these general recommendations, it remains unclear what role exogenous AVP may serve in patients with cirrhosis given the unique characteristics of septic shock in this population. Although low levels of AVP coinciding with AVP-vasosensitivity have been reported in patients with cirrhosis, the distinctive features of septic shock in this population including hyperdynamic circulation, relative adrenal insufficiency, blood volume sequestration in the splanchnic venous plexus, and hypothermia together with underlying thrombocytopenia and varying degrees of hepatic dysfunction introduce ambiguity as to whether the generic Surviving Sepsis guidelines ought to be applied to patients with cirrhosis<sup>[2,3,8-10]</sup>. Data regarding AVP and AVP analogue use in patients with cirrhosis and septic shock are sparse.

Recently published guidelines addressing management of critically ill patients with cirrhosis do incorporate AVP use for treatment of persistent hypotension, however this recommendation relies largely on studies of terlipressin in non-cirrhotic populations<sup>[11]</sup>. In this respect, it should be noted that only 11.3% of the patients enrolled in the VASST study had any liver disease at all. While AVP may have salient effects in this population relating to improved hemodynamics, mobilization of large splanchnic blood volume, norepinephrine sparing, and improved catecholamine resistance, potential adverse effects specific to the cirrhotic state cannot be excluded and may include acute-on-chronic liver failure, worsening thrombocytopenia and hyponatremia, and decreased cardiac output<sup>[4,12-17]</sup>. Decreased cardiac output may be particularly significant in this population, which may be more dependent on oxygen delivery for oxygen consumption<sup>[18]</sup>. Together, such hepatic, renal and hematologic effects of AVP may be disproportionately detrimental in a vulnerable cirrhotic population often characterized by baseline hyponatremia and thrombocytopenia complicating underlying hepatic dysfunction.

In this single center retrospective cohort study,

**Figure 1 Study enrollment.** CRRT: Crrtcontinuous renal replacement therapy; ICU: Intensive care unit; AVP: Arginine vasopressin.

we aimed to characterize 7-d and 28-d mortality outcomes of AVP use in patients with cirrhosis and catecholamine-refractory septic shock (CRSS). Secondly, we aimed to investigate the effect of AVP on 24-h changes in important laboratory parameters including aminotransferases, total bilirubin and platelet concentrations as well as heart rate. We hypothesized that use of AVP as a second vasopressor in cirrhosis patients with catecholamine-resistant septic shock would be associated with increased mortality when compared with cirrhosis patients receiving an alternate adjunct vasoactive agent (e.g., norepinephrine, phenylephrine, dopamine).

## MATERIALS AND METHODS

### Cohort selection

All adult patients with cirrhosis treated for CRSS shock requiring medical intensive care unit (ICU) care between March 4, 2011 and December 31, 2013 were identified through the University of Virginia Clinical Data Repository using billing and administrative codes in conjunction with data derived from medication administration reports. Cirrhosis of the liver was confirmed by direct histological examination of liver biopsy or by biochemical and imaging findings suggesting advanced liver disease with portal hypertension. Catecholamine-resistant septic shock was defined as a clinical requirement for  $\geq 2$  vasopressors (the first of which had to be a catecholaminergic agent) for hypotension attributable to an infectious origin on the basis of either culture data or clear clinical suspicion. Patients with cirrhosis meeting this definition of CRSS were included in our analysis. Patients with other etiologies of shock (e.g., hemorrhagic, obstructive, etc.) were excluded, as were patients who received AVP as the first vasopressor agent, patients who received vasopressors in the peri-transplant setting or for purposes of tolerating renal replacement therapy, or patients who were initiated on vasopressor therapy at an undetermined time prior to

interhospital transfer to our facility (Figure 1).

Baseline patient characteristics were reviewed, including demographics, medical comorbidities (coronary artery disease, congestive heart failure, chronic obstructive pulmonary disease, chronic kidney disease, diabetes, hypertension), smoking and alcohol use, etiology of liver disease with portal hypertensive complications (ascites, and hepatic encephalopathy), vital signs (heart rate, minimum mean arterial pressure, temperature, maximum respiratory rate) and laboratory values. MELD score was calculated using the standard formula:  $11.2 \times \ln(\text{INR}) + 9.57 \times \ln[\text{creatinine (mg/dL)}] + 3.78 \times \ln[\text{bilirubin (mg/dL)}] + 6.43$  with a lower limit of 1.0 for all variables<sup>[19]</sup>. ICU severity of illness variables were also collected including fraction of inspired oxygen, partial pressure of arterial carbon dioxide, partial pressure of arterial oxygen, pH, mean number of vasopressors, days on vasopressors, need for continuous renal replacement therapy, intubation, urine output over the first 24 h, new hemorrhage and new diagnosis of venous thrombosis. Illness severity scores were calculated [acute physiology and chronic health evaluation II (APACHE II), simplified acute physiology score (SAPS II), sequential organ failure assessment (SOFA)]. ICU medications were reviewed (volume of intravenous fluid, octreotide, antibiotic administration, albumin administration, proton pump inhibitor, corticosteroids and first vasopressor use). Captured outcomes included mean survival, hospital and ICU length of stay, ventilator free days, mortality (7-d, 28-d and 90-d), in-hospital mortality, in-ICU mortality and withdrawal of care. The 24-h changes in laboratory parameters (platelets, liver associated enzymes, heart rate, total bilirubin) were also extracted on the basis of the first available value of the parameter of interest available 24-48 h following vasopressor initiation.

### Statistical analysis

Subjects were sorted into two groups, those patients who received AVP as the second-line agent and those patients where another vasopressor was utilized as the second-line agent. The AVP group was compared to the non-AVP group in multiple factors including baseline patient demographics, medical comorbidities, smoking and alcohol use, etiology of liver disease, portal hypertensive complications, vital signs, laboratory values, severity of illness variables, ICU medications administered and patient-centered outcomes of mortality and withdrawal of care. Multivariable models were constructed to assess statistical associations and risk factors for 7-d and 28-d mortality. Individual factors were included in the multivariable model if they were statistically significant to  $P < 0.10$  in the univariate analysis, were clinically important, or have been shown in the literature to be of clinical significance. Univariate comparisons were performed using the Student-*t* test, Wilcoxon sign rank test,  $\chi^2$  test, or Fisher exact test as appropriate. Multivariable models were constructed using Cox proportional hazards models and analysis of maximum likelihood estimates. Modeling both with composite MELD score and

**Figure 2** Twenty-eight-day survival comparing second line vasopressors in catecholamine-resistant septic shock.

examining each variable in the MELD score independently were performed to ensure no one variable was dominant. Unadjusted, stratified Kaplan-Meier survival curves were constructed for 7-d and 28-d survival utilizing the log-rank test to determine statistical significance ( $P \leq 0.05$ ). All statistical tests for significance were two-sided and a significance level  $p$  less than or equal to 0.05 was considered statistically significant. All data set manipulation and statistical analyses were performed using SAS (version 9.4, Cary, NC). Institutional review board approval was obtained for this study.

## RESULTS

Forty-five consecutive patients with cirrhosis were treated for catecholamine-resistant septic shock; 21 received AVP as the second-line vasopressor while the remaining 24 received some other agent [phenylephrine (10), dopamine (6), norepinephrine (4), dobutamine (2), milrinone (2)]. Mean age was  $57.2 \pm 14.0$  years. The cohort was 53.3% male and nearly  $\frac{3}{4}$  had either alcoholic liver disease or chronic hepatitis C as the underlying etiology of cirrhosis (alcoholic alone 35.6%, chronic hepatitis C alone 26.7%, concomitant alcohol and hepatitis C 8.9%). All patients had either Child-Turcotte-Pugh Class B ( $n = 8$ , 14.5%) or Class C ( $n = 37$ , 85.5%) liver disease. Mean MELD score was  $29.0 \pm 9.0$ . Overall 7-d and 28-d mortality were 55.6% and 84.4% respectively, with two patients eventually undergoing liver transplantation at 34 and 67 d out from diagnosis of CRSS, respectively.

In general, no significant differences in baseline demographics, etiology of cirrhosis, laboratory values, vital signs or ICU mortality/severity of illness scores were observed when comparing those subjects who received AVP to those who received any other vasoactive agent, with the exception of higher MELD scores in the AVP group (32.4, 95%CI: 28.6-36.2 vs 27.1, 95%CI: 23.6-30.6,  $P = 0.041$ ) (Table 1). Glomerular filtration rates were also different between the two groups (23.9 mL/min, 95%CI: 18.6-29.2 in the AVP group vs 40.0 mL/min, 95%CI: 29.1-51.0 in the non-AVP group,  $P =$

0.013). Mean APACHE II scores were statistically similar (33.5, 95%CI: 30.6-36.5 in the AVP group vs 31.8, 95%CI: 29.4-34.2) as were SAPS II (72.6, 95%CI: 63.5-81.7 in the AVP group vs 70.3, 95%CI: 64.5-76.1 in the non-AVP group) and SOFA (17.6, 95%CI: 15.9-19.3 AVP vs 16.9, 95%CI: 15.9-18.0 non-AVP). Corticosteroid administration was also statistically similar (76.2% AVP vs 79.2% non-AVP) as was time to first vasopressor initiation (6.8, 95%CI: 4.9-8.7 h AVP vs 7.4, 95%CI: 5.7-9.3 h non-AVP). No statistically significant difference was observed in unadjusted 7-d mortality (52.4% AVP vs 58.3% and  $P = 0.408$ ) or 28-d mortality (81.0% AVP vs 87.5% non-AVP,  $P = 0.813$ ) (Figure 2). There was also no significant change in any recorded laboratory value of interest as measured 24-48 h after vasopressor initiation (Table 2).

On adjusted multivariable analysis, AVP use was not associated with increased 28-d mortality (HR = 0.77, 95%CI: 0.39-1.52,  $P = 0.771$ ). Age in years (HR = 1.05, 95%CI: 1.01-1.08,  $P = 0.004$ ) was associated with increased 28-d mortality (Table 3). In other words, for each addition year of age from the baseline cohort average, the mortality rate was increased 5%. Corticosteroid administration was a significant predictor of improved 28-d mortality (HR = 0.37, 95%CI: 0.16-0.86,  $P = 0.021$ ). The initiation of renal replacement therapy was associated with lower mortality (HR = 0.40, 95%CI: 0.19-0.85,  $P = 0.017$ ). No significant difference was found for MELD score.

## DISCUSSION

After adjusting for multiple confounding factors, we report that AVP is not associated with disparate outcomes when compared to all other vasoactive agents in terms of 7-d and 28-d mortality when used as a second line vasopressor in catecholamine-resistant septic shock. These results are particularly notable considering the extent to which our AVP group was comprised of patients with a higher severity of illness as reflected by statistically higher baseline MELD scores as well as severity of illness scores which, while not individually differing statistically between the two groups, nevertheless all tended to be higher in the AVP group. Estimated glomerular filtration rates were also significantly lower in the AVP group, however these data need to be interpreted with caution as several of these patients were already receiving some form of renal replacement therapy at the time of vasopressor initiation. Additionally, we report no statistically significant difference in the total number of vasoactive agents used among the groups with both groups receiving approximately three such agents during the study period, a surrogate outcome which may indicate that AVP did not impair attainment of target mean-arterial pressures when compared with other agents. We do acknowledge that, due to the high rate of transition to comfort care measures, these data should also be interpreted cautiously, nevertheless rates of changes in goals of care were essentially equivalent

in the 2 groups. Well-designed, prospective, randomized studies are needed to clarify whether AVP should be preferred as the second-line vasopressor in this patient population.

Potential adverse effects of AVP administration were not different when compared to all other vasoactive agents. While others have published reports suggesting acute-on-chronic liver failure, worsening thrombocytopenia and a decline in cardiac output with AVP use<sup>[4,12-17]</sup> our results do not lend support to these concerns during early treatment, as we did not find any significant laboratory

changes in these parameter between the two groups as measured 24-48 h after vasopressor initiation. Consonant with these findings, we report similar rates of *de novo* venous thromboembolic disease among the two groups. While direct measurement of cardiac output or cardiac index was not obtainable in our retrospective analysis, heart rate did not decline significantly after one-day of vasopressor therapy in the AVP group when compared with the non-AVP group, lessening concerns regarding clinically significant negative chronotropy affecting cardiac output in this population. Although some reports suggest mortality benefit with attenuation of tachycardia in patients with septic shock, a decline in cardiac output mediated by decreased heart rate may have a disparate and adverse effect in cirrhosis patients when compared to the general population given the possible underlying dependence of oxygen consumption on oxygen delivery in this population<sup>[18,20]</sup>.

From a safety and efficacy standpoint, our findings confirm a salient role for AVP use in cirrhosis patients with CRSS and strengthen the current level of evidence provided in support of recent consensus guidelines for critical care in patients with cirrhosis which are based largely on data extrapolated from studies of terlipressin administration<sup>[11]</sup>.

On adjusted multivariable analysis, corticosteroid use emerged as a marked predictor of improved 28-d mortality with a 63% reduction in death with corticosteroid administration. Current Surviving Sepsis guidelines do recommend low-dose hydrocortisone for patients with septic shock unresponsive to fluid resuscitation and 60 min of vasopressors support. However, while the prevalence of adrenal insufficiency among patients with cirrhosis and sepsis has been generally reported as higher than expected, upwards of some 76% of this population, a recent randomized-controlled trial did not evidence a mortality benefit when stress-dosed steroids were employed in the ICU management of these patients<sup>[10]</sup>. In a randomized, placebo-controlled trial of 75 cirrhosis patients admitted to an intensive care unit with septic shock that was stopped early due to futility, Arabi *et al.*<sup>[10]</sup> reported a 28-d mortality of 85% in the group of patients randomized to receive low-dose corticosteroids compared with 72% in the placebo-allocated group. While our mortality rates approximate those in the steroid-receiving group reported by Russell *et al.*<sup>[21]</sup> it is clear that our patients suffering CRSS represented a more critically ill population as evidenced not only by a pre-specified requirement for 2 or more vasopressors, but also by the higher APACHE II and SOFA scores which characterized our patients. While the discrepancy regarding steroid-benefit may be real and attributable to the differing populations under study, another intriguing hypothesis which emerged from a post-hoc substudy of VASST relates to a possible beneficial synergy between AVP and corticosteroid, with the authors of this substudy reporting a decrease in 28-d mortality from 44.7% to 35.9% in patients receiving corticosteroids plus AVP when compared with patients receiving corticosteroids in addition to norepinephrine.

Finally, rates of gastrointestinal hemorrhage, including that from gastroesophageal varices, were also similar between the AVP and non-AVP groups.

Our study has several limitations. First, it is retrospective in nature and suffers from missing data, a deficiency common to most retrospective analyses. Second, ours is a single center study with a relatively small sample size constraining analysis of additional variables. Third, we acknowledge the heterogeneity of the comparative group regarding the variety of second-line agents used. However, on the other hand, a salient feature of this study is that the 2<sup>nd</sup> vasoactive agent used in the comparator group was almost exclusively a catecholaminergic agent, which in effect resulted in a study comparing second-line vasopressin use vs second-line catecholaminergic augmentation.

Fourthly, an additional limitation relates to “cross-over” analysis, as we did not analyze our cohort of patients on the basis of whether or not they received AVP at any time during their course. Furthermore, we did not investigate the possible interaction between AVP and corticosteroids as discussed earlier. Our study is also relatively underpowered given the high 28-d mortality rates observed and the low-even rate of

patient survival. Other limitations include a lack of direct measurement of cardiac output or index with right heart catheterization in order to better characterize changes in hemodynamics following AVP administration.

Nevertheless, we provide more methodologically robust evidence for AVP use as a second-line vasopressor in catecholamine resistant septic shock and for attention to vasopressor selection in patients with cirrhosis. While further, large-scale multicenter prospective studies would be of benefit to refine current consensus standards, all potential lifesaving interventions, as long as the potential for iatrogenic harm is minimal, should be considered in this extremely sick patient population with 28-d mortality rates approaching 85%. Ultimately, the goal of correcting catecholamine-resistant septic shock in these patients involves both recovery from their immediate, life-threatening illness as well as providing for relative convalescence which may enable the individual patient to recover and receive a liver transplantation.

## COMMENTS

### Background

Cirrhosis patients with septic-shock requiring intensive care unit medical care have an exceedingly high mortality rate and are excluded from many existing clinical trials. Recent consensus guidelines suggest a role for vasopressin use in this patient population; however, this is based largely on expert opinion.

### Research frontiers

With the increasing prevalence of cirrhosis globally and improved access to tertiary medical care, the care of the critically ill patient with cirrhosis of the liver cannot be ignored. Current research and clinical care focuses largely on keeping the critically ill patient with cirrhosis alive in order to eventually receive a life-saving liver transplantation. The role of vasopressin in this population remains unknown.

### Innovations and breakthroughs

In the present study, the authors found that vasopressin is similar to all other vasopressors in terms of 7-d and 28-d mortality and in the absence of significantly more deleterious effects suggest a role for vasopressin use in patients with cirrhosis admitted to the intensive care unit with septic shock.

### Applications

The present report provides further evidence on the safety and efficacy of vasopressin use in patients with cirrhosis, and may suggest revisiting the currently available critical care guidelines.

### Peer-review

This retrospective cohort adds useful information for both clinical practice and further academic research with the goal of impacting common patient centered outcomes for critically ill patients with extremely high mortality rates.

## Abstract

### AIM

To delay surgery until the patient is in a better condition, and thus to decrease postoperative morbidity.

### METHODS

Using this algorithm we treated three patients aged 55, 75 and 80 years. In all three patients the clinical presentation was fever without a clear source of infection; all had nonspecific symptoms such as general malaise, dyspnea, and abdominal discomfort in the previous 15 d. They came to the emergency room at our hospital due to deterioration of their general condition. Analytical tests showed leukocytosis, neutrophilia and increased polymerase chain reaction. In all cases an abdominal computed tomography (CT) was performed and liver hydatid abscess (LHA) was detected. The mean size of the LHA was 12 cm.

### RESULTS

All patients underwent CT-guided percutaneous drainage. The purulent material obtained was cultured, and *Klebsiella pneumoniae*, *Streptococcus viridans* and *Streptococcus salivarius* were identified. Antibiotic treatment was given adapted to antibiotic sensitivity testing. Surgery was performed two weeks after admission, once the patient's condition had improved. All three patients underwent an almost total cystectomy, cholecystectomy and omentoplasty in the residual cavity. Complications were: Clavien I (atelectasis and pleural effusion) and Clavien II (transfusion). The average length of stay (pre and postoperative) was 23 d. At the follow-up, no

relapses were recorded.

## CONCLUSION

LHA management is not standardized. Emergency surgery offers suboptimal results. Percutaneous drainage plus antibiotics allows improving patient's general condition. This enables treating patients in greater safety and also reduces complications.

**Key words:** Hydatidosis; Review; Surgery; Abscess; Liver

**Core tip:** Liver hydatid abscess (LHA) management is not standardized. The traditional treatment is emergency surgery but the results are usually suboptimal because the patients are in poor medical condition. The initial treatment of LHA in septic patients with percutaneous drainage in combination with antibiotic therapy and supportive measures allows control of the infection and improves the patient's general condition. This enables the physician to treat the patient in greater safety and also reduces complications.

## INTRODUCTION

Cystic echinococcosis is a zoonotic disease that is found worldwide. It is caused by larvae of the genus *Echinococcus*, and is endemic in certain areas of the planet<sup>[1]</sup>. The liver is the most common location for cyst development<sup>[2]</sup>. Infection of the liver hydatid cyst (LHC) and pyogenic abscess formation is a rare but highly severe complication. The clinical course is insidious and it is usually diagnosed when the infection has progressed, affecting the patient's overall condition and possibly even causing septic shock<sup>[3]</sup>. The treatment of liver hydatid abscess (LHA) is not yet standardized. Several options are available with the dual purpose of draining the LHA and treating the LHC, including simple surgical drainage, or surgical drainage associated with total or subtotal pericystectomy and percutaneous drainage<sup>[3]</sup>. We propose percutaneous drainage of the LHA as a first therapeutic step, and later, when the patient's general condition improves, surgical treatment of the LHC.

## MATERIALS AND METHODS

From May 1, 2007 to March 1, 2016 we treated 135

patients with LHC, of whom 72 underwent surgery. Three of these patients debuted with a severe septic condition caused by LHA. These patients were initially treated with computed tomography (CT)-guided percutaneous drainage of the abscess, and then underwent scheduled surgery when their condition had improved. Their data are included in Table 1.

We also conducted an unlimited literature search in PubMed, updated on 1 January 2016, with the following strategy: [(echinococcosis hepatic complications) and (liver abscess)], which yielded 136 papers. Review of the abstracts found three papers related to the topic of the current paper, and their references were analyzed. The aim of this review was to assess the literature on the value of percutaneous drainage in LHA for delaying surgery until the patient is in a better overall condition, in order to reduce postoperative morbidity and to perform definitive treatment of LHC.

## RESULTS

### Patients 1

Male, 80 years old, came to the Emergency Department due to fever, dyspnea and general malaise of 15 d's duration with hypotension, tachypnea and tachycardia. Past medical history: Mild Alzheimer's disease. His analysis showed: 18610 leukocytes, 90.8% neutrophils, hemoglobin 8.4 g/dL, INR 1.13, Cr 0.75 mg/dL, GGT 433 U/L, AST 35 U/L. Abdominal ultrasound showed a right liver lesion with calcified wall and echoes inside, probably detritus, compatible with LHA. Abdominal CT revealed a 13 cm liver mass with hypodense fluid level suggestive of LHA (Figure 1). CT-guided percutaneous drainage was performed and obtained purulent material. In the microbiology cultures, *Klebsiella pneumoniae* was identified. The patient received antibiotic therapy adjusted to antibiogram (piperacillin-tazobactam 4 g-0.5 g/8 h). Sixteen days later, with the patient in a satisfactory clinical and analytical condition, a subtotal cystectomy was performed after extensive cleaning of the cyst, cholecystectomy, bile duct exploration, closure of small cystobiliary communications and omentoplasty. Histopathology study showed the typical pericystic wall of LHC. After surgery, the patient suffered atelectasis and pleural effusion, and fungaemia (*Candida Albicans*) treated by fluconazole and requiring transfusion. He was discharged on postoperative day 34 (total stay: 50 d). He died 14 mo later of other medical causes, with no evidence of LHC recurrence at the CT performed one year after surgery.

### Patients 2

Female, 75 years old. Past medical history: Hypertension and diabetes mellitus. She came to the Emergency Department due to fever and malaise of several days, severe, with hypotension, tachypnea and tachycardia. Analysis: 24610 leukocytes (95% neutrophils), Hb 10.9 g/dL, INR 1.24, Cr 1.56 mg/dL, polymerase chain

**Table 1 Clinical debut, analysis, diagnostic methods, surgery, morbidity and follow-up of our cases**

	Case 1	Case 2	Case 3
Sex	Male	Female	Female
Age (yr)	80	75	55
Age	80	75	55

reaction (PCR) 315 mg/L, GGT 70 U/L and AST 47 U/L. Abdominal CT revealed a 12 cm abscess in the left liver compatible with LHA. CT percutaneous drainage was performed, obtaining purulent material (Figure 2). In microbiological cultures *Streptococcus viridans* was identified. She received empiric antibiotic treatment adjusted later to amoxicillin/clavulanic acid (1 g/8 h) as a result of the antibiogram. She was admitted to the intensive care unit due to severe SIRS and finally underwent surgery after 12 d when her clinical condition had improved. A right subcostal laparotomy was performed, revealing a LHA located in segments III, IVb, V

and VI. Subtotal cystectomy, cholecystectomy and bile duct clearance were performed. Postoperative course was uneventful and the patient was discharged after 5 d (total stay: 17 d). Histopathology showed chronic cholecystitis and hydatid cyst wall. No recurrence was seen at follow-up sessions over a 6-year period.

### **Patients 3**

Female, 55 years old. Past medical history: Human immunodeficiency virus infection and pulmonary fibrosis. She came to the Emergency Department for high

Figure 3 Abdominal computed tomography: Liver hydatid abscess.

fever ( $>39^{\circ}\text{C}$ ) accompanied by discomfort in right hypochondrium, with hypotension, tachypnea and tachycardia. Analytical results: 18666 leukocytes, 84.8% neutrophils, Hgb 10.6 g/dL, INR 1.14, PCR 19.4 mg/dL, GGT 270 U/L, AST 379 U/L. Abdominal radiography revealed an abdominal mass with fluid level in right hypochondrium. Abdominal CT showed a 11.5 cm liver mass located in segments VI and VII with fluid level (Figure 3), communicating with the bile duct and causing inferior vena cava compression. Empirical broad spectrum antibiotic therapy (piperacillin-tazobactam) was given. CT-guided percutaneous drainage was performed obtaining purulent material. *Streptococcus salivarius* was identified in microbiological cultures. Antibiotic therapy was changed to amoxicillin/clavulanic acid (1 g/8 h) as a result of the antibiogram. ERCP plus sphincterotomy was performed because of a frank intrabiliary rupture identified on CT. She was scheduled for surgery 15 d after coming to our center. After right subcostal incision, an 11-cm LHC was found in segments VII and VIII attached to the diaphragm, right hepatic vein and inferior cava vein. A subtotal cystectomy was performed. Postoperatively, the patient required red blood cell transfusion and was discharged on the fourth day (total stay: 19 d). Histopathology showed a pericystic wall with fibrosis, inflammation and calcification. No recurrence was seen at the last follow-up visit 2.5 years later.

## DISCUSSION

The most severe complications of LHC are rupture, biliary fistula and infection of the cyst, evolving into a liver hydatid abscess<sup>[4]</sup>. LHA has a prevalence of about 25%. In Manterola's series it was the most frequent complication (24.6%), but in ours it accounted for only 4.1%<sup>[3]</sup>. We attribute this huge difference to the lack of a generally accepted worldwide definition of LHA. Some authors define LHA as any hydatid cyst which presents purulent content if opened during surgery, but others require bacterial growth in microbiological cultures in both cases with or without infectious symptoms. Our idea is that LHA should be defined not only in the presence of pus or positive cultures but always with

severe infectious symptoms such as high fever, malaise, or even septic shock. The infection that provokes LHA may be primary, due to the invasion of bacteria from small bile ducts communicating into the cyst or rarely through the hematogenous route, or secondary, due to a communication through a fistula with the peritoneal cavity, bronchi, digestive tract, or skin, and after conservative surgery or incomplete PAIR<sup>[4]</sup>.

LHA patients are generally asymptomatic or have nonspecific clinical manifestations. Diagnosis is often made due to the clinical manifestations of other complications such as acute cholangitis, peritonitis, pericarditis or bronchobiliary fistula<sup>[5]</sup>. In the days prior to diagnosis all our patients reported nonspecific and insidious symptoms such as fever, malaise, dyspnea, abdominal discomfort and a progressive and significant deterioration in their general condition. The scarcity of symptoms of LHA (compared with pyogenic liver or intra-abdominal abscess) is probably due to the action of the pericystic wall offering theoretical protection against infectious dissemination<sup>[6]</sup>.

Usually, the first tool for diagnosing LHA is ultrasound. The ultrasound image of the LHA may not be characteristic, and differential diagnosis should include uncomplicated cyst type I Gharbi, liver abscess from another origin, or infected simple cyst<sup>[7]</sup>. In one of the cases reported here abdominal radiography provided important clues for diagnosis. CT was the best diagnostic method in our short series, but no evidence-based medicine information can be drawn from only three cases.

The management of LHA is not standardized. Simple surgical drainage of the cyst has been described, but this technique may need subsequent additional surgical procedures; if cyst surgery is not performed, relapse and chronic complications due to the persistence of residual cyst cavity are frequent<sup>[6]</sup>. The most widely accepted approach is non-scheduled conservative surgery, usually subtotal pericystectomy including opening of the cavity, exhaustive cleaning of the cyst, eradication of the parasite and closing of the cystobiliary fistulas. But this type of surgery could be suboptimal because the patient is often in a poor clinical condition, and in fact LHA is a risk factor for postoperative complications (especially infections) in patients undergoing surgery for LHC<sup>[8]</sup>. To our knowledge, percutaneous drainage of the cyst, supportive measures and intravenous antibiotics as a therapeutic bridge to more radical and safer surgery have not been described previously. Here we present three patients treated with this approach in whom we were able to control the infection and improve the patients' clinical condition prior to scheduled surgery two weeks later. What is more, we were able to perform an ERCP in one of our patients with a frank intrabiliary rupture. The improved medical condition allowed us the possibility of resecting a greater quantity of cyst, thus reducing the risk of possible relapse.

To conclude, percutaneous drainage of LHA as a bridge to surgery may be a valid procedure especially

in patients at high surgical risk due to septic conditions. With this approach we were able to control the infection with antibiotics and perform surgery once the patient's overall condition had improved.

## COMMENTS

### Background

Cystic echinococcosis is a zoonotic disease that is found worldwide. It is caused by larvae of the genus *Echinococcus*, and is endemic in certain areas of the planet. The liver is the most common location for cyst development. Infection of the liver hydatid cyst (LHC) and pyogenic abscess formation is a rare but highly severe complication.

### Research frontiers

The clinical course is insidious and it is usually diagnosed when the infection has progressed. The treatment of liver hydatid abscess (LHA) is not yet standardized. Several options are available with the dual purpose of draining the LHA and treating the LHC, including simple surgical drainage, or surgical drainage associated with total or subtotal pericystectomy and percutaneous drainage.

### Innovations and breakthroughs

The authors propose percutaneous drainage of the LHA as a first therapeutic step, and later, when the patient's general condition improves, surgical treatment of the LHC.

### Applications

The authors present a new therapeutical option that could let surgeons to obtain better results.

### Peer-review

Interesting case series of three cases. Detailed description and very helpful Table 1.

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Peter L Lakatos, FEBG, PhD, Associate Professor, 1<sup>st</sup> Department of Medicine, Semmelweis University, H1083 Budapest, Hungary

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Liver cancer is the third leading cause of cancer mortality worldwide with hepatocellular carcinoma (HCC) representing more than 90% of primary liver cancers. Most HCC patients are also suffering from chronic liver disease (CLD). Evidence is emerging that the composition

of diet plays an important role in HCC and CLD development and may also have a chemoprotective role. In contrast to other types of cancer, there are few studies investigating the role of diet in hepatocarcinogenesis. From the available data it is evident that high intakes of red meat and dietary sugar positively correlate with HCC occurrence. On the contrary, high consumption of white meat, fish, vegetables, fruits and cereals are inversely associated with HCC risk. This letter discusses the potential role of dietary interventions in the prevention of hepatocarcinogenesis. The increasing HCC incidence and its high fatality are making HCC prevention an urgent matter. Dietary modifications are found to offer protection against HCC, however, new studies from well-designed and large prospective trials are required to confirm these results.

**Key words:** Cancer prevention; Diet; Hepatitis virus; Meat; Hepatocellular carcinoma

**Core tip:** Hepatocellular carcinoma (HCC) is the third leading cause of cancer mortality. Evidence shows that diet relates to HCC risk and may also have a protective role. Several dietary factors such as vegetables, cereals, fruits, white meat and fish have been found to be inversely associated with HCC risk, whereas a positive correlation has been found with red meat and dietary sugar intakes. The increasing HCC incidence makes its prevention an urgent matter and diet intervention represent an attractive potential. Dietary modifications are found to protect against HCC, however, new studies from well-designed and large prospective trials are required to confirm these results.

Koumbi L. Dietary factors can protect against liver cancer development. *World J Hepatol* 2017; 9(3): 119-125 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i3/119.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i3.119>

## INTRODUCTION

Hepatocellular carcinoma (HCC) is third leading cause of cancer mortality worldwide and accounts for about 90% of primary liver cancers. The major risk factors for HCC occurrence include chronic infection with hepatitis B virus (HBV) and hepatitis C virus (HCV), excess of alcohol consumption, non-alcoholic fatty liver disease (NAFLD), dietary aflatoxin exposure, obesity, smoking and diabetes mellitus<sup>[1]</sup>. Exposure to these factors can injure the liver leading to chronic liver disease (CLD) and patients with CLD are at high risk of developing HCC. A substantial proportion of HCC, however, occurs in patients without exposure to these risk factors<sup>[2]</sup>, suggesting the existence of additional factors.

For the past few decades, epidemiological evidence has shown that diet-related factors are closely related with cancer. A healthy diet is known to reduce the development of some types of cancer, while a poor diet increases cancer risk<sup>[3]</sup>. However, there is no current definition of healthy eating. Observational studies have indicated a protective role of vegetables, fruits and cereals in cancer prevention. In contrast to other types of cancer, there are relatively few studies that investigated the association of diet and HCC risk. Although studies have reached conflicting results, consistent evidence suggests that high intakes of red meat<sup>[4,5]</sup> and dietary sugar<sup>[6]</sup> should be avoided in at-risk populations. Higher intakes of white meat or fish<sup>[7-10]</sup>, vegetables<sup>[10-16]</sup>, fruits<sup>[10,14,17,18]</sup>, cereals<sup>[6]</sup>, eggs<sup>[10,17,18]</sup>, milk<sup>[18]</sup> and yogurt<sup>[10]</sup> have been reported to decrease HCC development. Dietary patterns can capture interactions between dietary components and other risk factors providing a better understanding of the association between dietary intakes and HCC risk. Here the impact of dietary patterns on the prevention of HCC is being discussed.

## RED MEAT

Red meat is an important dietary source of saturated and monounsaturated fatty acids and iron. A number of studies associated meat, especially red and processed meat, with gastrointestinal cancers, including HCC<sup>[5,10,13,17-23]</sup>. Nanji *et al*<sup>[24]</sup> was the first to report in 1985 that high pork intake correlated with liver cancer mortality and since then significant associations between total red meat and an increased risk of CLD and HCC have been found<sup>[4,25,26]</sup> (Table 1). A large prospective study by Freedman *et al*<sup>[4]</sup> with a United States cohort revealed an association between total fat, monounsaturated fat, and saturated fat with both CLD and HCC incident and another smaller study from Greece observed that that high saturated fat intake correlated with liver cirrhosis and HCC<sup>[26]</sup>. One study of daily beef, pork and poultry intake found a statistically significant positive association between red meat and HCC risk in an age- and sex-adjusted analysis<sup>[5]</sup>. On the contrary, Polesel *et al*<sup>[27]</sup> reported no direct association of HCC risk with saturated fat intake and results from a Greek case-control study showed no

association with any fat type<sup>[20]</sup>. Notably, Polesel *et al*<sup>[27]</sup> did report a positive association between iron intake and HCC. Furthermore, a recent meta-analysis study by Luo *et al*<sup>[28]</sup> as well as the multicenter prospective EPIC cohort study, which associates diet with various types of cancer, reported no association between different kinds of meats (red and processed meats or poultry) and increased HCC risk<sup>[7,28,29]</sup>. The EPIC study, however, found that a 20 g/d substitution of fish with meat results in a 16% decrease in HCC risk.

The link between red meat and liver cancer is biological plausible, since red meat contains high amounts of known carcinogens including heme iron, N-nitroso compounds (NOC) and heterocyclic amines (HCA) that are produced when meat is cooked in high temperatures<sup>[30]</sup>. Red meat contains high amounts of bioavailable heme iron while reactive oxygen species are being formed when iron undergoes reduction. Interestingly, individuals with hereditary hemochromatosis, an iron overload disease, have substantially increased HCC occurrence<sup>[31]</sup>. Also excess dietary iron has been shown to contribute to HCC risk in several parts of Africa, and treatment with chelating agents, repeated phlebotomy and low iron diet appear to reduce the HCC incident<sup>[32]</sup>. Freedman *et al*<sup>[4]</sup> 2010 observed that meat processing, its heme iron and NOCs associated with CLD but not with HCC. A case-control study with an Italian cohort revealed a significant positive association between dietary iron intake and HCC risk but did not investigate the role of heme iron<sup>[27]</sup>. HCA and polycyclic aromatic hydrocarbons, carcinogens are generated during high-temperature cooking, and NOCs compounds have been shown to induce liver tumour development<sup>[30]</sup> while high doses of HCAs cause liver tumours in primates<sup>[30]</sup>. The higher fat content of red meat could also explain the harmful effect. Red meat and processed meat contain high levels of cholesterol and saturated fat, and correlate with high risk of obesity and diabetes, which are known as cancer risk factors. In addition, fat intake may play a role in insulin resistance, which relates with liver disease and cancer. Fatty acid deposition in the liver can result in NAFLD therefore increasing the risk of CLD and HCC<sup>[33]</sup>.

Although conflicting results, it can be suggested that red meat intake positively associates with CLD and HCC risk. The observed discrepancies between the studies can be attributed to the limitations of the studies, including differences in the dietary patterns of the various countries studied. However, further large prospective randomized trials investigating the relationship between meat intake and HCC risk are required to reach conclusive results.

## WHITE MEAT AND FISH

Evidence from case control and prospective studies from the NIH-AARP Diet and Health study, Italy and Japan reported an inverse association of white meat, including chicken, turkey and fish, with HCC development<sup>[4,7,8,10,29]</sup> (Table 1). In the EPIC study, the subgroup analyses revealed that lean fish, fatty fish, crustaceans and

Association of red and processed meat intake with HCC risk	Study design: Case-control Cases: 403 Controls: 567169 Duration: 1995-2006 Type of meat: Processed meat	United States	Cross <i>et al</i> <sup>[25]</sup> , 2007
Association of dietary iron intake and HCC risk Inverse association of linoleic acid (white meat) intake and HCC risk	Study design: Case-control Cases: 185 Controls: 412 Duration: 1999-2002 Intake: Total meat	Italy	Polesel <i>et al</i> <sup>[27]</sup> , 2007
Association of red meat and saturated fat intake with CLD and HCC risk Inverse association of white meat with HCC and CLD risk	Study design: Case-control Cases: 338 Controls: 495006 Duration: 1995-2006 Intake: White and red meat	United States	Freedman <i>et al</i> <sup>[4]</sup> , 2010
Inverse association of fish or n-3 PUFAs intake and HCC risk	Study design: Cohort Cases: 398 Controls: 90296 Duration: 1990-2008 Intake: Fish	Japan	Sawada <i>et al</i> <sup>[9]</sup> , 2012
Inverse association of vegetables intake and HCC risk	Study design: Case control Cases: 267 Controls: 132837 Duration: 1997-2006 Intake: Meat	China	Zhang <i>et al</i> <sup>[41]</sup> , 2013
Inverse association of fish intake and HCC risk HCC risk decreases by 16% for 20 g/d substitution of fish with meat	Study design: Cohort Cases: 157 Controls: 35628 Duration: 1992-2000 Intake: Dietary flavonoids	World-wide	Zamora-Ros <i>et al</i> <sup>[46]</sup> , 2013
Inverse association of fish intake and HCC risk No association of meat and poultry intake and HCC development	Study design: Cohort Cases: 191 Controls: 477206 Duration: 1992-2010 Intake: Total meat, fish, red and white meat	Europe	Fedirko <i>et al</i> <sup>[7]</sup> , 2013
HCC risk decreases by 8% for every 100 g/d increase in vegetable intake	Study design: Meta-analysis Cases: 3912 Controls: 1290045 Duration: 1956-2014 Intake: Vegetables and fruits	World-wide	Yang <i>et al</i> <sup>[43]</sup> , 2014

HCC: Hepatocellular carcinoma; CLD: Chronic liver disease.

molluscs independently associated with low HCC risk<sup>[7]</sup>. In a large population-based prospective Japanese cohort, Sawada *et al*<sup>[9]</sup> revealed that the consumption of fish or n-3 polyunsaturated fatty acids (n-3 PUFA) protects against the HCC development even among subjects with HBV and/or HCV infection, and Freedman *et al*<sup>[4]</sup> reported an inverse association between fish intake and CLD risk.

The finding that both fish and white meat reduce HCC risk is unforeseen. Nutritionally, fish and white meat are a rich source of PUFA and have less cholesterol and saturated fat compared with red meat. Substantial evidence indicates that n-3 PUFA possess anti-inflammatory activity by inhibiting IL-1 and TNF synthesis<sup>[34]</sup>, which can contribute in HCC prevention, considering that chronic inflammation plays a central role in HCC development. PUFA might exert anticancer effects also through their ability to induce apoptosis, to modulate cell cycle and eicosanoid production<sup>[35]</sup>. In particular, n-3 PUFAs have been shown to inhibit HCC growth *in vitro* through the blockage of  $\beta$ -catenin and cyclooxygenase-2<sup>[36]</sup>. It is observed that n-3 PUFA supplementation can improve hepatic steatosis in patients with NAFLD in a pilot study<sup>[37]</sup>. All of this evidence support a possible chemoprotective effect for fish and white meat on HCC development and suggest a molecular mechanism of n-3 PUFA in HCC prevention. However, some fatty acids themselves can also have harmful effects, particularly the saturated fats and trans fatty acids since their increased consumption is strongly linked with the development of non-alcoholic steatohepatitis and its progression to cirrhosis and fibrosis<sup>[38]</sup>. As there is significant heterogeneity in fat subtypes within most foods, increasing fatty acid consumption should not be encouraged in at-risk populations at least until more studies prove the potential benefits of specific PUFA supplements.

## MILK AND EGGS

High intake of milk, yogurt and eggs was found to reduce liver cancer risk in a case control study<sup>[10]</sup>. Decreased risk of HCC with highest milk intakes was also reported in another case-control study from Italy<sup>[18]</sup>, while a Japanese case-control study revealed a higher risk with greater than average milk consumption<sup>[19]</sup>. Saturated fat from dairy products was also independently associated with CLD and HCC risk<sup>[4]</sup>. However, two other studies from China and Japan did not find such associations<sup>[17,39]</sup>. An inverse correlation between egg and HCC has been observed in two Italian case-control studies<sup>[10,18]</sup>, while a Japanese study reported an increased risk of HCC for high egg consumption in men only<sup>[19]</sup>. Such discrepancies, however, may be attributed to different dietary habits between the studied populations, such as the use of fat for cooking. Notably eggs are a different diet indicator in Italy and Japan. The inverse association with dairy products and eggs could be explained by their retinol content, since serum retinol levels have been

inversely related to HCC risk in a case-control study from China<sup>[40]</sup>.

## VEGETABLE, FRUIT AND CEREALS

The association of vegetable and fruit intakes with HCC incidence has been investigated by a number of observational studies since Negri *et al*<sup>[14]</sup> revealed in a case-control study in the 1990s that high intake of vegetables and fruit was inversely associated with risk of upper digestive cancers, including HCC. The majority of studies reported inverse associations between high vegetable consumption and liver cancer risk<sup>[1,10,11,13-15,17,41]</sup> (Table 1). In the large prospective study of a US cohort and two European cohorts it was revealed that adherence to the high vegetable content diets of the dietary recommendations and the Mediterranean diet decreases HCC risk<sup>[42,43]</sup>. This observation was confirmed by Yang *et al*<sup>[43]</sup> in a meta-analysis on 19 published studies where it was reported that HCC risk decreases by 8% for every 100 g/d increase in vegetable intake. On the contrary, two case-control studies from Greece reported no association, although they involved a small number of cases<sup>[20,44]</sup>. The role of fruit consumption in HCC risk is more controversial. Three case-control studies reported a decreased liver cancer risk with higher fruit intake<sup>[10,13,18]</sup>, while other four studies found no such association<sup>[19,20,28,41]</sup>. Another case-control study in northern Italy found that the population attributable-risk for liver cancer was as high as 40% for low vegetable and fruit consumptions<sup>[11]</sup>.

Vegetables and fruits are major sources of vitamins, minerals, dietary fibres, and other bioactive compounds, including flavonoids. Several *in vitro* studies have shown an anti-tumour effect of flavonoids in some hepatocarcinoma cell lines<sup>[45,46]</sup> while in animal models, flavonoids have been shown to modulate mechanisms involved in proliferation, invasion, angiogenesis, survival and metastasis<sup>[47]</sup>. According to the EPIC study and a case-control study from Greece an inverse association exists between the flavonoids subclass, flavones, and HCC occurrence<sup>[46,48]</sup>. Therefore, flavonoids may explain the favorable effects of vegetables and fruits against liver cancer. In addition, evidence is emerging from cell culture and animal model experiments that phytochemicals and other bioactive components found in vegetables, such as diallyl sulphides, lentinan, apigenin and luteolin, have cancer-inhibitory effects through their anti-oxidative properties, stimulation of the immune system, or inhibition of mutagenesis<sup>[41]</sup>. An animal study on effects of dietary dry bean on hepatic gene expression in rats, found that the expression of six genes was significantly altered after high bean intakes suggesting that these genes may exert cancer preventive effects in liver<sup>[49]</sup>.

A protective role of dietary fiber has been also suggested in HCC development<sup>[6]</sup>. High intake of fiber from cereals and cereal derivatives was found to be statistically significantly inverse associated with HCC risk. Consumption of fiber from vegetables or other sources (but not fruits)

was also revealed to have a chemoprotective role in HCC development although a statistical significance was not reached<sup>[6]</sup>. Diets with a high fiber content, like cereals, could lower HCC occurrence by decreasing subjective appetite and energy intake and hence contributing to the maintenance of normal body weight as well as exerting beneficial effects on postprandial glucose level and blood lipid profile. Further research is needed to understand the mechanisms underlying these associations.

## DIETARY SUGAR

Dietary glycemic load (GL) estimates how much the food will raise a person's blood glucose level after eating it and is therefore the extent to which carbohydrate-rich foods increase the concentration of glucose in the blood to represent the total glycemic effect of a diet. GL has been associated with diabetes mellitus and with several types of cancer. The mechanism for the role of high GL in carcinogenesis is thought to be *via* increased insulin concentrations, glucose intolerance and insulin resistance, even in the absence of diabetes mellitus. Foods such as added sugars, syrups, sweets, white bread and soft drinks are the main culprits. One case control study from Italy showed a positive association between GL and HCC overall and interestingly a stronger association was observed in patients with HBV and HCV<sup>[50]</sup>. On the contrary, the EPIC study reported that GL and total carbohydrate intakes did not correlate with HCC risk<sup>[6]</sup>. However, when specific carbohydrates were analysed, a positive association was found for total sugar. Increased fructose intake is known to underlie NAFLD and may therefore provide a possible explanation for the positive association seen in HCC<sup>[51]</sup>.

## DIET IN VIRAL HEPATITIS-INDUCED HCC

HBV and HCV infections are major risk factors for the development of CLD and HCC. Three studies in the United States and Italy agree that the risk estimates for meat and fish consumption were similar between subjects with or without HBV and/or HCV infection<sup>[4,7,10,27]</sup>. The association of n-3 PUFA, fibers and flavonoids with HCC risk has also been found to exist independently of the HBV and/or HCV status<sup>[6,9,46,48]</sup>. However, the positive correlation of GL and HCC was observed to be stronger in patients with HBV and HCV in one case control study from Italy<sup>[50]</sup>. This evidence indicates that the dietary patterns, possibly except the GL, do not appear to affect HCC outcome in chronically HBV or HCV infected individuals. However, the possibility that dietary intakes can protect against the HCC progression in viral hepatitis infection cannot be excluded.

## CONCLUSION

Considering the increasing trend of HCC incidence and its high fatality, prevention of HCC is an urgent matter. At present attempts to prevent HCC mainly include the

control of HBV or HCV infection, reduction of alcohol consumption, and reducing the prevalence of obesity and diabetes. It is of great importance to discover novel strategies to prevent HCC and dietary factors represent an attractive potential.

Up to date the results from studies investigating the impact of dietary factors in HCC development are conflicting and often inconclusive. Notably, there are several limitations in the methodology of most studies, including selection bias, errors in diet assessment and insufficient adjustment for potential confounders such as HBV/HCV status, diabetes, alcohol and energy intake. Since both case control and prospective studies include data that comes from questionnaires, which are based on self-reported food intakes it is important to consider the dietary habits. Food consumption categories are different across the studies and this can contribute to the heterogeneity of the results. In addition, the case-control studies assessed diet after HCC diagnosis, at which stage the health of individuals has already been compromised, affecting the accuracy of dietary recall. Indeed, a major problem of the case-control studies on HCC is reverse causation because HCC precedes chronic hepatitis and cirrhosis. Furthermore, in the large prospective EPIC study, the diet was assessed only at baseline without considering any potential dietary changes during the follow-up, the period of exposure to cancer initiation was not taken into account and also that dietary patterns of different European countries may have not been fully accounted. It is therefore possible that dietary errors may have occurred that might underestimate the true associations described in the EPIC study.

Nevertheless from the available data it is evident that dietary factors play an important role in CLD and HCC occurrence and their identification can be used for the development of new public health diet recommendations. In particular, consistent associations indicate that higher consumption of vegetables, white meat, fish, milk and cereals have beneficiary effects in liver cancer development. It should be noted that increased consumption of fatty acids correlates with the progression of cirrhosis and fibrosis. The potential benefits of fat subtypes, deriving from white meat, fish and milk, should not be encouraged until more well designed studies prove their chemoprotective effect. Furthermore, it can be inferred that red meat and dietary sugar consumption intake associates with CLD mortality and HCC risk and hence their intake should be monitored and controlled in at-risk populations to attempt to slow down HCC development. Flavonoids appear to reduce the risk of HCC, but pharmacological doses might be required in order to effectively protect against carcinogenesis. Although current studies on infections with HBV and HCV suggest that the effect of diet is independent of viral hepatitis infection, an association between diet and hepatitis virus related HCC progression is possible.

To prevent disease progression to CLD or HCC it is crucial to investigate the impact of diet and subsequently to lead to the development of clinical trials using new

dietary patterns. Evidence from well designed prospective interventional studies with large sample sizes and long-term follow-up are required to develop diet modifications to lower HCC incidence or to prolong survival in HCC patients. Additional experimental and molecular research is also needed to explore the possible mechanisms involved.

### Abstract

Liver transplantation has been used in treatment of transthyretin amyloidosis, and some patients undergo domino liver transplantation (DLT) with explanted liver

being transplanted to another patient with liver failure as the liver is otherwise usually functionally normal. Until end of 2015, there were 1154 DLT performed worldwide. DLT for transthyretin amyloidosis is associated with the risk of developing *de novo* systemic amyloidosis and amyloid neuropathy, and the risk may be greater with some non-Val30Met mutations. *De novo* amyloid neuropathy has been described in up to 23% of transplant recipients. Neuropathy may be preceded by asymptomatic amyloid deposition in various tissues and symptoms of neuropathy started after a median of 7 years following DLT ( $5.7 \pm 3.2$  years; range 2 mo to 10 years). Typical initial symptoms include neuropathic pain and sensory loss, while dysautonomia usually starts later. Progression of neuropathy may necessitate liver re-transplantation, and subsequent improvement of neuropathy has been reported in some patients. Explant allograft recipients need close monitoring for signs of systemic amyloidosis, neuropathy and dysautonomia as progressive symptoms may require re-transplantation.

**Key words:** Transthyretin; Familial amyloid neuropathy; Domino liver transplantation; Systemic amyloidosis; Acquired amyloid neuropathy

## INTRODUCTION

Transthyretin familial amyloidosis is an autosomal dominant multisystem disorder caused by deposition of insoluble transthyretin (TTR) amyloid deposits in various tissues<sup>[1]</sup>. Amyloid deposits are found in peripheral nerve, liver, skin, heart and other organs, and peripheral neuropathy is one of the major clinical manifestations. Three main phenotypes of transthyretin familial amyloidosis include familial amyloid polyneuropathy (TTR-FAP), cardiomyopathy and leptomeningeal amyloidosis. Additionally, wild type TTR may be also deposited in senile systemic amyloidosis which more commonly presents with cardiomyopathy, and only rarely as neuropathy. TTR-FAP is a progressive sensorimotor neuropathy with dysautonomia which results in a severe disability. The neuropathy usually starts with distal sensory loss and dysesthesias, followed by autonomic dysfunction, while motor function is usually affected only later<sup>[2]</sup>. Carpal tunnel syndrome is usually an early feature, but there is a significant variability of symptoms, even among the patients with the same TTR mutation. Overall prevalence of TTR-FAP is estimated at 0.9-1.1 per 1000000 people, with expected survival of 7-12 years after the onset of symptoms<sup>[3-5]</sup>. To date more than 120 mutations of TTR have been reported to cause TTR-FAP, and high prevalence is found in endemic regions in Portugal, Japan and Sweden (up to 1 in 1000 to 1 in 10000), and the most common genotype with predominant neuropathy is Val30Met TTR mutation<sup>[6]</sup>.

Transthyretin is mainly synthesized in the liver and liver transplantation has been used to ameliorate the progression of systemic amyloidosis by decreasing the synthesis of abnormal TTR<sup>[7,8]</sup>. There is a shortage of liver grafts available for transplantation, and explanted liver of the patient with TTR amyloidosis is sometimes transplanted to another patient with liver failure as the liver is otherwise usually functionally normal Domino liver transplantation (DLT)<sup>[8]</sup>. Until end of 2015, there were 1154 DLTs performed worldwide<sup>[9]</sup>. Best outcomes for liver transplantation have been reported in young Val30Met patients with mild symptoms, and the overall 20-year survival after liver transplantation for TTR-amyloidosis has reached 55%<sup>[8,10,11]</sup>. In transplant patients (DLT donors) with non-Val30Met genotype, there is a wide spectrum of survival rates which vary a lot depending on the underlying mutations<sup>[12]</sup>. The overall risk of amyloid production by transplanted domino liver was thought to be low with potential delayed manifestations of amyloidosis in patients with otherwise very short survival if they are not transplanted. Nevertheless, amyloid deposition in the tissue may start soon after domino

transplantation and iatrogenic amyloid neuropathy may affect up to 8%-24% of DLT recipients<sup>[13,14]</sup>.

In this manuscript, we review clinical features of acquired amyloid TTR neuropathy after DLT.

## LITERATURE

We have identified 16 case reports with detailed description of acquired TTR-FAP in recipients of DLT in the literature search (Table 1)<sup>[14-23]</sup>. The patients were 73% men with age of  $60.7 \pm 10.4$  years. The most common TTR mutation was Val30Met ( $n = 10$ ; 61.3%), and others included Ser23Asn, Ser77Tyr, Leu58His, Thr49Ala, Gly47Glu, Glu54Gly ( $n = 1$  each; 6.7%). Underlying causes of liver failure include hepatitis C infection ( $n = 8$ ), hepatocellular carcinoma ( $n = 6$ ), hepatitis B infection ( $n = 5$ ), primary sclerosing cholangitis, primary biliary cirrhosis and nonalcoholic liver steatosis ( $n = 1$  each; some patients had more than 1 cause).

*De novo* amyloid neuropathy presented at after a median of 7 years following DLT ( $5.7 \pm 3.2$  years; range 2 mo to 10 years). Initial symptoms included neuropathic pain ( $n = 14$ ), sensory loss ( $n = 5$ ), erectile dysfunction ( $n = 2$ ), weakness, diarrhea and orthostatic hypotension ( $n = 1$ , each). Nerve biopsies showed amyloid deposits in 3 reported cases<sup>[16,18,23]</sup>. Other abnormal tests included positive rectal and abdominal fat ( $n = 2$  each), duodenal and endomyocardial biopsies ( $n = 1$  each) showing amyloid deposits. Three patients were treated with retransplantation of the liver, with improved outcome in two patients (outcome not reported in the third case).

The age of donors and recipients of domino liver allografts was not associated with an earlier onset of amyloid neuropathy. Non-Val30Met TTR mutations were overall associated with earlier onset of *de novo* TTR-FAP neuropathy (latency 3.95 years vs 6.83 years after transplantation; range 2 mo to 10 years).

## CONCLUSION

DLT has been advocated to alleviate shortage of liver allografts for patients in liver failure who would not have survived without such procedure. Initial reports estimated a low risk of systemic amyloidosis from synthesis of abnormal transthyretin liver allografts. Nevertheless, subsequent studies demonstrated that recipients of DLT are indeed at risk from systemic amyloidosis and some patients may develop *de novo* amyloid neuropathy after a median of 7 years following transplantation ( $5.7 \pm 3.2$  years; range 2 mo to 10 years). Similarly, less favorable survival of patients with non-Val30Met after liver transplantations (domino liver donors) was paralleled by shorter latency of *de novo* amyloid neuropathy in domino liver recipients with allografts with non-Val30Met TTR mutations (3.95 years vs 6.83 years)<sup>[12]</sup>. Nevertheless, there seems to be a marked variability of clinical course, depending on the underlying TTR mutation in domino liver donors (and allografts). Exceptionally short latency of *de novo* amyloid neuropathy in DLT recipients was reported with Ser23Asn and Leu58His TTR mutations

**Table 1** *De novo* transthyretin amyloid neuropathy cases after liver transplantation

Ref.	TTR mutation	Age at transplant	Latency (yr)	Cause of liver failure	Initial Neuropathy symptoms

[23]	Val30Met	47	8	HCV cirr	Pain

PBC: Primary biliary cirrhosis; NASH: Nonalcoholic hepatic steatosis; EtOH: Alcoholic liver cirrhosis; HBV: Hepatitis B virus; HCV: Hepatitis C virus; cirr: Cirrhosis of the liver; PSC: Primary sclerosing cholangitis; HCC: Hepatocellular carcinoma.

(< 6 mo)<sup>[14,19]</sup>. These series did not show an association with donor or recipient age with *de novo* systemic TTR amyloidosis, although other studies suggest that recipient aging may accelerate tissue deposition of amyloid<sup>[24]</sup>.

Clinically, these patients typically present with sensory loss and neuropathic pain, while dysautonomia is often not the initial symptom and follows later (Table 1). Tissue deposition of amyloid in the gastrointestinal tract and skin may precede clinical symptoms of neuropathy by several years<sup>[20,25]</sup>, and prospective study showed deposition of amyloid in salivary glands in up to 48% of DLT recipients<sup>[14]</sup>. Additionally, amyloid deposits were also found on sural nerve biopsies in the absence of clinical signs of neuropathy (research study and autopsy)<sup>[13,26]</sup>. Transthyretin amyloid neuropathy in DLT recipients presents in the context of systemic amyloidosis and *de novo* amyloid produced by transplanted liver is also found in myocardium, gastrointestinal tract, skin and fatty tissues<sup>[15,17,19-22]</sup>. Autopsy case of a DLT patient with asymptomatic amyloidosis at 8 years after transplantation (died from lymphoma) showed amyloid deposits in the heart, lungs, gastrointestinal tract (upper and lower), pancreas, spleen, testes, epididymis, prostate, skeletal muscle, thoracic sympathetic ganglia and median nerve (carpal tunnel syndrome)<sup>[26]</sup>. Amyloid deposition in the myocardium after DLT is usually asymptomatic, and so far only two cases of *de novo* cardiomyopathy after DLT have been reported with Val71Ala and Val30Met mutations<sup>[27,28]</sup>. One of the patients developed cardiac amyloidosis 5 years after retransplantation for systemic *de novo* amyloidosis after DLT, and it is unclear whether cardiac amyloidosis was related to wild-type or mutant transthyretin<sup>[28]</sup>. Similarly, DLT donors continue to have deposition of amyloid in different tissues of FAP-TTR patients after transplantation, which is at least partly related to wild-type ("senile") amyloid<sup>[29]</sup>. Worsening of peripheral neuropathy after transplantation has been reported in 24% of DLT liver allograft donors<sup>[5]</sup>, and ocular deposition of amyloid is

not abated after liver transplantation, as mutant TTR continues to be synthesized in the retinal pigment epithelium<sup>[30]</sup>.

While *de novo* amyloid neuropathy is associated with significant morbidity, DLT recipients may also have other potential causes of neuropathy and nerve biopsy may be needed to establish the etiology and exclude alternative etiologies<sup>[14]</sup>. Nevertheless, nerve biopsy may be false negative with a reported sensitivity of 33%-80%, and this may be attributed to uneven distribution of amyloid along peripheral nerves<sup>[31-33]</sup>. Biopsies of gastrointestinal tract, myocardium and fat aspirate may also demonstrate systemic deposition of amyloid in DLT recipients<sup>[15,17,19-22]</sup>.

*De novo* amyloid neuropathy presents in the context of systemic amyloidosis and careful monitoring of clinical manifestations of amyloidosis is needed after DLT (Table 2)<sup>[34]</sup>. Once iatrogenic amyloid neuropathy and systemic amyloidosis are diagnosed, treatment options are limited and retransplantation has been reported to stabilize or improve neuropathy in some recipients<sup>[15,16]</sup>. Tafamidis, a tetramer stabilizer, is approved for treatment of FAP-TTR in Europe, Japan, Mexico and Argentina and is used as first-line treatment for early FAP-TTR<sup>[35]</sup>. In countries where tafamidis is available, liver transplantation is often considered as a second-line option for patients who progressed on tafamidis or did not tolerate the treatment. Liver-retransplantation typically carries worse prognosis and more significant morbidity than the initial transplantation, but the survival after liver retransplantation in DLT recipients seems to be greater than in other subgroups of liver retransplant recipients<sup>[36]</sup>. Despite a single report of benefits with deflunisal<sup>[37]</sup>, potential benefits of treatment with tetramer stabilizers in DLT recipients remain uncertain. There are also no reports on efficacy of inhibition of expression of *TTR* gene in this setting. At this time, tafamidis remains available in a limited number of countries, and new experimental treatments are still not ready to substitute the role of DLT in treatment of systemic amyloidosis. In conclusion, DLT

**Table 2** Evaluation and monitoring of possible *de novo* amyloidosis after domino liver transplantation

Clinical presentation	Signs and symptoms	Testing
Dysautonomia (small fiber neuropathy)	Orthostatic hypotension Sweating abnormalities (anhidrosis) Constipation/diarrhea Erectile dysfunction Neuropathic pain Arrhythmia Neurogenic bladder	Tilt table testing QSART with autonomic battery ECG Neurologic examination
Large fiber polyneuropathy	Sensory loss Weakness Neuropathic pain Ataxia Areflexia	EMG/NCS Nerve (and muscle) biopsy Neurologic examination
Cardiac amyloidosis	Fatigue Arrhythmia Syncope Orthostatic hypotension	ECG Transthoracic echo Radionuclide imaging Cardiac MRI Endomyocardial biopsy BNP/troponin GI tract biopsy
Gastrointestinal amyloidosis	Constipation/diarrhea Nausea/vomiting	
Ocular amyloidosis	Dry eye Vitreous opacity Glaucoma	Ophthalmologic evaluation
Leptomeningeal amyloidosis	Cerebral infarction/hemorrhage Hydrocephalus Ataxia Spastic paresis Seizures Dementia	MRI of brain and spinal cord Meningeal biopsy
Other system involvement	Coldness Weight loss Peripheral edema Anemia Dry mouth	Rectal and abdominal fat biopsy Salivary gland biopsy TSH Urinalysis/urine protein collection

QSART: Quantitative sudomotor axon reflex test; ECG: Electrocardiograph; EMG/NCS: Electromyography and nerve conduction studies; MRI: Magnetic resonance imaging; BNP: Brain natriuretic peptide; GI: Gastrointestinal; TSH: Thyroid stimulating hormone.

is associated with the risk of developing *de novo* systemic amyloidosis and amyloid neuropathy, and the risk may be greater with some non-Val30Met mutations. Explant allograft recipients need close monitoring for signs of systemic amyloidosis, neuropathy and dysautonomia as progressive symptoms may require re-transplantation.

### Abstract

The Cockcroft-Gault (CG) equation has become perhaps the most popular practical approach for estimating renal function among health care professionals. Despite its widespread use, clinicians often overlook not only the limitations of the original serum creatinine (SCr) based equation, but also may not appreciate the validity of the many variations used to compensate for these limitations. For cirrhotic patients in particular, the underlying pathophysiology of the disease contributes to a falsely low SCr, thereby overestimating renal function with use of the CG equation in this population. We reviewed the original CG trial from 1976 along with data surrounding clinician specific alterations to the CG equation that followed through time. These alterations included different formulas for body weight in obese patients and the "rounding up" approach in patients with low SCr. Additionally, we described the pathophysiology and hemodynamic changes that occur in cirrhosis; and reviewed several studies that attempted to estimate renal function in this population. The evidence we reviewed regarding the most accurate manipulation of the original CG equation to estimate creatinine clearance (CrCl) was inconclusive. Unfortunately, the homogeneity of the patient population in the original CG trial limited its external validity. Elimination of body weight in the CG equation actually produced the estimate closest to the measure CrCl. Furthermore, "rounding up" of SCr values often underestimated CrCl. This approach could lead to suboptimal dosing of drug therapies in patients with low SCr. In cirrhotic patients, utilization of SCr based methods overestimated true renal function by about 50% in the literature we reviewed.

## INTRODUCTION

In order to optimize efficacy and minimize potential toxicity of pharmacologic agents, appropriate patient-specific dosing of medications remains an inherent responsibility of all healthcare providers. Proper assessment of a patient's renal function is essential when managing medications that are primarily renally excreted<sup>[1]</sup>. With an estimated 14% of adults in the United States experiencing varying degrees of chronic kidney disease (CKD), optimization of drug therapies poses a frequent challenge to clinicians<sup>[2]</sup>. Renal impairment may significantly alters the pharmacokinetic (PK) properties of many medications<sup>[3]</sup>. Therefore, reasonably accurate yet convenient quantification of the degree of renal impairment is an essential tool for clinicians implementing renal dose adjustments<sup>[3]</sup>.

In the majority of clinical settings, calculating the creatinine clearance (CrCl) using the Cockcroft-Gault (CG) equation has become the most popular and practical approach for estimating renal function<sup>[4,5]</sup>. Many institutions provide dosing recommendations based on calculated CrCl, and even often utilize electronic health record (EHR) software that automatically calculates CrCl based on the CG equation. Unfortunately, some clinicians fail to realize the inherent limitations of a serum creatinine (SCr) based equation and the subsequent variations that stem from many of these limitations<sup>[1,4,6]</sup>.

SCr concentrations can be altered by patient specific factors including age, sex, weight, muscle mass, disease state, diet, and certain drug therapies, thus limiting the generalizability of the CG equation<sup>[1,4-6]</sup>. For example, patients with hepatic impairment not only experience altered drug metabolism, but also have secondarily reduced creatinine production. If not taken into consideration, these SCr-based formulas can lead to an overestimation of GFR in cirrhotic patients<sup>[7]</sup>.

To help clarify the true applicability of the CG equation, we will discuss the origins of the CG equation and

the evidence and reasoning behind specific alterations to the equation used in current practice.

## DATA SOURCES AND SELECTION

Data included in this review were identified from a PubMed search of publications starting in 1970 through June of 2016. Searches included the keywords "Cockcroft-Gault", "serum creatinine", "creatinine clearance", "renal function", "cirrhosis" and related search terms. Publications were considered for review if they were designed as meta-analyses, retrospective, or prospective studies that compared different methods of estimating CrCl using the CG equation.

## THE ORIGINS OF THE COCKCROFT-GAULT EQUATION

The CG equation (Table 1A; equation I) was derived from 236 patients (96% male), aged 18-92 years old in 1976 at the Queen Mary Veterans' Hospital in Canada. SCr values used in the equation were the mean values calculated from two 24-h SCr levels obtained from blood for each patient at steady state. The CrCl was calculated using 4 different formulas (Table 1A; equations I-IV) that were compared against each other and with each patient's 24-h urine creatinine excretion. The CG equation was found to provide an estimated CrCl that was  $80\% \pm 30\%$  of the actual creatinine clearance calculated from the 24-h urine creatinine excretion test<sup>[5]</sup>.

Limitations acknowledged at the end of this trial included requirements for SCr to be at steady state, the need for normal relationship between muscle mass and total body weight, and factors related to age, sex, and height. In addition to this, the formula was tested in a patient population that was 96% male, which obviously limits the external validity of the results in female cohorts. To compensate for females having different relative amounts of fat and muscle compared to males, a somewhat arbitrary 15% reduction of predicted CrCl was considered appropriate based on previous study estimations<sup>[8-10]</sup>. Furthermore, it was noted that certain patients had predictably low creatinine excretion for age and body weight. Examples included paraplegics and patients with marked obesity or ascites. To correct for these patients, although no data were presented to support this decision, the authors suggested using ideal body weight (IBW).

Finally, due to the delay in SCr fluctuations and the time needed to establish a new steady state, the authors acknowledged that CrCl can be significantly overestimated in early phases of acute renal failure<sup>[5]</sup>. This is an extremely important concept for clinicians to grasp. In patients with excellent renal function, the  $t_{1/2}$  is on the order of 4 h, and a new steady state could be reached in about 1 d. However, a 75% reduction in GFR would increase the half-life to about 15 h, and the time to steady state would increase to about  $2 \frac{1}{2}$  d<sup>[11]</sup>. In the

case of oliguric or anuric renal failure, it may take several days to reach a new steady state for the SCr<sup>[11,12]</sup>.

Despite the above acknowledged limitations of the CG equation, it has become the most popular renal function prediction method used for renal dosing by clinicians<sup>[1,13,14]</sup>. Attempts to validate CrCl calculated using the CG equation have produced mixed results<sup>[6,13]</sup>. In their 2010 Guidance for Industry, the Food and Drug Administration (FDA) advocated for the use of the CG equation in drug development because it has been widely used in PK studies<sup>[14]</sup>. For instance, where CrCl may be inaccurate (muscle wasting, malnutrition, amputation, etc.), alternative methods of calculating CrCl are suggested but not required<sup>[14]</sup>.

As clinicians, it is important to understand that attempts to modify the equation to compensate for some of these patient-specific factors often lead to variable results. In the sections that follow, we discuss the rationale and results that these various adjustments yield in predicting actual CrCl.

## WEIGHING YOUR OPTIONS

Once again, recall that the CG equation was derived based on the assumption that SCr represents muscle mass as a definite percentage of the patient's body weight, and that both of these values decline in a linear manner as patients age<sup>[13]</sup>. In obese patients, these assumptions may not be true, as body fat becomes the major contributor to body mass<sup>[13]</sup>. Given that over 50% of the United States population > 20 years old are overweight or obese, reviewing available literature comparing accuracy of different weights used in the CG equation may help clinicians optimize dose selection<sup>[1,15]</sup>.

The CG equation was derived from a population of

**Figure 1** Impact of various body weights used in estimating creatinine clearance from Winter *et al.*<sup>[1]</sup>. In patients with a BMI  $\geq 25 \text{ kg/m}^2$ , using AdjBW<sub>0.4</sub> was the most accurate weight to estimate CrCl when compared to a 24-h urine CrCl. Under Wt: BMI  $< 18.5 \text{ kg/m}^2$ ; Normal Wt: BMI  $18.5\text{--}24.9 \text{ kg/m}^2$ ; Overweight: BMI  $25\text{--}29.9 \text{ kg/m}^2$ ; Obese: BMI  $30\text{--}39.9 \text{ kg/m}^2$ ; Morbidly obese: BMI  $\geq 40 \text{ kg/m}^2$ ; CrCl: Creatinine clearance; ActBW: Actual body weight; IBW: Ideal body weight; AdjBW: Adjusted body weight; LBW: Lean body weight; BMI: Body mass index.

normal weight individuals (mean = 72 kg) using actual body weight; and therefore, its use in obese patients may lead to significant estimation errors<sup>[5,16]</sup>. Despite 40 years of clinical experience and numerous studies evaluating different weight calculations in obese patients (Table 1B), no uniform consensus appears to exist for estimating CrCl using the CG equation in this patient population<sup>[1,15-17]</sup>.

Winter *et al.*<sup>[1]</sup> studied the impact of various body weights used when calculating CrCl in obese and non-obese patients. They estimated CrCl using the CG equation with actual body weight (actBW) for body mass index (BMI)  $< 18.5 \text{ kg/m}^2$ ; IBW and actBW for BMI  $18.5\text{--}24.9 \text{ kg/m}^2$ ; and actBW, IBW, adjusted body weight (adjBW<sub>0.3</sub>), adjBW<sub>0.4</sub>, and lean body weight (LBW) for all patients with BMI  $> 25 \text{ kg/m}^2$ . The calculated CrCl was compared to a CrCl derived from a measured 24-h urine collection for all 952 patients in the study. ActBW was shown to underestimate CrCl by 0.221 mL/min in underweight patients (BMI  $< 18.5 \text{ kg/m}^2$ ); in normal weight patients (BMI:  $18.5\text{--}24.9 \text{ kg/m}^2$ ), IBW was shown to be more accurate than actBW (IBW underestimated CrCl by 1.3 mL/min vs actBW overestimated by 4.7 mL/min); and in patients with a BMI  $> 25 \text{ kg/m}^2$ , adjBW<sub>0.4</sub> was shown to be the most accurate method of predicting CrCl (BMI  $25\text{--}29.9 \text{ kg/m}^2$  -2.4 mL/min; BMI  $30\text{--}39.9 \text{ kg/m}^2$  -6.2 mL/min; BMI  $> 40 \text{ kg/m}^2$  -5.9 mL/min) (Figure 1).

In a similar study, Demirovic *et al.*<sup>[15]</sup> prospectively evaluated the impact different body-size descriptors would have on the accuracy of the CG equation when compared to a timed 24-h urine collection. They estimated the CrCl in only obese patients with a BMI  $\geq 40 \text{ kg/m}^2$  and used ActBW, IBW, AdjBW<sub>0.3</sub>, AdjBW<sub>0.4</sub>, fat free weight (FFW), and LBW in the CG equation. Bioelectric impedance analysis (BIA) was used to estimate the FFW in patients. The calculated CrCl was compared to

**Table 2** Estimating creatinine clearance in morbidly obese patients by Demirovic *et al.*<sup>[15]</sup> showed that using fat free weight and lean body weight provided the closest estimate to the control 24-h urine creatinine clearance

Method <sup>1</sup>	Mean estimated CrCl ± SD	Mean bias (mL/min)	± 30% of measured CrCl	± 50% of measured CrCl
Measured CrCl	109.5 ± 44.4

MDRD4<sup>[18]</sup>:  $186 \times \text{SCr}^{-1.154} \times \text{age}^{-0.203} \times (0.742 \text{ if female}) \times (1.210 \text{ if black})$ ; Salazar-Corcoran<sup>[19]</sup>: Male:  $(137 - \text{age}) \times [(0.285 \times \text{Wt}) + (12.1 \times \text{height meters}^2)]$ ,  $51 \times \text{SCr}$ ; Female:  $(146 - \text{age}) \times [(0.287 \times \text{Wt}) + (9.74 \times \text{height meters}^2)]$ ,  $60 \times \text{SCr}$ ; ActBW: Actual body weight; AdjBW<sub>0.3</sub>: 30% adjusted body weight; AdjBW<sub>0.4</sub>: 40% adjusted body weight; CG: Cockcroft-Gault; CrCl: Creatinine clearance; FFW: Fat free weight; IBW: Ideal body weight; LBW: Lean body weight; MDRD: Modification of diet in renal disease study equation; SD: Standard deviation; Wt: Weight.

a CrCl derived from a measured 24-h urine collection for all 54 patients in the study (Table 2). On average, the CG equation using a patient's actBW overestimated the CrCl by 107.4 mL/min; using IBW underestimated CrCl by 24.3 mL/min; using AdjBW<sub>0.3</sub> and AdjBW<sub>0.4</sub> both overestimated the CrCl by 19.8 and 32.3 mL/min, respectively; FFW and LBW were found to be the most accurate estimate of the measured CrCl, as the FFW underestimated CrCl by 6.8 mL/min and LBW underestimated by 8.1 mL/min (Table 2)<sup>[15,18,19]</sup>.

A meta-analysis by Wilhelm *et al.*<sup>[17]</sup> analyzed a total of 1197 patients from 13 different trials and compared CrCl calculated with CG using ActBW, IBW, AdjBW<sub>0.3</sub>, AdjBW<sub>0.4</sub>, and no body weight (NBW) with a measured 24-h urine collection. For NBW, the authors assumed the patient weight to be 72 kg, as this was the average weight from the original CG trial<sup>[5]</sup>. NBW slightly modified the CG equation as it only incorporates age and SCr (Table 1A; Equation V). When using actBW, the mean difference in the CG estimated CrCl was an overestimation of 15.91 mL/min; using IBW underestimated CrCl by 5.15 mL/min; using adjBW<sub>0.3</sub> slightly underestimated the CrCl by 4.55 mL/min whereas the adjBW<sub>0.4</sub> considerably underestimated the CrCl by 19.94 mL/min. The most accurate method of estimating CrCl was using the modified CG equation without a variable for body weight (NBW), which underestimated CrCl by 0.43 mL/min.

The studies presented above reiterate the challenges faced by many clinicians when estimating CrCl using the CG equation. The CG equation was not originally studied in obese patients, and therefore, has limited applicability in this population. The study by Winter *et al.*<sup>[1]</sup> showed that in patients with a BMI > 25 kg/m<sup>2</sup>, use of adjBW<sub>0.4</sub> was the most accurate method of estimating CrCl when

using the CG methods. Unfortunately, Demirovic *et al.*<sup>[15]</sup> did not come to the same conclusion with the results found by Winter *et al.*<sup>[1]</sup> and Demirovic *et al.*<sup>[15]</sup>. They found that FFW and LBW provided the most accurate estimate of CrCl when compared to a measured 24-h urine collection. These findings support what was originally assumed by CG. That is, that SCr can best be used as a surrogate marker for renal function when an accurate assessment of a patient's muscle mass is used to calculate CrCl<sup>[5]</sup>. Unfortunately, calculating FFW and LBW on a daily basis is not practical in most clinical settings. Finally, Wilhelm's study illustrated that in a large, heterogeneous sample, removing the weight variable from the CG equation actually produced the estimate closest to the measured CrCl<sup>[17]</sup>. Although body weight remains controversial, utilizing the NBW equation assumes SCr predictable declines with age. Like the original CG equation, the NBW equation may be of limited use in patients with low SCr or falsely low SCr due to muscle mass or underlying disease. Certainly, the evidence presented by the authors of this review reiterate the potential limitations of the CG equation, and why this equation cannot be used as the sole means of estimating renal function in all patients.

## SERUM CREATININE - HOW LOW CAN YOU GO?

It is well known that, due to a decrease in muscle mass beyond about age 40, SCr and CrCl decline as a patient ages. The CG equation assumes this decline is linear<sup>[5,20]</sup>. In patients with a SCr ≤ 0.6 mg/dL, CrCl estimation using the CG equation often overestimate CrCl, and may consequently lead to supratherapeutic dosing of renally excreted drugs<sup>[21]</sup>. To compensate for this, clinicians often arbitrarily round a SCr ≤ 0.6 mg/dL to a closer-to-normal value (0.8-1 mg/dL)<sup>[21]</sup>. Although "rounding up" of SCr is a widely used technique by many clinicians, it has not been robustly validated<sup>[21]</sup>.

Dooley *et al.*<sup>[21]</sup> performed a study comparing measured GFR using diethyl triamine penta-acetic acid (DTPA) to an estimated CrCl calculated using the CG equation in patients with low SCr levels (< 0.6 mg/dL), and determined the impact of rounding SCr to 0.6 mg/dL. This retrospective study analyzed 26 patients with an average age of 57 years old. When compared to the measured GFR, the CG equation, using actual SCr overestimated CrCl by 12.9%, whereas the rounded SCr of 0.6 mg/dL underestimated CrCl by 7% (Table 3). Although rounding of SCr to 0.6 mg/dL was more accurate when calculating CrCl in this study, it was noted by the authors that clinicians typically round to either 0.8 or 1 mg/dL which would increase the underestimation when calculating CrCl. Furthermore, in patients with a measured CrCl that was > 100 mL/min, the rounding of SCr to 0.6 mg/dL underestimated CrCl by 18.9% vs 0.1% using the actual SCr.

Smythe *et al.*<sup>[22]</sup> performed a prospective study in elderly patients, but chose to round SCr to 1.0 mg/dL

**Table 3** Results from Dooley *et al.*<sup>[21]</sup> illustrated that rounding of serum creatinine to 0.6 mg/dL underestimated creatinine clearance by 7%; of note, the majority of clinicians round low serum creatinine values to 0.8 or 1.0 mg/dL

		Mean $\pm$ SD (mL/min)	Range (mL/min)	Mean % error	P value
DTPA	All	111 $\pm$ 46	45-256		
	$\leq 100$ mL/min	77 $\pm$ 14	45-96		
	$> 100$ mL/min	140 $\pm$ 45	103-256		
CG (no rounding)	All	117 $\pm$ 38	55-207	12.9	0.352
	$\leq 100$ mL/min	98 $\pm$ 28	55-152	29.2	0.024
	$> 100$ mL/min	135 $\pm$ 38	86-207	-0.1	0.631
CG (rounding SCr to 0.6 mg/dL)	All	97 $\pm$ 30	46-172	-7.0	0.029
	$\leq 100$ mL/min	82 $\pm$ 23	46-127	7.9	0.543
	$> 100$ mL/min	110 $\pm$ 29	72-172	-18.9	0.003

CG: Cockcroft-Gault; DTPA: Diethyl triamine penta-acetic acid; SCr: Serum creatinine.

**Table 4** Results from Smythe *et al.*<sup>[22]</sup> showed that rounding of serum creatinine to 1.0 in elderly patients was less accurate than using the patients actual serum creatinine

Method	Bias = CrCl <sub>meas</sub> - CrCl <sub>calc</sub> (CI)	Precision
CG using IBW without gender adjustment		
Actual SCr	2.3 (-10.3-14.8)	22.5
Rounded SCr	28.8 (19.1-38.4)	17.4
CG using ActBW without gender adjustment		
Actual SCr	-13.6 [-26.8-(-0.43)]	23.6
Rounded SCr	16.3 (4.5-28.1)	21.2
CG using ActBW with gender adjustment		
Actual SCr	-5.2 (-17.2-7.1)	22.1
Rounded SCr	22.6 (11.5-33.7)	19.9

when calculating CrCl using the CG. This study included 23 patients (age  $69.2 \pm 8.1$  years old) and compared the calculated CrCl using various body weights with or without rounding of SCr to 1 mg/dL with a 24-h measured CrCl. The results of this study showed that of all three examples of calculating CrCl, using the actual SCr values produced the most accurate estimate of CrCl (Table 4).

The inverse relationship between SCr and CrCl has lead clinicians to further deviate from the studied CG equation in order to broaden the applicability of the equation<sup>[22]</sup>. Rounding of low SCr values ( $\leq 0.6$  mg/dL) when calculating CrCl is often used by clinicians to prevent overestimation of renal function and over-dosing of renally excreted drugs<sup>[21]</sup>. The fact that "rounding up" of SCr has not been validated by strong evidence, clinicians who routinely round low SCr in patients may underestimate CrCl and consequently overcompensate for a perceived problem<sup>[21,22]</sup>. The studies presented in this section confirm the limitations of the CG equation in elderly patients and the use of SCr as a surrogate marker of GFR. Unfortunately, the limitations of SCr based equations extend to additional populations where SCr is falsely low due to underlying disease.

## CIRRHOTICS - THE EXCEPTION TO THE RULE

Among the many complications that arise in patients with liver cirrhosis, renal dysfunction has become a well-established predictor associated with poor prognosis and increased mortality<sup>[7,23]</sup>. The overall survival of patients with cirrhosis who develop hepatorenal syndrome (HRS) is approximately 50% at 1 mo and 20% at 6 mo<sup>[24]</sup>. Given the frequency at which cirrhotics demonstrate "cryptic" renal impairment and so often go on to develop HRS, it is critical that clinicians appropriately dose all drugs in cirrhotic patients, particularly those that are nephrotoxic<sup>[25]</sup>. Unfortunately, due to the underlying disease pathophysiology producing a falsely low SCr, SCr based calculations of CrCl are of limited use in cirrhotics<sup>[7]</sup>.

Underlying CKD in cirrhotics results from alterations in hemodynamics, renal autoregulatory mechanisms, and cardiac function (Figure 2)<sup>[26,27]</sup>. Hemodynamically, because of increased portal vein pressure, compensatory vasodilators such as nitrous oxide (NO) decrease peripheral vascular resistance and dilate the splanchnic circulation<sup>[26,27]</sup>. Progressive vasodilation in the presence of portal hypertension results in a decrease in effective arterial blood volume and activation of sodium retention mechanisms such as the renin-angiotensin-aldosterone system (RAAS)<sup>[26,27]</sup>. Unfortunately, these compensatory mechanisms lead to renal vasoconstriction and reduced GFR<sup>[26,27]</sup>.

In addition to the above hemodynamic changes, cirrhotics have falsely low-to-normal levels of SCr, thus further complicating a clinician's assessment of renal function. Creatine is originally produced in the liver before it is transferred to the skeletal muscles to be stored for energy. In the muscles, it is then phosphorylated, converted to creatinine, and then transferred back into the bloodstream<sup>[28]</sup>. As cirrhosis progresses, creatine production declines and becomes inconsistent<sup>[28]</sup>. Furthermore, due to malnutrition and low androgen levels, muscle wasting in cirrhotics limits the storage capacity and phosphorylation of creatine, thereby further decreasing the serum concentration of creatinine<sup>[28-30]</sup>. Finally,

**Figure 2 Systemic effects of cirrhosis.** Increased portal vein pressure results in vasodilation decreasing peripheral vascular resistance (PVR) and effective arterial blood volume (EABV). To compensate for this, increased renin-angiotensin-aldosterone (RAA) activation leads to sodium and fluid retention along with renal vasoconstriction and reduced glomerular filtration rate. Adopted with permission from Ho *et al*<sup>[27]</sup>. HE: Hepatic encephalopathy.

detecting early acute kidney injury (AKI) in cirrhotics using SCr is already tenuous, and may require far greater than 24 h given the pharmacokinetic properties of creatinine in patients with reduced GFRs<sup>[11]</sup>.

MacAulay *et al*<sup>[31]</sup> compared estimates of GFR using three SCr based formulas (CG, MDRD and SCr<sub>rec</sub>) with standard radionuclide measurements (DTPA) of GFR in patients with advanced liver disease. Of the 57 patients in their trial, the mean GFR *via* DTPA was 83 mL/min per 1.73 m<sup>2</sup> (range 28-173 mL/min per 1.73 m<sup>2</sup>). On average, estimation using the MDRD was most accurate (mean difference % = +4.0; CI = -5.73-20.39), followed by the CG equation (mean difference % = +18.56; CI = 8.48-22.83), and the SCr<sub>rec</sub> (mean difference % = +28.68; CI = 14.3-30.28). The authors concluded that using the CG and SCr<sub>rec</sub> (Table 1A equation VI) equations to estimate GFR in this population can lead to a significant overestimation of GFR.

A similar study by Rognant *et al*<sup>[32]</sup> compared GFR estimates using the CG and MDRD equations to a measured GFR using inulin. Estimating CrCl using the CG was normalized to 1.73 m<sup>2</sup> body surface area (Table 1A equation I). The 143 patients in this study all had decompensated alcoholic cirrhosis. The mean measured GFR using inulin was 76.9 ± 28 mL/min per 1.73 m<sup>2</sup>, and 30.4% of patients had a GFR ≥ 90 mL/min per 1.73 m<sup>2</sup> (group 1), 39.2% had a GFR between 60-89.9 mL/min per 1.73 m<sup>2</sup> (group 2), 26.3% had a GFR < 60 mL/min per 1.73 m<sup>2</sup> (group 3) with 4.1% of these patients having a GFR ≤ 30 mL/min per 1.73 m<sup>2</sup>. Mean GFR estimates using the CG and MDRD equations were 98.7 ± 32 mL/min and 99.4 ± 34 mL/min per 1.73 m<sup>2</sup>. The mean estimates using the CG and MDRD equations both overestimated the GFR mean by 21.8 mL/min (28.3%) and 22.5 mL/min (29.3%), respectively. For patients in group 1, the mean absolute bias for the CG was 20 ± 25 mL/min and 18 ± 23 mL/min per 1.73 m<sup>2</sup>. In group 2, the mean absolute bias for the CG was 25 ± 18 mL/min and 27 ± 19 mL/min per 1.73 m<sup>2</sup> using the MDRD. For those in group 3, the mean absolute bias using the CG was 21 ± 19 mL/min and 19 ± 25 mL/min per 1.73 m<sup>2</sup>.

The authors of the study concluded that although the differences between the CG and MDRD estimations were not statistically significant, their findings suggest both equations significantly overestimated renal function in cirrhotics, particularly in those with lower GFRs.

A third study assessing renal function in cirrhotics by Caregaro *et al*<sup>[33]</sup> was designed to evaluate the sensitivity of SCr and CrCl in detecting renal insufficiency and the magnitude of overestimation of GFR by CrCl. Estimation of CrCl was made using the CG equation and a 24-h urine collection. Estimates of CrCl were compared to measured GFR using inulin (Inulin Clearance = InCl). Patients in this study were divided into 2 groups based on measured GFR; group 1 (*n* = 29) had a GFR > 80 mL/min per 1.73 m<sup>2</sup> and group 2 (*n* = 27) had a GFR ≤ 80 mL/min per 1.73 m<sup>2</sup>. For the patients in groups 1 and 2, the mean measured GFR (InCl) was 113.5 ± 27.9 mL/min per 1.73 m<sup>2</sup> and 56.8 ± 19.8 mL/min per 1.73 m<sup>2</sup>, respectively. Estimating CrCl using the CG and 24-h urine collection provided an adequate assessment of measured GFR (InCl) in group 1 (CG = 106.3 ± 34.0 mL/min; 24-h = 121.5 ± 28.8 mL/min) but significantly overestimated measured GFR in group 2 (CG = 75.9 ± 40.1 mL/min; 24-h = 78.7 ± 39.2 mL/min) (Figure 3). Only 18.5% of patients in group 2 had a SCr level above normal limits and 81.5% of patients with a GFR ≤ 60 mL/min per 1.73 m<sup>2</sup> had normal SCr levels. Overall, the sensitivity of SCr, CrCl estimated using the CG equation and 24-h urine collection in detecting renal insufficiency was 18.5%, 51% and 74%, respectively.

The authors concluded renal failure in cirrhotic patients is greatly underestimated because of the low sensitivity and accuracy of SCr levels in this population (Figure 3). Based on the data presented in this study, utilization of SCr based methods overestimated true renal function by about 50% in cirrhotic patients with a GFR ≤ 80 mL/min per 1.73 m<sup>2</sup>.

## CONCLUSION

The importance of accurate and appropriate dosing of all medications remains a critical component of healthcare to maximize efficacy while limiting toxicity. For renally excreted medications, assessment and interpretation of renal function often dictates dosage selection. Due to the impractical nature of a 24-h urine collection, SCr has become a widely accepted surrogate marker of renal function used in several equations including the CG equation. With now over 40 years since its development, the CG equation remains one of the most widely used methods of assessing renal function. Unfortunately, because of its seemingly ubiquitous use and acceptance, many have forgotten its limitations and provider-specific variations used to compensate for these limitations.

Many of the limitations of the CG equation largely stem from the original study supporting its accuracy. The homogenous sample population limits the external validity and creates opportunity for the implementation of empiric correction factors that may or may not be

**Figure 3** In cirrhotics, as renal function declines, conventional methods of estimating renal function are no longer accurate. Both the Cockcroft-Gault (CG) equation and a 24-h urine creatinine clearance (Ccr) significantly overestimated true renal function as measured by inulin clearance (InCl) in cirrhotics with a baseline InCl ≤ 80 mL/min. The CG equation and Ccr were better estimates in those with a baseline InCl > 80 mL/min<sup>[33]</sup>.

supported by data<sup>[5]</sup>. As outlined in this review, selection of appropriate weight and rounding of low SCr levels are two examples of techniques used to broaden the applicability of the CG equation. These techniques vary among clinicians, largely because of a lack of evidence unanimously supporting one method over another. Unfortunately, additional limitations in the CG equation extend beyond body composition and habitus to include the subtle manifestations of the underlying disease process in a patient.

In cirrhotic patients, in addition to declining liver function, secondary physiological hemodynamic changes lead to a resultant reduction in GFR. Meanwhile, reductions in creatinine production and reduced muscle mass result in low SCr levels. Because of this, a sort of “cryptic renal failure” picture ensues, whereby SCr-based formulae will overestimate actual GFR by an average of about 50%<sup>[28-30]</sup>. Based on the evidence presented in this review and in the authors experience, multiplying the SCr by 1.5 in patients with decompensated cirrhosis provides a better CrCl estimate using the CG equation.

Utilization of the CG equation plays a significant role in the dosing decisions of many clinicians. In order to appropriately utilize this equation, clinicians have an inherent responsibility to understand its origins and limitations. True clinicians comprehensively assess each patient and consider SCr and CrCl as two variables that carry equal weight with several other parameters. Regardless of one’s approach to dosing medications, sole reliance on CrCl will undoubtedly lead to the ultimate realization that there is indeed fault in the CG.

## Abstract

### AIM

To examine if liver transplant recipients with high-risk non-alcoholic steatohepatitis (NASH) are at increased risk for pre-transplant portal venous thrombosis.

### METHODS

Data on all liver transplants in the United States from February 2002 through September 2014 were analyzed. Recipients were sorted into three distinct groups: High-risk (age > 60, body mass index > 30 kg/m<sup>2</sup>, hypertension and diabetes), low-risk and non-NASH cirrhosis. Multivariable logistic regression models were constructed.

### RESULTS

Thirty-five thousand and seventy-two candidates underwent liver transplantation and of those organ recipients, 465 were transplanted for high-risk and 2775 for low-risk NASH. Two thousand six hundred and twenty-six (7.5%) recipients had pre-transplant portal vein thrombosis; 66 (14.2%) of the high-risk NASH group had portal vein thrombosis vs 328 (11.8%) of the low-risk NASH group. In general, all NASH recipients were less likely to be male or African American and more likely to be obese. In adjusted multivariable regression analyses, high-risk recipients had the greatest risk of

pre-transplant portal vein thrombosis with OR = 2.11 (95%CI: 1.60-2.76,  $P < 0.001$ ) when referenced to the non-NASH group.

## CONCLUSION

Liver transplant candidates with high-risk NASH are at the greatest risk for portal vein thrombosis development prior to transplantation. These candidates may benefit from interventions to decrease their likelihood of clot formation and resultant downstream hepatic decompensating events. Prospective study is needed.

**Key words:** Liver transplantation; Non-alcoholic fatty liver disease; Portal hypertension; Hepatology; Coagulopathy

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Non-alcoholic steatohepatitis (NASH) is increasing in prevalence and is expected to be the leading indication for liver transplantation in the foreseeable future. There is a growing body of evidence supporting the clinical importance of a thrombophilic state in patients with NASH. In NASH patients, the most severe hypercoagulable environment is found in patients with NASH cirrhosis. High-risk NASH patients (concomitant age > 60 years, obesity, diabetes and hypertension) have inferior post transplantation outcomes, however, how this group's risk of clotting compares to other etiologies of liver disease is unknown. In a retrospective nationwide United States based cohort, we provide further evidence of coagulation derangement in NASH and identify a new high-risk subtype in the high-risk NASH population. Whether or not this high-risk group may benefit from preventative anticoagulation remains unknown.

Advanced non-alcoholic steatohepatitis cirrhosis: A high-risk population for pre-liver transplant portal vein thrombosis. *World J Hepatol* 2017; 9(3): 139-146 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i3/139.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i3.139>

## INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is a spectrum of hepatic disorders ranging from simple steatosis with or without mild inflammation to non-alcoholic steatohepatitis (NASH) which is diagnosed by the presence of inflammation, cellular injury with hepatocyte ballooning and accumulation of Mallory-Denk bodies and in the most advanced cases, fibrosis<sup>[1]</sup>. NAFLD is increasing in prevalence in Western society<sup>[2]</sup> with rates approaching 20%-30%<sup>[3]</sup> and more importantly, NASH is projected to become the number one indication for liver transplantation in the foreseeable future<sup>[4]</sup>, especially in light of the new all oral direct acting antiviral treatment regimens for

hepatitis C virus (HCV), and it is the most rapidly growing indication for simultaneous liver-kidney transplantation<sup>[5]</sup>. High-risk NASH (HR-NASH) is a subtype of NASH defined by the presence of the following: Age > 60 years, body mass index (BMI) > 30 kg/m<sup>2</sup>, hypertension and diabetes<sup>[6,7]</sup>. In general, liver transplant recipients with NASH have similar liver graft and overall one-, three- and five-year survival rates when compared to other etiologies<sup>[4-6,8,9]</sup>. Outcomes for HR-NASH recipients are less promising with single center experiences showing significantly lower one-<sup>[7]</sup> and five-year survival rates<sup>[6]</sup>. While the exact explanation for this remains relatively unexplored, post-transplant cardiovascular events<sup>[8]</sup>, some of which are attributable to macrovascular arterial thrombosis<sup>[7,9]</sup>, and chronic renal dysfunction<sup>[10]</sup> are more common in NASH patients and these could contribute to lesser outcomes.

Venous thromboembolism (VTE) including portal vein thrombosis (PVT) is a common affliction in patients with cirrhosis<sup>[11]</sup>. Incidence rates of PVT are reported to be as high as 16%<sup>[12]</sup> and 30-d mortality is increased in patients with pulmonary embolism (PE) or deep vein thrombosis (DVT)<sup>[11]</sup>. In a matched retrospective case-control study of 414 patients, Di Minno *et al.*<sup>[13]</sup> found that NAFLD was associated with VTE (PE or DVT) with an OR of 1.8 on adjusted multivariable analysis controlling for additional VTE and NAFLD risk factors. While the presence of PVT may mirror the degree of liver disease burden, it is nonetheless associated with adverse outcomes including increased pre- and post-liver transplant mortality and impaired quality of life, as well as technical challenges during the transplant procedure<sup>[14,15]</sup>. We have previously shown that liver transplant recipients with NASH are predisposed to pre-transplant PVT<sup>[16]</sup>. Patients with NASH and metabolic syndrome, which encompasses many of the features of the HR-NASH definition, are known to have increased degrees of fibrosis<sup>[17]</sup>, and presumably increased thrombotic risk. To date, there is a lack of data investigating the relationship between pre-transplant PVT and HR-NASH. We aim to explore this potential association and hypothesize that liver transplant recipients with HR-NASH are at increased risk for PVT when compared directly to other NASH patients and all other etiologies of liver disease.

## MATERIALS AND METHODS

### Study design and recipient characteristics

Data on all transplants in the United States during the model for end-stage liver disease (MELD era) through September 2014 were reviewed from the Organ Procurement and Transplantation Network (OPTN) with permission from the United Network for Organ Sharing (UNOS). Status 1a, multi-organ, living donor, re-transplants, pediatric recipients, donation after cardiac death, recipients with pre-transplantation transjugular intrahepatic portosystemic shunts and malignancy (hepatocellular carcinoma, hepatoblastoma, cholangiocarcinoma) were excluded. Recipients with cryptogenic

cirrhosis were also excluded due to the potential for misclassification of NASH. The conclusions of the model were not significantly changed with the exclusion of the cryptogenic recipients. Recipients were sorted into two distinct groups: Those with NASH and those without NASH (all other etiologies except cryptogenic cirrhosis, which was excluded due to the potential for misclassification of NASH). The NASH group was then subdivided into HR and low-risk (LR) subgroups. HR-NASH was based on the standard definition used in previous large-scale single center experiences and was defined as the presence of all of the following: Age > 60 years, BMI > 30 kg/m<sup>2</sup>, and pre-transplantation hypertension and diabetes<sup>[6,7]</sup>. Recipient characteristics (age at listing and at transplantation, ethnicity, gender, BMI, diabetes), severity of liver disease based on native laboratory MELD score at allocation, laboratory values [international normalized ratio (INR), bilirubin, creatinine, albumin], and clinically relevant manifestations of portal hypertension (ascites and hepatic encephalopathy) were reviewed in each of the three groups to compare baseline covariates.

### Outcomes analysis

Separate analyses were performed comparing recipients with NASH to non-NASH controls and comparing HR-NASH to LR-NASH. In the UNOS data set, PVT is categorized as "Present", "Not present", or "Unknown" and the data are based upon direct surgical evaluation of the veins at the time of hepatectomy. The degree of clot burden is not specified in the dataset nor is the chronicity. Based on previously validated methodology and due to the potential for misclassification bias<sup>[16]</sup>, 831 recipients with "Unknown" PVT status were excluded. In general, univariate comparisons of the excluded cases to the included cohort with known PVT status did not reveal any baseline differences with the exception that the included cohort had a greater percentage of patients with cholestatic liver disease (10.2% vs 5.5%,  $P < 0.001$ ). It was felt by the study team that this was not a significant clinical factor in the analysis. The dataset also does not contain information on treatment of PVT or testing for thrombophilia.

### Statistical analysis

Recipients were statistically evaluated in multiple factors including demographics, medical comorbidities, waiting list and transplantation characteristics. Univariate comparisons were performed using the Student-*t* test, Wilcoxon sign rank test,  $\chi^2$  test, or Fisher exact test as appropriate. Multivariable models were constructed using logistic regression and analysis of maximum likelihood estimates to test the primary hypothesis that patients with HR-NASH are at increased risk for the development of PVT and to assess statistical associations and risk factors for the development of PVT. Individual covariates were included in the multivariable model if they were statistically significant to  $P < 0.20$  in univariate analysis, have been shown in the literature to be important or

were deemed to be clinically important by the study team<sup>[18,19]</sup>. In separate models, individual components of the HR-NASH definition (hypertension, age, BMI and diabetes) were entered into the model as individual variables to ensure one of these did not dominate. Final variables included in the regression model included HR-NASH, LR-NASH, individual laboratory values at transplant (creatinine, bilirubin, INR, albumin, sodium), HCV, cholestatic liver disease, male gender, African American race, Hispanic race, encephalopathy (which was dichotomized into those with severe encephalopathy with score > 2), ascites (similarly dichotomized), pre-transplant dialysis treatment and autoimmune liver disease. No data imputation was performed. All statistical tests for significance were two sided and a significance level  $P$  less than or equal to 0.05 was considered statistically significant. All data set manipulation and statistical analyses were performed using SAS (version 9.4, Cary, NC). No transplants involving prisoners were included in this analysis. Institutional review board approval was not required for this study as the UNOS/OPTN dataset is de-identified.

## RESULTS

Thirty-five thousand and seventy-two candidates underwent liver transplantation and of those organ recipients, 3240 (9.2%) were transplanted for NASH of which 465 met criteria for HR-NASH (1.3%) and 2775 for LR-NASH (7.9%). Two thousand six hundred and twenty-six (7.5%) recipients had pre-transplant PVT, of which 394 (12.2%) were in the NASH group (Figure 1). The prevalence of PVT was not significantly different between HR-NASH and LR-NASH ( $n = 66$ , 14.2% vs  $n = 328$ , 11.8%,  $P = 0.145$ ). In general, NASH recipients were older, more likely to be female, less likely to be African American or Hispanic, had higher BMI values and were more likely to have diabetes, hypertension and renal dysfunction (Table 1). Severity of liver disease, while statistically significantly different, was not deemed to be clinically significantly different (e.g., MELD at listing of 20.0, 95%CI: 19.8-20.3 for NASH vs 19.6, 95%CI: 19.5-19.7 for non-NASH). The leading indication for transplantation in the non-NASH group was chronic HCV (46.6%) while alcoholic liver disease was the second leading indication (19.0%).

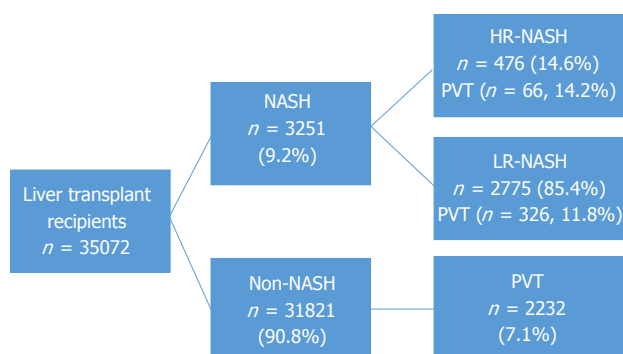

When comparing HR-NASH recipients to LR-NASH recipients, several differences were noted (Table 2). As expected by definition, HR-NASH recipients were older both at listing (64.0 years, 95%CI: 63.8-64.3 vs 56.7 years, 95%CI: 56.2-56.9,  $P < 0.001$ ) and at transplantation (64.5 years, 95%CI: 64.2-64.7 vs 57.0 years, 95%CI: 56.8-57.4,  $P < 0.001$ ). BMI values were greater for HR-NASH (35.1 kg/m<sup>2</sup>, 95%CI: 34.7-35.5 vs 31.8 kg/m<sup>2</sup>, 95%CI: 31.5-32.0,  $P < 0.001$ ) as was renal dysfunction (mean creatinine 1.98 g/dL, 95%CI: 1.85-2.11 vs 1.78 g/dL, 95%CI: 1.73-1.85,  $P = 0.003$ ).

Severity of liver disease based on MELD scores and portal hypertensive manifestations of ascites and

In general, NASH recipients were older, more likely to be female, less likely to be African American or Hispanic, had higher BMI values and were more likely to have diabetes, hypertension and renal dysfunction. BMI: Body mass index; NASH: Non-alcoholic steatohepatitis; NS: Not significant; INR: International normalized ratio; MELD: Model for end-stage liver disease.

**Figure 1** Study enrollment. HR: High-risk; LR: Low-risk; NASH: Non-alcoholic steatohepatitis; PVT: Portal vein thrombosis.

encephalopathy were similar between the two groups. Interestingly, non-NASH recipients with HR features were not at increased odds of PVT ( $P = 0.11$ ), albeit only 58 patients met criteria for this subgroup.

In adjusted multivariable analysis (Table 3), recipients with HR-NASH had the greatest risk of pre-transplant PVT with OR = 2.11 (95%CI: 1.60-2.76,  $P < 0.001$ ) when referenced to the non-NASH cohort and 30% increased odds when compared to LR-NASH recipients (OR = 1.71, 95%CI: 1.49-1.96,  $P < 0.001$ ). Other significant associations with pre-transplant PVT included male gender (OR = 1.18, 95%CI: 1.07-1.29,  $P$

< 0.001), Hispanic race (OR = 1.24, 95%CI: 1.10-1.39,  $P < 0.001$ ) moderate-to-severe ascites (OR = 1.14, 95%CI: 1.04-1.25,  $P = 0.007$ ) and autoimmune liver disease (OR = 1.43, 95%CI: 1.14-1.79,  $P = 0.002$ ). African Americans were less likely to have pre-transplant PVT with OR = 0.75 (95%CI: 0.64-0.89,  $P < 0.001$ ), similar to our previous findings<sup>[16]</sup>.

While MELD was significantly different on univariate analysis, the individual factors (bilirubin, INR, creatinine) involved in the MELD regression equation were not clinically important statistically significant predictors in adjusted multivariable analysis nor was pre-transplantation dialysis.

## DISCUSSION

Based on a large national liver transplant database and building on our previous work in transplant recipients with NASH<sup>[16]</sup>, we have shown an independent cross-sectional association documenting an increased risk of pre-transplant PVT in recipients undergoing transplantation for HR-NASH. This association was significant despite adjustment for multiple established risk factors for pre-transplant PVT. Given the technical difficulties associated with pre-transplant PVT, careful recipient selection is paramount in preventing post-transplant vascular complications.

**Table 2** Baseline characteristics comparing high-risk non-alcoholic steatohepatitis to low-risk non-alcoholic steatohepatitis recipients

	High-risk NASH (n = 465)	Low-risk NASH (n = 2775)	P value
Recipient characteristics			
Age at listing, mean years (95%CI)	64.0 (63.8-64.3)	56.7 (56.2-56.9)	< 0.001
Age at transplant, mean years (95%CI)	64.5 (64.2-64.7)	57.0 (56.8-57.4)	< 0.001
Male gender	247 (52.4)	1500 (53.0)	NS
African American race	7 (0.2)	58 (1.6)	NS
Hispanic race	43 (9.1)	305 (10.8)	NS
BMI at transplant, kg/m <sup>2</sup> , mean (95%CI)	35.1 (34.7-35.5)	31.8 (31.5-32.0)	< 0.001
Portal vein thrombosis	66 (14.2)	326 (11.8)	NS
Severity of liver disease			
MELD score at listing, mean (95%CI)	19.5 (18.7-20.3)	20.1 (19.8-20.4)	NS
MELD score at transplantation, mean (95%CI)	22.8 (21.9-23.6)	23.7 (23.3-24.0)	NS
Laboratory values			
Serum bilirubin, mg/dL, mean (95%CI)	6.2 (5.4-7.0)	7.7 (7.3-8.0)	0.002
INR, mean (95%CI)	1.81 (1.75-1.86)	1.94 (1.91-1.97)	0.002
Serum albumin, g/dL, mean (95%CI)	3.1 (3.0-3.2)	3.0 (2.9-3.1)	0.006
Creatinine, g/dL, mean (95%CI)	1.98 (1.85-2.11)	1.78 (1.73-1.83)	0.003
On dialysis at transplantation	73 (15.5)	415 (14.7)	NS
Portal hypertension manifestations			
Moderate-severe ascites at transplant	178 (37.8)	1032 (36.5)	NS
Moderate-severe hepatic encephalopathy at transplant	51 (10.8)	324 (11.5)	NS

HR-NASH recipients were older, had higher BMI values and were more likely to have renal dysfunction. BMI: Body mass index; HR: High-risk; NASH: Non-alcoholic steatohepatitis; NS: Not significant; INR: International normalized ratio.

**Table 3** Adjusted multivariable analysis for predictors of portal vein thrombosis at the time of liver transplantation

	Odds ratio	95%CI	P value
African American race	0.75	0.64-0.89	< 0.001
AIH	1.43	1.14-1.79	0.002
Hispanic race	1.24	1.10-1.39	< 0.001
HR-NASH	2.11	1.60-2.76	< 0.001
LR-NASH	1.71	1.49-1.96	< 0.001
Male gender	1.18	1.07-1.29	< 0.001
Moderate-severe ascites	1.14	1.04-1.25	0.007

Recipients with HR-NASH had the greatest risk of pre-transplant PVT when referenced both to the non-NASH cohort and to LR-NASH recipients. Variables that were not significant in the model: Albumin levels, bilirubin levels, cholestatic liver disease, creatinine levels, hepatitis C, international normalized ratio (INR); moderate-severe encephalopathy, pre-transplant dialysis treatment, sodium levels. AIH: Autoimmune hepatitis; HR: High-risk; LR: Low-risk; NASH: Non-alcoholic steatohepatitis.

Patients with NASH and in particular NASH cirrhosis, have *in vivo* abnormalities in primary, secondary and tertiary hemostasis<sup>[20,21]</sup>. The role of platelet dysfunction *via* increased activation, adherence and aggregation is the best described abnormality in primary hemostasis<sup>[22-24]</sup>, however multiple investigators have shown elevations in vonWillebrand factor as a surrogate for endothelial dysfunction as well<sup>[21,25]</sup>. Secondary hemostasis is impaired in NASH due to elevations in fibrinogen, factor VIII, IX, XI, XII, increased clotting activity of factor VII, and low levels of antithrombin III<sup>[20,21,25-27]</sup>. Protein C levels may be increased or decreased in patients with NASH<sup>[20]</sup>. Tertiary hemostasis is disrupted due to elevations in plasminogen activator inhibitor-1 and low levels in both thrombin activatable fibrinolysis inhibitor and tissue plasminogen activator<sup>[20,21,27]</sup>. The aggregate of these impaired mechanisms of coagulation leads to the hypercoagulable milieu

responsible in part for the development of PVT.

Whether or not the presence of pre-transplant PVT plays a role in the decreased survival of HR-NASH<sup>[6,7]</sup> remains unknown as our study did not investigate patient centered outcomes such as graft and overall patient survival. We did not attempt to do this due to the limitations of the UNOS/OPTN dataset, which does not contain information on the use of anticoagulants and data on post-transplant vascular complications is hindered by a large degree of missing data. The lack of this information introduces significant heterogeneity into the dataset and concrete post-transplant outcomes based conclusions for patients with PVT are problematic. However, what is clear is that the high-risk subgroup of NASH is the most at risk for PVT both in comparison to other NASH recipients not meeting the HR definition and also to all other etiologies of liver disease. We have previously shown that the independent factors of diabetes and obesity do not predispose to PVT on an individual basis<sup>[16]</sup>. It is only in combination with advanced age > 60 years and hypertension that these factors interact in a way to produce clinically meaningful thrombotic disease, perhaps due to increased physiologic endothelial dysfunction with advancing age<sup>[28]</sup>.

In general, treatment outcomes for patients with PVT are impaired by a lack of large-scale, randomized, placebo-controlled trials that are generalizable. Villa *et al.*<sup>[29]</sup> demonstrated in an un-blinded, single center randomized controlled trial that daily prophylactic dosing of low molecular weight heparin (40 mg daily) for twelve months prevented the development of PVT in patients with compensated cirrhosis at 48 wk, an effect that persisted through the 5-year follow-up period when compared to standard of care<sup>[29]</sup>. This study also demonstrated significantly less hepatic decompensation in the low

molecular weight heparin arm and a survival benefit in the absence of a single bleeding event<sup>[29]</sup>. Building on this, Cui *et al*<sup>[30]</sup> recently published a controlled trial evaluating the efficacy and safety of anticoagulation therapy with different doses of enoxaparin (1 mg/kg twice a day vs 1.5 mg/kg daily) for PVT in patients with cirrhosis secondary to chronic hepatitis B in 65 patients, the majority of which had partial thrombosis. Importantly, 79% of patients achieved partial or complete response with anticoagulation based on follow-up imaging, however, non-variceal bleeding was significantly greater in the daily group (23.5% vs 6.4%) and the authors concluded that dosing at 1 mg/kg of enoxaparin subcutaneously twice a day was the preferred anticoagulation regimen. While the inclusion criteria were stringent limiting generalizability and the imaging guided definition of PVT open for criticism in these studies, the findings are nonetheless intriguing. A recent meta-analysis by Qi *et al*<sup>[31]</sup> of 16 studies (the authors did not include either of the aforementioned studies) and 960 patients found a pooled OR of 4.16 (95%CI: 1.88-9.20,  $P < 0.001$ ) for complete portal vein recanalization with anticoagulation. Interestingly, the pooled rate of bleeding was only 3.3% (95%CI: 1.1%-6.7%). A recently published animal model found that 3 mo of dabigatran significantly reduced fibrin deposition, inflammation, hepatocellular injury, steatosis and weight gain<sup>[32]</sup> through mitigation of thrombin generation, the end-result of the coagulation abnormalities in NASH, suggesting a potential novel therapeutic approach. Newer data regarding the potential use of prothrombin complex concentrates in combination with antithrombin with or without concurrent fibrinogen administration to restore the delicate homeostasis of coagulation and normal thrombin and fibrinogen is emerging<sup>[33,34]</sup>. However, this combination of therapy has not been broadly studied in patients with chronic liver disease and concrete recommendations about the utility of this treatment cannot be made at this juncture.

In general, prospective, randomized, placebo-controlled studies are sorely needed in all patients with cirrhosis, however, targeting those most at risk including patients with HR-NASH, may provide the most substantial benefits including the potential to reduce disease burden from cerebrovascular accidents that this population is at risk for. If the reduction in inflammation and fibrosis with the direct thrombin inhibitors is validated in human subjects, these agents may provide an antifibrotic therapy which could alter the prognosis of liver disease.

Our study has several limitations. Despite containing a large number of transplant recipients in the MELD era, it is a retrospective study. Furthermore, missing data and correct diagnostic coding are potentially problematic with all large datasets. We attempted to control for missing data by excluding the small percentage of patients with unknown PVT status who were demographically similar to our included cohort to ensure bias towards or away from the null was not introduced. Although transplant

centers are gaining increased experience transplanting recipients with PVT, it is possible that small volume centers may not have the same surgical technique or experience and pre-transplant PVT may in fact preclude transplantation in a subset of patients that would go on to be excluded from this study. The PVT variable in the dataset also has inherent heterogeneity as there is no differentiating between partial and complete thrombus or the chronicity of the clot. Our analysis also could not account for thrombophilia disorders and therapy in the pre-transplant phase. Additionally, our study excluded HCC patients in the event that PVT was associated with HCC as tumor thrombus, which may limit generalizability.

In conclusion, as the *in vivo* evidence of a thrombophilic state in patients with NASH continues to grow, epidemiologic evidence continues to lag behind. Building on our previous work, we have shown that liver transplant candidates with HR-NASH are at the highest risk for PVT development when compared to other NASH patients and also to all other etiologies of liver disease. Prospective study enrolling HR-NASH patients in anticoagulation trials seems warranted in order to determine a direct benefit in improving patient centered outcomes including the potential for overall and post-transplantation graft survival.

## ACKNOWLEDGMENTS

We would like to thank Dr. Timothy L McMurray for his statistical review of our manuscript. This work was presented at Digestive Diseases Week 2016.

## COMMENTS

### Background

Non-alcoholic steatohepatitis (NASH) is increasing in prevalence and will soon be the leading indication for liver transplantation in western nations. Patients with NASH are at increased risk for thrombosis. Patients with high-risk NASH have inferior liver transplantation outcomes. Whether or not this high-risk group has an increased risk of portal vein thrombosis (PVT) remains unknown.

### Research frontiers

The field of coagulation disorders in chronic liver disease continues to grow. Much of the research focuses on PVT and/or venothromboembolic disease. Identifying high-risk groups for possible preventative intervention through clinical trials remains a goal of the liver and hematology fields alike.

### Innovations and breakthroughs

In the present study, the authors investigated the association between high-risk NASH and PVT in liver transplant recipients with cirrhosis. This is the first report of PVT risk in patients with high-risk NASH.

### Applications

The present report furthers understanding regarding the thrombophilic state of NASH and highlights a potential high-risk group who may benefit from further prospective study.

### Peer-review

This is an excellent very large retrospective review that clearly shows that high risk NASH patients are more thrombophilic than low risk NASH patients and much more thrombophilic than non-NASH cirrhotic patients.

## Abstract

### AIM

To identify independent risk factors for biliary complications in a center with three decades of experience in liver transplantation.

### METHODS

A total of 1607 consecutive liver transplantations were analyzed in a retrospective study. Detailed subset analysis was performed in 417 patients, which have been transplanted since the introduction of Model of End-Stage Liver Disease (MELD)-based liver allocation. Risk factors for the onset of anastomotic biliary complications were identified with multivariable binary logistic

regression analyses. The identified risk factors in regression analyses were compiled into a prognostic model. The applicability was evaluated with receiver operating characteristic curve analyses. Furthermore, Kaplan-Meier analyses with the log rank test were applied where appropriate.

## RESULTS

Biliary complications were observed in 227 cases (14.1%). Four hundred and seventeen (26%) transplantations were performed after the introduction of MELD-based donor organ allocation. Since then, 21% ( $n = 89$ ) of the patients suffered from biliary complications, which are further categorized into anastomotic bile leaks [46% ( $n = 41$ )], anastomotic strictures [25% ( $n = 22$ )], cholangitis [8% ( $n = 7$ )] and non-anastomotic strictures [3% ( $n = 3$ )]. The remaining 18% ( $n = 16$ ) were not further classified. After adjustment for all univariably significant variables, the recipient MELD-score at transplantation ( $P = 0.006$ ; OR = 1.035; 95%CI: 1.010-1.060), the development of hepatic artery thrombosis post-operatively ( $P = 0.019$ ; OR = 3.543; 95%CI: 1.233-10.178), as well as the donor creatinine prior to explantation ( $P = 0.010$ ; OR = 1.003; 95%CI: 1.001-1.006) were revealed as independent risk factors for biliary complications. The compilation of these identified risk factors into a prognostic model was shown to have good prognostic abilities in the investigated cohort with an area under the receiver operating curve of 0.702.

## CONCLUSION

The parallel occurrence of high recipient MELD and impaired donor kidney function should be avoided. Risk is especially increased when post-transplant hepatic artery thrombosis occurs.

**Key words:** Biliary complications; Liver transplantation; Prognostic model; Risk factors; Multivariable analyses

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This retrospective study investigates the occurrence of biliary complications in a total of 1607 consecutive liver transplant patients throughout three decades. Since introduction of Model of End-Stage Liver Disease (MELD)-based liver allocation, the recipient's MELD-score at transplantation, the development of hepatic artery thrombosis post-operatively, as well as the donor creatinine prior to explantation were identified as independent risk factors, thus a combination of high recipient MELD-score and impaired donor kidney function should be avoided. Risk is especially increased when post-transplant hepatic artery thrombosis occurs. A prognostic model for the prediction of anastomotic biliary complications was developed and successfully internally validated.

Kaltenborn A, Gutcke A, Gwiasda J, Klempnauer J, Schrem H. Biliary complications following liver transplantation: Single-

center experience over three decades and recent risk factors. *World J Hepatol* 2017; 9(3): 147-154 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i3/147.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i3.147>

## INTRODUCTION

Since its introduction as standard procedure in 1983, liver transplantation is nowadays widely accepted as the only live-saving treatment for end stage liver diseases. Nevertheless, several serious complications still endanger successful short- and long-term outcome. Biliary complications appear to be one of the most common issues during follow-up<sup>[1]</sup>. Diverse studies reveal their notable association with mortality and an overall incidence of 10%-40% is described<sup>[2]</sup>. Moreover, the socio-economic implications due to prolonged morbidity are of increasing relevance and represent a serious burden to health care systems<sup>[3]</sup>.

As the bile duct is supplied only arterially without the benefit of portal vein nourishment, there is a pre-determined breaking point to cause repercussions<sup>[4]</sup>. Furthermore, donor parameters, surgical aspects as well as the recipients' condition prior to transplant seem to affect the outcome<sup>[2]</sup>. In general, anastomotic lesions are distinguished from non-anastomotic stenosis or leakage<sup>[5]</sup>. The most common manifestations of biliary complications are strictures of the bile duct<sup>[5]</sup>. Anastomotic lesions are usually due to mechanical and surgical issues which alter the bile duct's arterial support and occur mainly within the first 90 d after transplantation, whereas non-anastomotic lesions show a predominantly manifestation period of about six to nine month after transplant<sup>[5]</sup>. Under the term of non-anastomotic lesions systemic complications such as post-thrombotic, inflammatory and immunological processes as well as the presence of cytotoxic hydrophobic bile salts are summarized, which all lead to damage of the biliary epithelium<sup>[6]</sup>.

In recent studies, inadequate surgical technique, arterial complications such as hepatic artery thrombosis, as well as donor age and macrovesicular graft steatosis could be identified as relevant risk factors for the occurrence of biliary complications in risk-adjusted multivariate analyses<sup>[5,7,8]</sup>.

This study has two aims. Firstly, a historical overview over three decades of biliary complications after liver transplantation should show the development of their incidence. Secondly, main focus was to identify independent risk factors in the most recent years, which contribute to the development of early biliary complications, occurring during the direct hospital stay after liver transplantation.

## MATERIALS AND METHODS

In this single-center, retrospective, observational study, the influence of pre-, inter- and post-transplant aspects as relevant risk factors for the occurrence of early biliary

complications, which occur during the direct hospital stay after liver transplantation, were investigated.

### **Follow-up period and exclusion criteria**

During follow-up patients were routinely seen in the transplant outpatient clinic at least once per year and follow-up visits consisted of physical examination, blood chemistry, as well as standardized abdominal ultrasound. Mean follow-up was 9.4 years (SD: 7.5 years). Included were all consecutive adult liver transplantations (pediatric was defined as younger than 18 years of age). Excluded from analysis were combined transplantations, split liver transplantations, and patients with re-transplantation during initial hospital stay. Since donation after cardiac death is not allowed in Germany by current law, there are no such transplantations included in this study.

### **Definition of eras in 30 years of liver transplantation**

In this study, the three decades of liver transplantation were divided into four eras. Era 1 reaches from 01.01.1983-31.12.1991, Era 2 from 01.01.1992-31.12.1999. Era 3 (Child-Pugh) includes the years 2000-2006 until the Model of End-Stage Liver Disease (MELD) allocation (Era 4) started in 2006.

### **Study endpoints**

Onset of biliary complications during the post-transplant hospital stay is defined as primary study endpoint. In the MELD-era, a more detailed analysis was performed. The further respective study endpoints are complications occurring at the bile duct anastomosis, defined as anastomotic biliary leak or stricture.

### **Regular operative procedure and clinical diagnosis scheme of biliary complications**

For the detection of early biliary complications after liver transplantation, daily ultrasound/Doppler investigations, daily laboratory works, and daily clinical rounds were applied. It is standard operating procedure to implant abdominal drainages during the transplant procedure, which are regularly pulled after the secretion is less than 100 mL post-transplant. The biliary anastomosis was usually performed as end- to end-anastomosis between donor common bile duct and recipient common hepatic duct using a 6/0 prolene suture in continuous manner. University of Wisconsin preservation solution was routinely used until recently, the application of HTK solution increased since its introduction in the early 1990s and is nowadays the mostly applied preservation solution. A more detailed analysis of preservation solutions and their application at the study center is given elsewhere<sup>[10]</sup>. Due to certain indications for liver transplantation, such as primary biliary diseases, a hepaticojejunostomy in Roux-Y-technique is implemented<sup>[11]</sup>. The implantation of T-tube was omitted as standard procedure at our center around 2004 and has not been applied since.

### **Treatment schemes for biliary complications**

There are various therapy options for biliary com-

plications. Early biliary complications, such as biliary leaks can be managed *via* endoscopic retrograde cholangiopancreatography with stent implantation, whereas late complications, such as biliary stenosis or a diffuse leakage often require a percutaneous transhepatic biliary drainage, surgical revision with a Y-Roux hepaticojejunostomy or at last resort a re-transplantation.

### **Ethics statement**

The study was reviewed and approved by the institutional review board of Hannover Medical School (application number 1683-2013).

### **Statistical analysis**

Risk factors for the onset of study endpoints after liver transplantation were identified with univariable and multivariable binary logistic regression analyses. The alpha-level for inclusion into multivariate modeling was set at 0.05. All variables which were significant in univariable binary logistic regression analysis were considered for the multivariable binary regression model. Variables which were included in the multivariable regression model were compiled as the prognostic score for the prediction of anastomotic biliary complications. The clinical usefulness of this score was assessed with receiver operating characteristic curve analysis. Areas under the receiver operating curve (AUROCs) larger than 0.700 indicate a clinically useful prognostic model<sup>[9]</sup>. For internal validation of the developed score, randomized backwards bootstrapping was applied. Kaplan-Meier analysis with the Log-Rank test was applied where appropriate. For all statistical tests a *P*-value < 0.05 was defined as significant. The SPSS statistics software version 21.0 (IBM, Somers, NY, United States) was used to perform statistical analysis.

## **RESULTS**

Descriptive statistics of the investigated study population of 1607 consecutive liver transplants is summarized in Tables 1-3. During 30 years of follow-up, 561 (35.1%) patients deceased. The documented causes of death are summarized in Table 4.

### **Biliary complications during 30 years of liver transplantation**

During 30 years of liver transplantation at a single center, biliary complications were observed in 227 cases (14.1%). The development of biliary complication incidence since 1983 is shown in Figure 1. Patient as well as graft survival were significantly associated to the occurrence of biliary complications during 30 years of follow-up, as shown in Kaplan Meier analysis (Figure 2).

### **Detailed analysis of biliary complications in the MELD era**

Of the 1607 included transplantations, 417 (26%) were performed after introduction of MELD-based donor

organ allocation in December 2006. During this MELD-era, 21% of patients ( $n = 89$ ) suffered from early biliary complications during the initial post-transplant hospital stay. The distribution of complication type in the MELD-era is shown in Figure 3. In 46% ( $n = 41$ ) of the patients an anastomotic bile leak occurred, whereas 25% ( $n = 22$ ) showed an anastomotic stricture. Cholangitis occurred in 8% ( $n = 7$ ), non-anastomotic strictures in 3% ( $n = 3$ ) of the cases. The remaining 18% ( $n = 16$ ) were not further classified.

Since the biliary anastomosis can be influenced the most by the operating surgeon, risk factors were evaluated for anastomotic biliary complications, which included biliary strictures and anastomotic leakage. In 63 patients (15.1%) anastomotic complications were observed. Table 5 shows the results of univariable and multivariable binary regression analysis for identification of significant, independent risk factors for the development of anastomotic biliary complications during the initial post-transplant hospital stay. After adjustment for all univariable significant variables, the recipient MELD-score at transplantation ( $P = 0.006$ ;

variable analysis [recipient MELD-score, post-operative HAT, donor creatinine, donor body mass index (BMI), recipient intensive care unit (ICU) stay in days, donor gender, donor bilirubin] in a regression equation, this model provides good prognostic abilities in the investigated cohort with an AUROC of 0.702 (Figure 4). The model was internally validated applying a backwards randomized bootstrap analysis in 100 cases [mean AUROC: 0.720 (SD: 0.040)]. The proposed prognostic

Figure 3 Different biliary complications in the Model of End-Stage Liver Disease era.

model is:  $y = 1.030 \times \text{MELD at transplantation} + 0.937 \times \text{donor BMI} + 1.021 \times \text{donor bilirubin} + 1.003 \times \text{donor creatinine} + 1.005 \times \text{posttransplant ICU days} + 3.117 \times \text{posttransplant HAT} + 1.741 \times \text{male donor gender}$ .

## DISCUSSION

Biliary complications are a common post-operative issue after liver transplantation. Liver transplantation has been established in the 1980s as the only life-saving standard treatment for many conditions leading to end-stage liver disease. Therefore, the number of performed liver transplantations has been increasing ever since. Biliary complications endanger early as well as long-term success of liver transplantation and are thus constantly in focus of research to improve care for transplant recipients. However, evidence from large single-center databases on the long-term follow-up of liver transplant recipients including risk-adjusted identification of probable risk factors for the development of biliary complications is still scarce. In the current study,

**Table 5 Univariable and multivariable analyses for identification of risk factors for anastomotic biliary complications since 2006**

MELD: Model of End-Stage Liver Disease; BMI: Body mass index; ICU: Intensive care unit; ALT: Alanine aminotransferase; AST: Aspartate transaminase; GGT: Gamma glutamyltransferase; CMV: Cytomegalovirus; PVT: Portal vein thromboses; HCC: Hepatocellular carcinoma; PSC: Primary sclerosing cholangitis; ALF: Acute liver failure; HCV: Hepatitis C virus; CRP: C-reactive protein.

a large European center reports its results regarding biliary complications overlooking over three decades of transplant experience. Moreover, in the recent era with the introduction of MELD-based organ allocation in late 2006 as defined starting point, relevant independent risk factors were investigated.

It could be shown that the onset of post-transplant biliary complications endangers patient as well as graft survival even in the long run (Figure 2;  $P = 0.006$ ;  $P = 0.001$ , resp.). This also has serious implications for healthcare economy. A recent analysis of a large dataset with more than 12800 liver transplantations could show that biliary complications in recipients receiving a graft after brain death donation were responsible for an increment of cost of nearly 55000\$ in the first post-transplant year<sup>[3]</sup>. These findings could be confirmed in the following post-transplant years as well as in donation after cardiac death transplantations.

As shown in Figure 1, the number of patients suffering from biliary complications after liver transplantation decreased very early in the observed series to a minimum of closely over 5% in 1985. This early drop might well be a result of the early surgical learning curve. It can also be assumed that some biliary complications might not be detected in these years due to technically less developed diagnostic capabilities, such as computed tomography or ultrasound. Furthermore, early mortality was comparatively high and recipients might have died before developing detectable/treatable biliary complications.

In the years between 1985 and 2006, the incidence of biliary complications was ranging from 5% to 25% of performed transplantations per year, which is comparable to other reported data<sup>[3,5,6]</sup>. These years were characterized by introduction of the Child-Pugh score-based center allocation scheme in the year 2000, which represents a paradigm shift and is therefore regarded in

**Figure 4** Receiver operating characteristic-curve of the developed prognostic model for the prediction of anastomotic biliary complications in the Model of End-Stage Liver Disease-era ( $n = 417$  liver transplants). The area under the receiver operating-curve is 0.702 indicating a useful and clinical applicable prognostic model.

the analysis as a new era. After introduction of MELD-based organ allocation in late 2006, the rate of biliary complications starts to fluctuate in a wider range from 10% to as high as 30%. The notion that donor organ quality might have decreased as well as the general condition of the transplant recipients since the start of this recent era has led to a controversial discussion in the German transplant community about the usefulness of this current allocation policy.

As early as 2009, Weismüller *et al.*<sup>[12]</sup> reported of decreased short-term survival since the introduction of MELD-based liver allocation. An association with longer surgery duration and higher recipient morbidity could be revealed as possible underlying causes. As another example, it was reported recently that indications with high chances for successful long-term survival after liver transplantation such as primary sclerosing cholangitis did not show any improved outcome since MELD-introduction in Germany and that there is relevant outcome stagnation for this entity<sup>[13]</sup>.

Therefore, a more detailed analysis was applied on the MELD-era data, in which a categorization of the biliary complication into different subtypes was possible due to consequent and clear documentation, as well as electronic patient files. Since the biliary anastomosis seems to be the most susceptible part for surgical improvement measures, the anastomotic complications are in a special focus of this investigation. Multivariable, risk-adjusted analysis revealed that the MELD-score at transplantation, the donor creatinine at time of graft donation and the development of HAT after transplantation were statistically significant, independent risk factors for the onset of anastomotic biliary complications. The association of post-transplant HAT and the development of biliary complications has been observed several times and can be explained by an anatomical circumstance. The biliary tract tissue is

especially vulnerable to impaired arterial vascular supply. Whereas the liver parenchyma is nourished *via* a dual vascular supply *via* portal vein and hepatic artery, the bile ducts are supplied only arterially<sup>[5]</sup>. Therefore, the biliary epithelium is more susceptible to decreased perfusion than hepatocytes, which is the case in ischemic injury and severe hypotension, both occurring in the donor organ during transplantation and after HAT.

The finding that the recipient MELD score has influence on the onset of post-transplant biliary complications seems not to be surprising. The MELD-score was shown to accurately depict the recipients state of morbidity prior to transplantation<sup>[14,15]</sup>, thus identifying patients with a risk profile to have impaired healing capabilities at the bile duct anastomosis. This is further confirmed by the finding that impaired donor kidney function as depicted *via* increased donor creatinine levels contributes to the development of anastomotic bile duct lesions, since this further intensifies the unfavorable metabolic situation at the anastomosis, which is at risk for ischemic injury.

After a relevant drop of the incidence of biliary complications in 2011, the number of observed complications increased again in 2012. The data does not clearly provide insights into the root-causes of this observed development, thus, only assumptions can be discussed here. There was no notable change in allocation policies at that time, MELD-based allocation was introduced in late 2006 in Germany as mentioned above. Furthermore, the clinical setting did not change significantly, just a slight increase in the application of Histidine-Tryptophane-Ketoglutarat (HTK) preservation solution could be detected in 2012. HTK-solution was suspected to be associated to biliary complications previously and a trend towards this association was shown in our center in previously published research<sup>[10,16]</sup>.

The proposed prognostic model, which is basing on the results of regression analyses, was shown to have good predictive capabilities with an AUROC > 0.700. Furthermore, it could be internally validated successfully with 100 randomized backwards bootstraps. These promising results regarding this model warrant its validation in an external dataset, which is definitely necessary before a broad application in clinical transplantation seems useful. This validation is preferably performed in a prospective, multi-centric cohort or a large transplant registry, which contains all relevant data as described above.

This study is limited by its single center design and its retrospective character. Furthermore, the long observation period of three decades naturally includes changes in diagnostics and management of biliary complications. This circumstance was addressed with the categorization of the data into four eras, which was taken into account during statistical analysis.

Taken together, the results of the current study lead to the assumption that high recipient MELD scores in combination with impaired donor kidney function as depicted in donor creatinine levels at the time of transplantation should be avoided to protect the recipient from

the onset of early biliary complications. This is especially the case, when HAT occurs in the post-transplant setting, which further endangers the recipient to develop serious anastomotic bile duct issues.

## COMMENTS

### Background

Biliary complications account for a great part of early issues after liver transplantation leading to re-intervention, serious morbidity and even mortality. Moreover, they are responsible for a high amount of healthcare costs after transplantation.

### Research frontiers

In recent years, studies were outlined and published to identify relevant risk factors for the development of biliary complications. However, long-term follow-up data and large series overlooking decades of liver transplant experience are scarce. There is especially no prognostic model available so far, which helps to identify patients who are threatened by this serious complication.

### Applications

The results of this study should reduce the incidence of anastomotic biliary complications after liver transplantation. The proposed prognostic model for the prediction of anastomotic biliary complications can be a tool for the transplant clinician to identify patients at high risk for the development of biliary complications, which then can be included into a stricter diagnostic observation scheme, e.g., with repeating abdominal ultrasound examinations and blood works.

### Terminology

Biliary complications do regularly occur after liver transplantation. They can be classified into anastomotic (bile leak vs strictures) and non-anastomotic lesions. In many countries, liver grafts are currently allocated on the basis of the Model of End-Stage Liver Disease (MELD)-score, which is a score including the recipient's bilirubine levels, creatinine levels as well as the coagulation state via the international normalized ratio-value. The MELD-score is able to reliably predict short-term death on the liver transplant waiting lists in many transplantation systems.

### Peer-review

An interesting well-written study.

### Abstract

Mucosa-associated lymphoid tissue (MALT) lymphoma of the liver is a very rare condition and thus the diagnosis may be challenging. The clinical presentation is usually variable, ranging from minimal clinical symptoms to severe end stage liver disease. In this paper, we describe the clinicopathologic findings in two cases of primary hepatic MALT lymphoma. One case is an 80-year-old female with no underlying chronic liver disease and the second case is a 30-year-old female with autoimmune hepatitis complicated by MALT lymphoma. In both specimens, there was diffuse infiltration of atypical B-lymphocytes that were positive for CD20 and CD79a, but negative for CD5, CD43 and CD10. There were occasional lymphoepithelial lesions involving the hepatocytes or bile ducts. Polymerase chain reaction analysis showed monoclonal immunoglobulin heavy chain gene rearrangement in both cases. The first case was treated with surgery but developed pulmonary recurrence a year after complete resection but went into remission following treatment with rituximab. A second recurrence occurred in the right parotid gland 7 years later, which was treated with idelalisib. The second case was effectively treated with rituximab. To our knowledge, the second case is the first reported case linked to autoimmune hepatitis.

**Key words:** Extranodal; Mucosa-associated lymphoid tissue; Lymphoepithelial; Lymphoma; Polymerase chain reaction

**Core tip:** The diagnosis and management of mucosa-associated lymphoid tissue lymphoma of the liver can be a clinical dilemma. Recognition of the clinic-pathologic

pattern and its associations with underlying autoimmune disease can prevent misdiagnosis. This case report not only represents the first reported association with autoimmune hepatitis and the development of multiple recurrences of the lymphoma in the literature, but also it applies new successful treatment regimens as an alternative to current clinical practice.

## INTRODUCTION

Mucosa-associated lymphoid tissue (MALT) lymphoma, is a distinct subgroup of non-Hodgkin's lymphoma (NHL) that accounts for 7%-8% of all B cell lymphomas<sup>[1]</sup>. MALT lymphomas are considered low-grade and they can occur in a variety of organs, including the stomach, orbit, conjunctiva, salivary gland, skin, thyroid, lung, stomach, intestine, dura and rarely liver. MALT lymphomas usually arise in areas that are devoid of lymphoid tissue, but are preceded by chronic inflammation, either infectious or autoimmune, which result in the accumulation of extranodal lymphoid proliferation<sup>[1]</sup>. Prolonged lymphoid proliferation can eventually result in the development of a malignant clone. The stomach is the most common site of MALT lymphoma and its association with *H. pylori* is well documented<sup>[2-4]</sup>. An increased occurrence of MALT lymphomas, especially in the salivary glands has been reported in patients with Sjögren's syndrome<sup>[5-7]</sup>. Patients with Hashimoto's thyroiditis have a 67- to 80-fold increased risk of developing primary thyroid lymphoma<sup>[8-10]</sup> and B-cell type NHL is the most common type and features of MALT lymphoma can be seen in over one-third of cases<sup>[10]</sup>. Case studies on MALT lymphoma of the liver have been rarely reported and very little is known about this disease entity. Here we present two cases with primary MALT lymphoma of the liver, one with no underlying chronic liver disorder and the other is associated with autoimmune hepatitis.

## CASE REPORT

### Case 1

An 80-year-old Caucasian female, presents with a history of nausea, loss of appetite and a 20-pound weight loss. History was negative for any underlying infectious or autoimmune process. Physical examination was notable for weight loss. Abnormal laboratory results obtained was as follows: WBC 13.5 K/UL, aspartate aminotransferase (AST) 137 U/L and alanine aminotransferase (ALT) 166 U/L, alkaline phosphatase 53 U/L, albumin 2.5 g/dL, bilirubin total 1.1 mg/dL, Bilirubin direct 0.2 mg/dL. Abdominal computed tomography (CT) scan identified

a bi-lobed mass in the left hepatic lobe (Figure 1A). No dilatation of the intra- or extra-hepatic bile ducts was seen. The spleen, pancreas, gallbladder kidneys and adrenal glands were unremarkable. Histological sections of the mass revealed a nodular infiltrate of atypical lymphocytes with small irregular nuclei and abundant clear cytoplasm surrounding occasional reactive germinal centers (Figure 1B and C). Focal fibrosis and plasmacytosis was identified at the periphery of the nodules. There were occasional lymphoepithelial lesions (Figure 1D). Immunohistochemical staining showed that the neoplastic cells were positive for CD20 (Figure 1E), CD79a and BCL-2 and negative for CD10, CD5 (Figure 1F), CD23, BCL-6, CD43, CD3, CD21, CD138 and IgD. Ki-67 was positive in approximately 30% of the cells. Polymerase chain reaction (PCR) analysis by capillary electrophoresis was clonal for immunoglobulin heavy chain (IgH) rearrangement. Bone marrow biopsy showed normocellular marrow with trilineage hematopoiesis and no evidence of lymphoma. These results supported the diagnosis of MALT lymphoma of the liver. On further follow-up, a year later, the patient developed pulmonary nodules which were proven to be MALT lymphoma on biopsy. She went into remission following treatment with rituximab for one year. Seven years later she presented with a right neck mass which was positive for MALT lymphoma of the parotid gland. The lung and parotid MALT lymphoma showed the same IgH rearrangement by PCR, which indicated that they were the same clones.

### Case 2

A 30-year-old lady presented to the clinic for management of a previously diagnosed autoimmune hepatitis. At 10 years of age, she was diagnosed with Hashimoto's thyroiditis and further work up revealed autoimmune hepatitis on a liver biopsy which was managed on azathioprine. In the previous year prior to presentation, she had a flare up of the autoimmune hepatitis when her liver enzymes were found to be in the 500's range and remained abnormal despite having been on medication. At the time of presentation, the patient was asymptomatic. The laboratory results obtained were as follows: WBC 1.5 K/UL, platelet 70 K/UL, HB 11.1 g/dL, AST 209 mg/dL, ALT 232U/L, alkaline phosphatase 239 U/L, bilirubin total 1.4 mg/dL, bilirubin direct 0.5 mg/dL. Biochemical investigation for chronic viral hepatitis was negative. Although previously positive, her current report for anti-smooth muscle antibodies was negative. Positron emission tomography/CT abdomen showed an enlarged liver (20 cm) with heterogeneity and diffuse FDG activity (Figure 2A), which was highly suspicious for malignancy. The spleen was slightly enlarged with mild portacaval and left paraaortic adenopathy. Liver biopsy identified atypical lymphoid infiltrate with focal interface activity, fibrosis and lymphoepithelial lesions on histopathological examination (Figure 2B). Immunohistochemistry analysis showed predominantly CD20 positive B-lymphocytes in the infiltrate (Figure 2C) that were negative for CD5, CD10, or CD43. Ki-67 proliferative index was low (30%)

**Figure 1 Abdominal computed tomography scan and histology of the mass.** A: Computed tomography of the abdomen reveals a large mass, highlighted in red, in the left lobe; B: Effacement of normal liver by nodules of atypical lymphocytes [hematoxylin-eosin (H and E), 2.5  $\times$ ]; C: Hepatocytes are admixed with neoplastic lymphocytes (H and E, 20  $\times$ ); D: Lymphoma cells infiltrate into the bile duct forming lymphoepithelial lesions (arrows) (H and E, 40  $\times$ ); E, F: By immunohistochemistry, the neoplastic cells are positive for CD20 (E) and negative for CD5 (F) (40  $\times$ , each).

**Figure 2 Positron emission tomography-computed tomography and histology of the liver mass.** A: Liver shows diffuse fluorodeoxyglucose activity throughout the parenchyma with the maximum standardized uptake value of 8.6; B: The atypical lymphocytes grow diffusely forming mass with occasional lymphoepithelial lesions (40  $\times$ ); C, D: By immunohistochemistry, the neoplastic lymphocytes are positive for CD20 (C, 40  $\times$ ) and have low MIB-1 proliferative index (D, 40  $\times$ ).

except in the reactive germinal center (Figure 2D). PCR analysis of the liver biopsy was positive for the *IgH* gene rearrangement, indicating monoclonal B cell proliferation.

Her bone marrow biopsy showed trilineage maturation with no evidence of lymphoma. Treatment with rituximab was commenced and the patient is still in remission three

years later.

## DISCUSSION

The etiology of MALT lymphoma of the liver is still unclear. In most extranodal MALT lymphomas, chronic inflammation due to either an infectious process or autoimmune process has been implicated. Several disease conditions have been associated with the development of hepatic MALT lymphoma which makes initial diagnosis very difficult. Nagata *et al*<sup>[11]</sup> reviewed 51 cases of MALT lymphoma of the liver. They reported that 25% was not associated with any disease condition. However, hepatic MALT lymphoma was associated with carcinomas (21%), viral and drug related-hepatitis (20%), biliary cirrhosis (10%), liver cirrhosis (10%), ascariasis (4%), gastric MALT lymphoma (4%), rheumatoid arthritis (2%), multiple biliary unilocular cysts (2%) and no information was reported in 2% of the cases. Majority of the cases presented as a solitary mass and were effectively treated with surgical resection without any adjuvant therapy. Our first case had no underlying history of hepatitis, infection, cancer or autoimmune condition. The only concerning clinical sign was drastic weight loss. The abnormal liver enzymes and liver mass were incidental findings. Clinically an initial diagnosis of hepatocellular carcinoma was made and the patient underwent surgery with complete resection of the lesion, which prevented recurrence in the liver but the lymphoma recurred in the lungs. The most frequent location of recurrence of hepatic MALT lymphoma following treatment appears to be the lungs<sup>[11,12]</sup> and this occurs at a mean average of 65 mo. Of the 3 reported cases in the literature, 2 patients were treated with resection and the remaining one, with radiation. Hepatic recurrence is rare after complete resection and only one case has been reported<sup>[11]</sup>. Our patient developed pulmonary recurrence only after one year, but after treatment with rituximab the patient remained in remission for 7 years. However, the lymphoma recurred in the right parotid gland which was treated with 7 mo of idelalisib. The patient is currently in remission a year later. MALT lymphoma generally has an indolent course but recurrences can occur over many years and it tends to involve other common extranodal sites<sup>[13]</sup>. In our experience, we report for the first time multiple recurrences of MALT lymphoma following complete resection of hepatic MALT lymphoma.

The mean age of patients with MALT lymphoma of the liver is about 60 years of age<sup>[11,14]</sup>, however our second case was 30 years old with an underlying confirmed diagnosis of autoimmune hepatitis which is a disorder frequently seen in young women. Wöhrer *et al*<sup>[15]</sup> analyzed 158 patients with MALT lymphoma and 39% had an autoimmune disease. The patients were predominantly women and significantly younger at lymphoma diagnosis. The most commonly reported autoimmune disorder associated with liver MALT lymphoma is biliary cirrhosis<sup>[14,16,17]</sup> and the usual presentation is as a solitary mass. To our knowledge, this is the first reported case associated with autoimmune

hepatitis. Autoimmune hepatitis is a chronic progressive liver disease, characterized by hepatocellular inflammation and liver damage and a tendency to progress to liver cirrhosis. Most patients also have other autoimmune diseases including type 1 diabetes, thyroiditis, vitiligo and Sjögren's syndrome. In support of this, in addition to autoimmune hepatitis, our patient had hashimoto thyroiditis. Similar to MALT lymphoma in other organs, chronic immune activation in autoimmune hepatitis may contribute to lymphomagenesis in the liver. Perhaps the prolonged history and severity of the disease in case 2 explains the diffuse liver involvement with MALT lymphoma. It is important to note that reactive lymphoid hyperplasia, also known as pseudolymphoma, is associated with autoimmune hepatitis<sup>[18]</sup>. Interestingly pseudolymphoma of the liver can cause a focal liver mass with atypical lymphoid proliferation on histology, which predominantly stain positive for CD20 and reactive germinal center formation<sup>[19]</sup>. The benign entity can be difficult to differentiate from hepatic MALT lymphoma without further molecular investigation and majority of these lesions are resected due to suspicion for a malignancy. Sato *et al*<sup>[20]</sup> reported transformation of a pseudolymphoma of the liver, in a background of biliary cirrhosis, into a diffuse B cell NHL. Accordingly, patients with pseudolymphoma will require close follow-up to prevent a misdiagnosis of MALT lymphoma. Indeed, further studies are needed to determine if there is an association between pseudolymphoma and subsequent transformation into low grade lymphomas such as MALT lymphoma.

Rituximab has shown promise as an effective treatment in extra-gastric MALT lymphoma<sup>[21,22]</sup> but very few cases involving treatment with rituximab have been reported in hepatic MALT lymphoma. Stable remission have been described in patients treated with rituximab following surgical resection<sup>[23]</sup> or in combination with chemotherapy<sup>[24]</sup> or radiofrequency ablation<sup>[25]</sup>. Both of our patients were treated with rituximab and our second case had no previous surgical treatment or chemotherapy. Although high remission rates are achieved by chemotherapy<sup>[26]</sup>, treatment with rituximab can minimize toxicity while maintaining efficacy. Idelalisib, a selective inhibitor of the delta isoform of phosphatidylinositol 3-kinase<sup>[27]</sup>, which plays an important role in B-cell development, proliferation, migration, adhesion and survival<sup>[28]</sup> has shown efficacy by inducing apoptosis in malignant B-cells in patients with relapsed follicular lymphoma or refractory chronic lymphocytic lymphoma<sup>[27,29]</sup>. To our knowledge, our study is the first reported case to use idelalisib in the treatment of recurrent MALT lymphoma of the liver and should be considered as a possible effective therapy following treatment failure with rituximab.

Primary hepatic MALT lymphoma is very rare. From our experience, we recommend that young patients with autoimmune hepatitis with sudden elevation of liver enzymes, should raise the suspicion of MALT lymphoma of the liver. Since the liver was diffusely involved, rituximab as the sole agent can be used as an effective treatment of choice. Patients with hepatic MALT lymphoma should

be closely followed up for recurrence especially in common extranodal sites. Rituximab or Idelalisib can be a suitable treatment in patients with relapse. In solitary cases of MALT lymphoma of the liver, complete resection of the lesion with adjuvant rituximab therapy should be considered to prevent recurrence.

## COMMENTS

### Case characteristics

Mucosa-associated lymphoid tissue (MALT) lymphoma of the liver is a very rare condition, which can be misdiagnosed.

### Clinical diagnosis

Hepatic MALT lymphoma is associated with various inflammatory and autoimmune diseases, and one of the authors' patients had autoimmune hepatitis. The disease may also occur in the absence of any underlying disorder.

### Differential diagnosis

Hepatocellular carcinoma (HCC), hepatic reactive lymphoid hyperplasia, cholangiocarcinoma, metastatic carcinoma to the liver.

### Laboratory diagnosis

The liver enzymes were elevated in both cases of MALT lymphoma of the liver.

### Imaging diagnosis

Lesions of hepatic MALT lymphoma may resemble HCC, cholangiocarcinoma or hepatic metastasis on computed tomography or position emission tomography scan, often leading to misdiagnosis.

### Pathological diagnosis

MALT lymphoma of the liver often presents as infiltration of the liver with atypical lymphocytes, forming lymphoepithelial lesions on histologic sections and monoclonal immunoglobulin heavy chain gene rearrangement on PCR analysis.

### Treatment

Complete surgical excision of lesion or rituximab in localized disease and the use of rituximab or idelalisib in recurrent or advanced disease.

### Related reports

Although MALT lymphoma of the liver is considered a low grade lymphoma, patients should be closely followed up for recurrence especially in common extranodal sites. Recurrences or advanced disease can be treated with biological targeted therapy to achieve remission while avoiding the toxic effects of chemotherapy.

### Term explanation

MALT lymphoma of the liver is associated with an inflammatory or autoimmune condition such as, primary biliary cirrhosis, hashimoto disease or like in our patient, autoimmune hepatitis. In some cases, there may be no underlying associations.

### Experiences and lessons

MALT lymphoma of the liver should be considered when imaging studies show a hepatic lesion with an underlying autoimmune condition or when a solitary liver mass is identified in a patient with no clear risk factors for HCC and cholangiocarcinoma.

### Peer-review

Well written and excellent case report on two patients with MALT lymphoma of the liver.

### Abstract

Chronic hepatitis C virus (HCV) infection is one of the main causes of chronic liver disease worldwide. In the last 5 years, treatment for HCV infection has experienced a marked development. In 2014, the use of ledipasvir/sofosbuvir with or without concomitant weight-based ribavirin was approved with a very significant increase in the sustained virological response. However, new side effects have been associated. We report the first case of an HCV infected patient treated for 12 wk with the combination of sofosbuvir/ledipasvir plus ribavirin who developed a miliary tuberculosis (TB) infection while on therapy. The patient was a 65-year-old woman, who referred malaise, asthenia, hyporexia, 7 kg weight loss, productive cough, evening fever and night sweats, right after finishing the treatment. The chest computed tomography-scan revealed a superior mediastinal widening secondary to numerous lymphadenopathies with extensive necrosis and bilateral diffuse lung miliary pattern with little subsequent bilateral pleural effusion, highly suggestive of lymph node tuberculosis with lung miliary spread. A bronchoscopy was performed and bronchial suction showed more than 50 acid-alcohol resistant bacillus per line. A *Mycobacterium tuberculosis* DNA was detected in blood by polymerase chain reaction, which confirmed the diagnosis of miliary tuberculosis. Some cases of TB infection have been identified with  $\alpha$ -interferon-based therapy and with the triple therapy of pegylated interferon, ribavirin and boceprevir or telaprevir. However, significant infection has not been reported with sofosbuvir/ledipasvir plus ribavirin.

We believe that the case is relevant to increase awareness of opportunistic infections and particularly TB infection. Although the international guidelines offer no recommendation regarding TB screening, we wonder whether it would be advisable to screen for opportunistic infections prior to the introduction of HCV therapy.

**Key words:** Tuberculosis; Ledipasvir; Ribavirin; Sofosbuvir; Hepatitis C

**Core tip:** Cases of tuberculosis (TB) infection have been identified with  $\alpha$ -interferon-based therapy and the triple therapy with pegylated-interferon, ribavirin and boceprevir or telaprevir. This is the first case of a TB infection during treatment with sofosbuvir/ledipasvir plus ribavirin. It is relevant to increase awareness of TB due to its variety of symptoms, which can be confused with those associated to the hepatitis C virus or the antiviral treatment. Considering the impaired immune system of cirrhotic patients and that these drugs arrived slightly more than one year ago it is important to be conscious of the potential events that can be related with the treatment.

## INTRODUCTION

Affecting more than 160 million people and at an increasingly higher rate, hepatitis C virus (HCV) infection is one of the main causes of chronic liver disease worldwide. In the last 5 years, treatment for HCV infection has experienced a marked development, especially in the case of treatment for genotype 1. Previously, treatment was based on pegylated interferon and ribavirin for 48 wk, which achieved a sustained virological response (SVR) rate of 45% to 50%. In 2011, the first generation of protease inhibitors-telaprevir and boceprevir-reached the market. The triple therapy with peg-interferon, ribavirin and a protease inhibitor was then adopted as the standard of care, followed in 2013 by the approval of the second generation of protease inhibitor, simeprevir, and the polymerase inhibitor, sofosbuvir. In 2014, the use of ledipasvir/sofosbuvir was approved, as well as the use of ombitasvir/paritaprevir/ritonavir plus dasabuvir for the treatment of HCV genotype 1 infections with or without concomitant weight-based ribavirin. These changes have brought a very significant increase in the SVR, with rates rising above 90%. However, new side effects, such as decompensation of cirrhosis, liver toxicity and some

infections, have been associated<sup>[1]</sup>.

We report the first case of an HCV-infected patient treated for 12 wk with the combination of sofosbuvir/ledipasvir plus ribavirin who developed a miliary tuberculosis infection while on therapy.

## CASE REPORT

The patient was a 65-year-old woman from Equatorial Guinea, who had been residing in Spain since 2000 (16 years), without any recent trip reported. Her medical history included a blood transfusion event in 1996, diabetes mellitus type 2 diagnosed in 1997 under treatment with insulin, no current nor previous smoking habits and no underlying pulmonary disease or symptoms. In 2000 the patient was admitted to the hospital with abdominal pain. On physical examination hepatomegaly was detected. The blood test revealed hypertransaminasemia and the serology test permitted the diagnosis of chronic HCV infection. HCV genotype was 1a and viral load was 720000 IU/mL. An abdominal ultrasonography revealed a discrete homogeneous hepatomegaly with no focal liver lesions and a transient elastography resulted in 7.9 kPa. A liver biopsy was performed showing chronic HCV infection with Batts and Ludwig<sup>[2]</sup> stage 1, grade 1. In January, 2008, the patient was treated with the standard at that time, based on the combination of peg-interferon- $\alpha$  2a (180  $\mu$ g/wk) with ribavirin (1200 mg/d) during 12 mo. Unfortunately, treatment had to be stopped three mo after starting due to the appearance of side effects: Gluteus abscess, leucopenia and anemia. The patient was followed up in outpatients' clinic without further therapy for hepatitis C until 2015 when she was evaluated for starting treatment with the new direct antiviral agents (DAAs). She was asymptomatic and there were no signs of ascites, edema, bleeding or encephalopathy nor lymphadenopathies on physical examination. Body weight was 54 kg. Hemoglobin level was 12.9 g/dL (reference range -RR-: 11.5-15.5), leucocyte count 5.56 cells/ $\mu$ L (RR: 3.9-11), absolute neutrophil count 1.14 cells/ $\mu$ L (RR: 2.5-7.5), absolute lymphocyte count 2.46 cells/ $\mu$ L (RR: 1.5-4.5) and platelet count 144.000 cells/ $\mu$ L (RR: 160.000-400.000). Albumin was 4 g/dL (RR: 3.5-5.2), total bilirubin 0.43 mg/dL (RR: 0.10-1.00), INR was 1.09 (RR: 0.85-1.35), alanine aminotransferase (ALT) 126 U/L (RR: 1-31), aspartate aminotransferase 120 U/L (RR: 1-31), gamma glutamyl transpeptidase 52 U/L (RR: 1-38) and alkaline phosphatase 90 U/L (RR: 30-120). Alpha-fetoprotein was 9.3 ng/mL (RR: 0.0-7.0) and glycosylated-hemoglobine was 5.2% (RR: 4.0-6.1). Human immunodeficiency virus (HIV) serology was negative. Viral load was 1300000 IU/mL and HCV genotype was 1a and the *IL28B* gene was TC. An abdominal ultrasound exam revealed signs of hypertrophy of the left and caudate liver segments with a focal benign lesion (hemangioma) of 9 mm in segment IV with no changes when compared to previous tests, normal portal vein caliber with hepatopetal flow and a splenomegaly of 13 cm. Transient elastography scored a

Figure 1 Chest X-ray: Left hilar widening (arrow).

result of 11.1 kPa. Treatment with ledipasvir/sofosbuvir plus ribavirin during 12 wk was initiated in June, 2015. The check-up at the clinic one month later showed no symptoms or pathological signs on physical examination. The treatment was completed but in September, 2015, the patient complained about malaise, asthenia, hyporexia, 7 kg weight loss and dry cough. She referred that these symptoms had appeared one month before she was attended at the emergency unit. However, due to the clinical and hemodynamic stability, the patient was discharged with further outpatient control. In the next 2 wk, in early October, a more productive cough with white sputum, evening fever and night sweats were added to the previous symptoms and upon examination at the emergency unit again, the patient's temperature was 39 °C, blood pressure was 131/94 mmHg, heart rate was 130 bpm with 98% oxygen saturation. She was conscious with no signs of neurologic impairment. Cardiac and pulmonary auscultation were normal, the abdomen was soft with a 3 cm hepatomegaly and a 2 cm splenomegaly without signs of ascites or abdominal pain, limbs showed no signs of edema and no cervical, axillary or inguinal adenopathies were found. The blood test highlighted a sodium level of 129 mmol/L (RR: 135-145), ALT 38 U/L, CRP 94 mg/L (RR: < 5), hemoglobin level 9.6 g/dL, leucocyte count 5.98 cells/ $\mu$ L, absolute neutrophil count 4.84 cells/ $\mu$ L, absolute lymphocyte count 0.78 cells/ $\mu$ L, platelet count 114000 cells/ $\mu$ L and INR 1.26 with the rest of parameters standing within the normal range. The arterial gasometry showed pH 7.51 (RR: 7.35-7.45), pO<sub>2</sub> 126 mmHg (RR: 83-108), pCO<sub>2</sub> 29 mmHg (RR: 35-45), lactate 1.6 mmol/L (RR: 0.6-1.17) and bicarbonate 25 mEq/L (RR: 20-29). The urine test, abdominal X-ray and cranial computed tomography (CT) scan that were carried out revealed no abnormalities. The chest X-ray showed a left hilar widening (Figure 1) and the patient was admitted to the hospital for further studies. The blood culture was negative, as well as the malaria and leishmania tests. The sputum direct vision showed mixed microbiota with predominance of gram-negative bacillus with no acid-alcohol resistant bacillus (AARB) seen. Nevertheless, *Mycobacterium tuberculosis* showed up in the culture of the sputum after 10 d. Chest and abdomen CT scan revealed a superior mediastinal

widening secondary to numerous lymphadenopathies with extensive necrosis, causing a displacement of the esophagus and trachea, and contiguous to these lymphadenopathies, a left hilar mass displaying an air bubble communicated with the left bronchial tree (Figure 2), as well as a bilateral diffuse lung miliary pattern with little subsequent bilateral pleural effusion (Figure 3). These findings were highly suggestive of lymph node tuberculosis with lung miliary spread, being less likely to be attributed to a malignant left hilar mass. A flexible bronchoscopy was performed showing a bossing in the upper part of the trachea and mucosa thickening in both main bronchi with partial stenosis of the left upper lobule bronchi. The retrotracheal mass was biopsied, displaying acute inflammation in the pathological study with negative Zielh Neelsen test. However, in the bronchial suction there were more than 50 AARB per line. A *Mycobacterium tuberculosis* DNA was detected in blood by RCP which confirmed the diagnosis of miliary tuberculosis. The first line treatment for tuberculosis with rifampin, isoniazid, pyrazinamide and ethambutol was initiated, presenting remission of the symptoms and a good tolerance with no signs of liver toxicity (Figure 4).

## DISCUSSION

Tuberculosis, caused by *Mycobacterium tuberculosis*, is a worldwide health problem, remaining as the leading cause of death from infectious diseases. It is estimated that 30% of the global population hosts TB in its latent form, which can be reactivated with the presence of several factors, such as aging, smoking, alcohol use, diabetes, chronic renal failure, cancer, a weakened immune system, glucocorticoids or tumor necrosis factor- $\alpha$  inhibitors use. Furthermore, miliary tuberculosis form, has only been described in immunocompromised hosts, especially in patients with underlying T-cell deficiencies such as HIV infection. The classic presenting symptoms of pulmonary TB include persistent fever, weight loss, drenching night sweats, persistent cough (often with sputum production), and hemoptysis; whilst extra-pulmonary TB can affect any organ with a wide variety of symptoms, and therefore requires a high index of clinical suspicion. Without treatment, TB has a mortality rate of 50% within 5 years. Various cell types and cytokines are crucial: T cells (CD4<sup>+</sup>, CD8<sup>+</sup>, and natural killer) and macrophages participate in protection against TB, and interferon- $\alpha$  and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) are essential cytokines for the control of acute TB infection<sup>[3]</sup>.

Two conditions might have contributed to the TB infection. On one hand, cirrhosis by itself is associated with lymphocyte and macrophage dysfunction and decreased production of interferon- $\alpha$  and TNF- $\alpha$  and it may be linked to a higher TB risk. A Taiwan study, showed that active TB incidence rates were significantly higher among cirrhotic patients compared with non-cirrhotic patients, particularly those with alcoholism and HCV infection<sup>[4]</sup>.

On the other hand, TB infection has been reported

**Figure 2** Chest computed tomography scan (scale W500:L50): Soft tissue window. Axial (A) and coronal (B, C) views: Superior mediastinal widening secondary to numerous lymphadenopathies (arrows) and a left hilar mass.

**Figure 3** Chest computed tomography scan (scale W500:L50): Pulmonary windows. Axial view: Bilateral lung miliary pattern (arrows) with little bilateral pleural effusion.

**Figure 4** Course of haemoglobin, leucocytes and viral load during and after antiviral treatment. Attendance to the emergency unit, tuberculosis diagnosis and start of therapy are shown according to time. TB: Tuberculosis.

anecdotically in patients with HCV infection undergoing  $\alpha$ -interferon-based therapy, usually as a reactivation of latent cases. As an example, 18 cases of TB were observed in patients under HCV treatment in Brazil<sup>[5]</sup>. Many studies have already shown that  $\alpha$ -interferon inhibits type 1 immune response, which is characterized by IL-2, interferon- $\alpha$  and TNF- $\alpha$  production, cytokines that restrain *Mycobacterium tuberculosis*. On the contrary, ribavirin is a guanosine analogue that has demonstrated to have an immunomodulatory effect, shifting a type 2 response to a type 1 in plaque-forming cells *in vivo*. When human T-lymphocytes are activated, ribavirin enhances a type 1 cytokine response producing increased levels of IL-2, interferon- $\alpha$  and TNF- $\alpha$  while suppressing the type 2 response with IL-4, IL-5 and IL-10<sup>[6]</sup>. Therefore, ribavirin stimulates the host adaptive immune response responsible for protection against TB infection and it may act as a protective factor; however, no studies have been specifically performed to prove it. Some other cases of TB infection have also been reported with the triple therapy of pegylated interferon, ribavirin and boceprevir or telaprevir, the first generation of protease inhibitors<sup>[1]</sup>. Ledipasvir and sofosbuvir are both DAAs. Sofosbuvir works as an inhibitor of the HCV NS5B RNA-dependent RNA polymerase. Ledipasvir is

an NS5A inhibitor and its exact mechanism of action is unknown, but one suggested mechanism is its inhibition of hyperphosphorylation of NS5A, which seems to be required for viral production. Ledipasvir/Sofosbuvir phase III studies for HCV infection treatment showed that the most common adverse events reported by patients were fatigue, headache and nausea<sup>[7]</sup>. Addition of ribavirin to ledipasvir/sofosbuvir for HCV therapy for patients without cirrhosis or with compensated cirrhosis was associated with a greater incidence of common adverse effects, concomitant medication use and laboratory abnormalities such as anemia, increased levels of total bilirubin and lymphopenia; but rates of severe side effects and interruptions of treatment resulted similar, and no increased infection episodes were detected despite the reported decrease in lymphocytes<sup>[8]</sup>. In order to reduce the side effects of these drugs, advanced technologies are used during their development such as computer-aided leading drug optimization<sup>[9]</sup>.

Indeed, significant infection has not been reported with the new era of free-interferon regimen treatment. This case is, to the best of our knowledge, the first case report of a miliary TB infection during HCV infection treatment with sofosbuvir/ledipasvir plus ribavirin. Although the association with the DAAs has not been proven and

it may be a coincidence that the two infections have occurred in a close time frame, several data should make clinicians wonder: The patient had diabetes and chronic liver disease as a risk factors for TB, nevertheless both were well controlled; she was asymptomatic and with no signs on physical examination neither before starting the treatment nor after one month of the beginning, which goes against the hypothesis that she may have reactivated TB prior to therapy and it has just presented late; moreover, the mechanisms underlying these drugs effects are currently unknown and further immunological studies should be performed in order to find out how the innate and adaptive immune responses are altered by the different treatment regimens<sup>[10]</sup>.

We believe that the case we have reported is relevant to increase awareness of opportunistic infections, particularly TB infection due to its variety of symptoms which can be confused with those associated to the HCV infection or the antiviral treatment and the high mortality rate of TB infection without treatment. Considering the impaired immune system of cirrhotic patients and the fact that these DAAs arrived on the market slightly more than one year ago and no long-term side effects have been described, we consider that it is important to be conscious of the potential events that can be related with the HCV treatment. In addition, although the international guidelines for the management of HCV infection<sup>[11,12]</sup> offer no recommendation regarding TB screening, we wonder whether it would be advisable to screen for opportunistic infections, *via* tuberculin skin test and/or interferon gamma releasing assays, prior to the introduction of HCV therapy.

## COMMENTS

### Case characteristics

A 65-year-old woman with history of diabetes mellitus type 2, chronic hepatitis C virus (HCV) infection and no current nor previous smoking habits and no underlying pulmonary disease or symptoms.

### Clinical diagnosis

The patient presented with malaise, asthenia, hyporexia, 7 kg weight loss, productive cough with white sputum, evening fever and night sweats right after finishing the HCV treatment with sofosbuvir/ledipasvir plus ribavirin for 12 wk.

### Differential diagnosis

Respiratory infection, side effects of HCV treatment.

### Laboratory diagnosis

The blood test highlighted a sodium level of 129 mmol/L (RR: 135-145), ALT 38 U/L, CRP 94 mg/L (RR: < 5), hemoglobin level 9.6 g/dL, leucocyte count 5.98 cells/ $\mu$ L, absolute neutrophil count 4.84 cells/ $\mu$ L, absolute lymphocyte count 0.78 cells/ $\mu$ L, platelet count 114000 cells/ $\mu$ L and INR 1.26 with the rest of parameters standing within the normal range. The arterial gasometry showed pH 7.51 (RR: 7.35-7.45), pO<sub>2</sub> 126 mmHg (RR: 83-108), pCO<sub>2</sub> 29 mmHg (RR: 35-45), lactate 1.6 mmol/L (RR: 0.6-1.17) and bicarbonate 25 mEq/L (RR: 20-29).

### Imaging diagnosis

The chest X-ray showed a left hilar widening. The chest computed tomography scan revealed a superior mediastinal widening secondary to numerous

lymphadenopathies with extensive necrosis, causing a displacement of the esophagus and trachea, and contiguous to these lymphadenopathies, a left hilar mass displaying an air bubble communicated with the left bronchial tree, as well as a bilateral diffuse lung miliary pattern with little subsequent bilateral pleural effusion.

### Treatment

The first line treatment for tuberculosis with rifampin, isoniazid, pyrazinamide and ethambutol.

### Related reports

Cases of tuberculosis infection have been identified with  $\alpha$ -interferon-based therapy and the triple therapy with pegylated-interferon, ribavirin and boceprevir or telaprevir.

### Experiences and lessons

This is the first case of a TB infection during treatment with sofosbuvir/ledipasvir plus ribavirin.

### Peer-review

The manuscript is reasonably well written and is thought to have useful information for readers.

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Hakan Alagozlu, MD, Professor, Department of Gastroenterology, Cumhuriyet University Hospital, 58040 Sivas, Turkey

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

**FLYLEAF**

### Abstract

The low perioperative morbidity and shorter hospital stay associated with laparoscopic hepatectomy have made it an often-used option at many liver centers, despite the fact that many patients with hepatocellular carcinoma have cirrhosis, which makes the procedure more difficult and dangerous. Type of surgical procedure proves not to be a primary risk factor for poor outcomes after hepatic resection for hepatocellular carcinoma, the available evidence clearly shows that laparoscopic hepatectomy is an effective alternative to the open procedure for patients with early-stage hepatocellular carcinoma, even in the presence of cirrhosis. Whether the same is true for patients with intermediate or advanced disease is less clear, since laparoscopic major hepatectomy remains a technically demanding procedure.

**Key words:** Hepatocellular carcinoma; Laparoscopic hepatectomy; Open hepatectomy

<sup>1</sup>With complication of Clavien-Dindo grade IIIA or above.

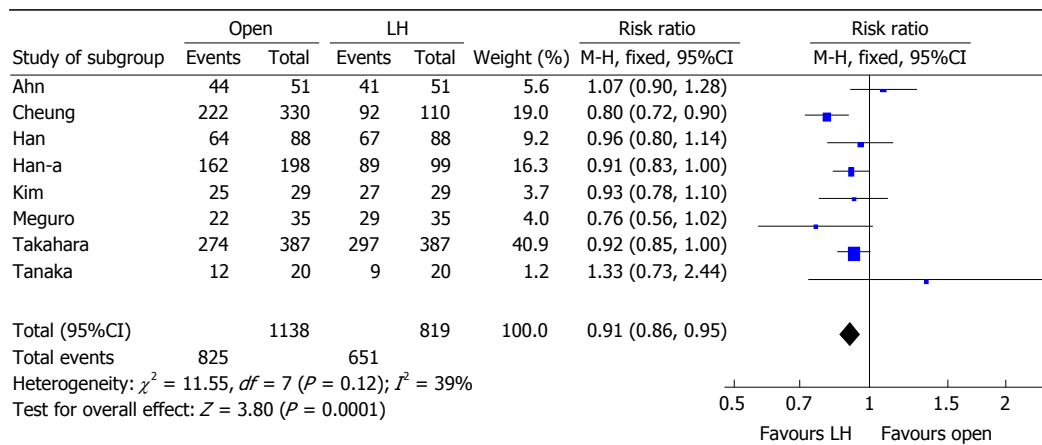

Recently, a large propensity score study comparing laparoscopic and open hepatectomy for treating hepatocellular carcinoma (HCC) was published in *Ann Surg*<sup>[1]</sup>. This parallel comparison comes at an important time, because technical and procedural improvements have led to increasing use of laparoscopic hepatectomy, including for more extensive hepatectomy and particularly in cases of left lateral sectionectomy<sup>[2]</sup>. In fact, the low perioperative morbidity and shorter hospital stay associated with laparoscopic hepatectomy have made it an often-used option at many liver centers<sup>[3-8]</sup>, despite the fact that many patients with HCC have cirrhosis, which makes the procedure more difficult and dangerous. The long-term benefits of laparoscopic hepatectomy remain controversial, and this study<sup>[1]</sup> provides the first evidence that it is associated with better long-term overall survival (OS) than open hepatectomy ( $P = 0.033$ ).

Our own clinical experience and evidence in the literature suggest that mortality risk following liver resection depends primarily not on the type of surgical procedure but on tumor-related factors<sup>[9-11]</sup>. In order to examine this possibility in more detail, we reviewed all randomized controlled trials and other studies involving propensity score analysis comparing laparoscopic and open hepatectomy published in 2014-2016. We identified 10 studies involving 2275 patients, comprising one from China<sup>[1]</sup>, five from South Korea<sup>[12-16]</sup>, three from Japan<sup>[17-19]</sup>, and one from Italy<sup>[20]</sup> (Table 1). Across these 10 studies, 90% of patients had single tumors and 84% underwent minor hepatectomy. This means that most patients had early-stage HCC and surgical procedures were relatively straight forward. In 7 of 10 studies (accounting for 73% of all patients), laparoscopic hepatectomy was associated with a significantly lower rate of perioperative morbidity. None of the studies found significant differences in perioperative mortality or disease-free survival (DFS) between the laparoscopic and open procedures. Eight of the 10 studies (accounting for 86% of all patients) reported 5-year OS and DFS<sup>[1,12-15,17-19]</sup>. Meta-analyses based on these eight studies revealed that patients in the laparoscopic group had significantly higher 5-year OS than those in the open group [risk ratio (RR) = 0.91,

95% confidence interval (95%CI): 0.86-0.95,  $P < 0.001$ ;  $I^2 = 39\%$ ; Figure 1A], but similar 5-year DFS (RR = 0.96, 95%CI: 0.87-1.06,  $P = 0.440$ ;  $I^2 = 0\%$ ; Figure 1B). Similar results were obtained when the study by Cheung *et al*<sup>[11]</sup> was excluded.

Thus, substantial evidence suggests that laparoscopic hepatectomy is associated with significantly better long-term OS than open hepatectomy. It is possible that this reflects less tissue manipulation - and therefore less hematogenous dissemination of malignant tumor cells - in "no-touch" anterior-approach laparoscopic hepatectomy<sup>[1]</sup>. However, the two techniques were associated with similar DFS, indicating similar rates of tumor recurrence, which is the main cause of death among HCC patients. In fact, patients in the two groups across all 10 studies showed similar tumor characteristics, including diameter, number, vascular invasion, and New Edmondson grade. Since these characteristics are the main risk factors of tumor recurrence, the available evidence appears to be consistent with the idea that mortality risk following liver resection depends on tumor-related factors and not on type of surgical procedure.

To examine this hypothesis rigorously, at least two questions must be answered. One is whether differences in blood loss and surgical complexity may help explain the difference in OS. Six of the 10 studies<sup>[1,13,16-19]</sup> reported significantly less blood loss in the laparoscopic group, yet the studies did not report whether tumors were close to the hepatic vein or portal hepatis, which would make the surgery more complex and increase risk of blood loss. Another question is whether economic differences may help explain the OS difference. Since laparoscopic hepatectomy costs substantially more than open hepatectomy, it stands to reason that patients opting for the laparoscopic procedure may be in a better financial position. This raises the possibility that such patients also receive better postoperative therapies, such as antiviral therapy, liver-protecting therapy, and/or psychological intervention. Such patients may also receive more extensive and/or more aggressive therapy after tumor recurrence. All these factors may explain the observed long-term OS advantage of laparoscopic hepatectomy

**A****B**

**Figure 1 Forest plots of meta-analysis comparing the efficacy of laparoscopic with open hepatectomy. A:** Rate of 5-year overall survival; **B:** Rate of 5-year disease-free survival. LH: Laparoscopic hepatectomy.

over open hepatectomy. Therefore, assessing the long-term impact of this procedure requires large randomized controlled trials that take surgical complexity and patient financial condition into account. At least, comparative studies with propensity score analysis should adjust surgical complexity and financial condition between groups.

Even if, as we suspect, type of surgical procedure proves not to be a primary risk factor for poor outcomes after resection, the available evidence clearly shows that laparoscopic hepatectomy is an effective alternative to the open procedure for patients with early-stage HCC, even in the presence of cirrhosis. Whether the same is true for patients with intermediate or advanced disease is less clear, since laparoscopic major hepatectomy remains a technically demanding procedure. Even so, we agree that laparoscopic hepatectomy is an alternative choice for treatment of HCC.

### Abstract

Kaposi sarcoma (KS) is an aggressive cancer caused by human herpesvirus-8, primarily seen in immunocompromised patients. As opposed to the well-described cutaneous manifestations and pulmonary complications of KS, hepatic KS is rarely reported before death as most patients with hepatic KS do not manifest symptoms or evidence of liver injury. In patients with acquired immune deficiency syndrome, hepatic involvement of KS is present in 12%-24% of the population on incidental imaging and in approximately 35% of patients with cutaneous KS if an autopsy was completed after their death. Patients with clinically significant hepatic injury due to hepatic KS usually have an aggressive course of disease with hepatic failure often progressing to multi-organ failure and death. Here we report an unusual presentation of acute liver injury due to hepatic KS and briefly review the published literature on hepatic KS.

**Core tip:** Hepatic Kaposi sarcoma (KS) is a clinical presentation that disproportionately affects the human immunodeficiency virus/acquired immune deficiency syndrome (AIDS) population. Up to 34% of patients with AIDS and KS have hepatic involvement. Usually hepatic KS is clinically indolent and diagnosed during autopsy. When clinically significant, hepatic KS presents with evidence of liver injury with elevation in bilirubin and liver enzymes, has characteristic findings on imaging and may progress to liver failure and death. Treatment is indicated in patients with progressive and symptomatic hepatic disease in the absence of other etiologies.

## CASE PRESENTATION

A forty-eight years old African American male with HIV and CD4 count of 8/ $\mu$ L presented with conjunctival icterus. Physical exam showed cachexia, icterus, a violaceous 1 cm plaque on the soft palate and similar lesion on the chest wall, and a soft, non-distended, non-tender abdomen. He denied prior treatment with antiretroviral medications. Laboratory studies were significant for AST (SPGT) 172 U/L, ALT (SGOT) 201 U/L, total bilirubin of 20.0 mg/dL, direct bilirubin 14.9 mg/dL, alkaline phosphatase 947 U/L, INR 2.5, and platelet count 52000/ $\mu$ L. Acute and chronic serologies for hepatitis A, B and C, histoplasma, and cytomegalovirus as well as a toxicology screen were negative. Patient did report taking cotrimoxazole for five days which he completed a month prior to presentation. Magnetic resonance imaging (MRI) of the Abdomen showed innumerable 10 mm T2 intense hepatic nodules without enhancement (Figure 1). Liver biopsy was positive for Cytokeratin 7 and human herpes virus-8, consistent with infiltrative Kaposi sarcoma (KS) (Figures 2 and 3). There was no evidence of drug induced liver injury on histopathology. There was no lymphadenopathy indicative of hemophagocytic lymphohistiocytosis or Castleman's disease. The diagnosis was most consistent with acute liver injury (ALI) secondary to infiltrative hepatic KS, stage T1, I1, S1. The patient was not a candidate for cytotoxic therapy given progressive liver injury and was started on rituximab and ganciclovir. Liver injury progressed and was further complicated by acute kidney injury, hypoxic respiratory failure, consumptive coagulopathy and septic shock. The patient received broad-spectrum antibiotics, blood products, vasopressors and ventilator support but unfortunately expired.

## BACKGROUND

KS is an angioproliferative low-grade neoplasm that is associated with human herpesvirus-8 (HHV-8). KS can be codified into different clinical variants depending on the patient cohort and the presentation of the disease<sup>[1]</sup>. The "classical" form primarily affects men of Ashkenazic Jewish or Mediterranean background and follows an indolent cutaneous course. The "African endemic" form of the disease commonly affects Africans as the name implies, presents with lymphadenopathy and is usually fatal within 1-3 years. The "iatrogenic" form is due to HHV-8 activation caused by medical immunosuppression from treatment of autoimmune disorders or post-organ transplantation. The fourth and most common variant, acquired immune deficiency syndrome (AIDS)-related KS,

is rapidly progressive and holds the highest rate of hepatic involvement<sup>[2]</sup>.

The most common presentation of KS is a cutaneous papular disease with lesions on the legs, oral cavity, and genitalia. However, the most common site of visceral organ involvement is the gastrointestinal tract<sup>[3]</sup>. First described by Moritz Kaposi in 1872, hepatic KS was an autopsy diagnosis that rarely resulted in clinically significant disease or ALI<sup>[4]</sup>. To further understand hepatic KS, a systematic search of the literature was conducted on PubMed (1954 to 2015), EBSCO HOST (1956 to 2015), the Cochrane Database of Systematic Review, and the OVID interface (1946 to 2015) with comprehensive search terms as documented in Table 1.

## EPIDEMIOLOGY

While most herpesviruses are widespread in the adult population, the prevalence of HHV-8 varies with human immunodeficiency virus (HIV) status and exposure risk factors. In the United States, only 5% of HIV uninfected men are seropositive for HHV-8 compared to 25%-60% of HIV-positive men who have sex with men (MSM)<sup>[5]</sup>. These rates are reflective of HHV-8 and HIV co-infection in MSM in other countries as well<sup>[6]</sup>.

AIDS-patients have 20000 times greater risk of developing KS than the general population. Patients on HAART with a CD4 count of < 200 cells/ $\mu$ L are 18.9 times more likely to have KS than those with CD4  $\geq$  500 cells/ $\mu$ L<sup>[7]</sup>. In the era of ARV therapy, improved control of HIV viremia and preserved CD4 T-cell function has lead to an 80% decreased incidence of AIDS-associated KS<sup>[8]</sup>, AIDS-related KS currently affects < 1% of AIDS patients, compared to 15% in the pre-HAART era<sup>[9]</sup>.

## MODES OF TRANSMISSION

Behavioral risk factors for HHV-8 transmission are incompletely understood. Saliva exchange appears to be an important factor with HHV-8 DNA detected in the saliva of 61% of HHV-8-infected MSM<sup>[10,11]</sup>. With HHV-8 seropositivity higher in the MSM population, commercial sex workers and those with other sexually transmitted infections, a sexual route of transmission has also been proposed. HHV-8 DNA can be isolated from semen and vaginal secretions, but viral load is lower than that found in saliva, calling into question the clinical significance of sexual transmission<sup>[12]</sup>. HHV-8 seroprevalence in HIV-infected injection drug users is substantially lower than hepatitis B and C rates in HIV-infected MSM<sup>[13]</sup>. This finding is suggestive that blood exchange through contaminated needle sharing is a less significant route of HHV-8 transmission compared to salivary or sexual contact<sup>[14]</sup>.

## HEPATIC INVOLVEMENT

Hepatic KS is typically asymptomatic and rarely diagnosed in life. Therefore the true incidence of hepatic KS is not

Figure 1 Spindle cells with cytokeratin 7 staining positive.

Figure 2 Positive human herpesvirus-8 immunohistochemical staining.

well-documented and is limited to small case series and reports. Prevalence of hepatic KS has primarily been determined from autopsy series with small sample sizes, which accounts for the wide variation in prevalence reported. In one autopsy series, approximately 34% of AIDS-related KS cases involved the liver while in another report, 8.3% had liver involvement<sup>[15,16]</sup>. In another retrospective review, hepatic involvement was present in 9 of 41 patients or 22% of cases of AIDS-related KS in post mortem dissection<sup>[17]</sup>. In this study ante-mortem hepatic KS was suspected in only one patient, in whom a computerized tomography (CT) scan demonstrated hepatosplenomegaly with a confluence of hypodense lesions in the left hepatic lobe. Autopsy confirmed disseminated KS. Schneiderman *et al.*<sup>[18]</sup> found KS on liver biopsy in 18.6% of AIDS patients making KS the most common hepatic pathological diagnosis caused by AIDS. All of these patients already had a diagnosis of extrahepatic KS at time of biopsy. In contrast, 66% of patients with extrahepatic KS did not manifest hepatic involvement.

As mentioned above, most cases of hepatic KS were not clinically significant. In the study by Schneiderman *et al.*<sup>[18]</sup>, there were no statistically significant differences in transaminases, lactic dehydrogenase, alkaline phosphatase or bilirubin based on liver involvement with KS. However, in the few reported patients with clinically significant disease, a rapid progression to liver and multi-organ failure has

been reported, usually with fatal outcomes (Table 2).

In the non-HIV population, the incidence of KS is 0.2% in liver transplant patients from the United States, but the prevalence is higher in patients from Africa, the Middle East or the Mediterranean<sup>[19]</sup>. KS affected 4.7% of renal transplant patients in Saudi Arabia, 2.4% of recipients in Israel and 0.52% of recipients in France. While there is a well described clinical burden of post-transplant lymphoproliferative disorder including cutaneous and visceral manifestations of KS, there is no described literature of post-transplant hepatic KS.

## PATHOGENESIS OF HHV-8 ASSOCIATED TUMORS

HHV-8 consists of a large double stranded DNA genome that includes approximately 145 kilobases (kbases) long region encoding all the expressed viral genes, flanked by approximately 20-30 kbases that encode a number of mimicked human genes, several of which have immunologic or angiogenic properties<sup>[20,21]</sup>. HHV-8 has a tropism for both hematopoietic and non-hematopoietic cells including monocytes, B cells, endothelial cells and also hepatocytes<sup>[22]</sup>. Endothelial cells appear to be the most important host cells for oncogenic transformation as HHV-8 infection of these cells leads to their long-term proliferation and survival<sup>[23]</sup>. Similar to other herpesviruses, HHV-8 alternates between two metabolic cycles: Latent infection, where few genes are expressed, and the active lytic infection, where viral replication and multiple gene expression occurs. Lytic replication can be induced by oxidative stress, hypoxia, inflammatory cytokines, chemical exposure or concomitant infections, including HIV<sup>[24-27]</sup>.

In hepatocytes infected with HHV8 genome by DNA polymerase chain reaction amplification, immunohistochemistry demonstrates expression of the transcriptional regulator, latency-associated nuclear antigen-1 (LANA-1)<sup>[28]</sup>. It has also been directly implicated in oncogenesis because of its ability to bind to the tumour-suppressing protein p53<sup>[29]</sup>. Furthermore, hepatocyte growth factor/scatter factor, a kinase that mediates epithelial cell proliferation and angiogenesis<sup>[30]</sup> has been demonstrated to induce HHV-8 lytic replication, providing a means of KS pro-

gression in the liver<sup>[31]</sup>.

## DIAGNOSIS OF KS

A full integumentary survey including oral and rectal examination quantifying extent of disease should be completed in patients with suspected KS. Cutaneous or visceral biopsy is required for diagnosis. On gross pathology, there are usually multiple, grossly irregular, variable sized red-brown spongiform nodules seen in the periportal connective tissue<sup>[32]</sup>. Histopathologic features of disease include thin walled vascular formations and inflammatory infiltration. Spindle cell formation is also characteristic of angioproliferative HHV-8-infected cells that have undergone reprogramming of vascular endothelium and tumorigenesis<sup>[33]</sup>. Immunohistochemical staining is characteristic for HHV-8 LANA expression within the spindle cell formation<sup>[34]</sup>. Immunohistochemistry staining for endothelial cell markers factor VIII, CD31, CD34 and lymphatic vessel endothelial receptor 1 further corroborate a diagnosis of KS<sup>[35]</sup>.

Further investigation of visceral KS is warranted in the presence of adenopathy or occult bleeding. Patients

with cutaneous KS and iron deficiency anemia, fecal occult blood or gastrointestinal symptoms warrant GI endoscopic evaluation. Patients with cutaneous KS and concurrent adenopathy should receive CT of the chest, abdomen, and pelvis to evaluate for visceral KS and HHV-8-related lymphoproliferative disorders including primary effusion lymphoma, Castleman disease, and plasmablastic lymphoma<sup>[36]</sup>.

## KS STAGING AND PROGNOSIS

As KS is a disseminated angioproliferative virally mediated malignancy, classic tumor, node, metastasis staging as used in other cancers does not accurately prognosticate disease or dictate treatment. AIDS Clinical Trials Group (ACTG) Oncology Committee has codified staging of AIDS-associated KS<sup>[37]</sup>. The ACTG staging system risk stratifies patients low risk (0) or high risk (1) based on three criteria: Tumor burden (T), immune status (I), and systemic illness (S). For tumor burden, poor risk (T1) is defined by presence of extensive cutaneous, oral disease or visceral disease. For immune status, poor risk (I1) is defined by CD4 count of less than 150 cells/ $\mu$ L. For

Figure 3 Ultrasound image with multiple small round hyperechoic nodules.

systemic illness, poor risk (S1) is defined by the presence of constitutional symptoms, poor performance status, or other opportunistic infections. While these criteria were validated in the pre-ART era, post-ART therapy, a CD4 cutoff of 100 cells/mm<sup>3</sup> has an unclear role in predicting mortality<sup>[38,39]</sup>.

## IMAGING IN HEPATIC KS

Hepatic KS has characteristic findings on individual imaging modalities that can help delineate clinically significant disease. Abdominal ultrasound imaging of the liver can demonstrate inhomogeneous cystic lesions with hyperechoic bands and nodules along the peripheral branches of portal veins. Likewise, computed tomography of the abdomen is characteristic for inhomogeneous hepatomegaly with multiple small hypodense nodules, often in the periportal area<sup>[40]</sup> (Figure 4). Mild hepatomegaly is a non-specific finding in 19% of patients with AIDS-related KS<sup>[41]</sup>. MRI shows hyperintense nodules on T1-weighted in-phase imaging and hypointense nodules on T1-weighted out-of-phase imaging (Figure 5). Neither T2-weighted imaging nor late hepatobiliary volumetric interpolated breath hold examination have any specific findings in hepatic KS<sup>[42]</sup>.

Image guided biopsy of hepatic nodules in patients suspected to have liver involvement demonstrate hyaline globules, hemosiderin accumulation, macrovacuolar steatosis, large fibrotic portal spaces, bile duct ectasia, neoductogenesis and spindle cells with large, irregular nuclei. Staining of the perinodular tissues is positive for CD31, CD34 and factor VIII as can be seen in extrahepatic KS as well.

## TREATMENT

As shown in Table 2, hepatic KS is predominantly manifested in patients with HIV/AIDS. While overall HIV mortality is improving in the era of ARV therapy, patients with AIDS-associated KS have an increased risk of death, compared to HIV controls, irrespective of CD4 count<sup>[43]</sup>. HIV-infected patients initiating ARV commonly have progression of their KS lesions<sup>[44]</sup>. However, long term

Figure 4 Computerized tomography scan enlarged inhomogeneous liver with multiple hypodense lesions.

ARV therapy is associated with a reduced incidence of KS. Guidelines currently recommend correcting underlying immunodeficiency by treating AIDS with ARV therapy. Studies indicate that control of KS progression is related to the degree of control of HIV, rather than the specific cART regimen utilized<sup>[45]</sup>. Beyond ARVs, a variety of systemic therapies may be used in KS. Usually systemic therapy is indicated in progressive disease, with symptomatic visceral involvement, in the presence of immune reconstitution inflammatory syndrome (IRIS) or with extensive cutaneous involvement. These strategies are not specific to hepatic dysfunction in the setting of KS.

Radiotherapy is a well-established treatment and has a robust clinical response for classic nodular KS but tends to be a palliative approach. While it may be a good modality for superficial lesions, electron beam radiation therapy (EBRT) has limited penetration below the dermis; deeper or unresponsive KS may be treated with standard non-EBRT approaches<sup>[46]</sup>.

Retinoid products appear to inhibit IL-6, a cytokine implicated in KS pathogenesis, and have an antiproliferative effect on KS lesions<sup>[47]</sup>. Application of alitretinoin can reduce cutaneous lesions of both classic and HIV-KS but has no role in systemic disease<sup>[48]</sup>.

The role of chemotherapy in addition to standard antiretroviral therapy has been explored. A meta-analysis of studies demonstrated that although chemotherapy in addition to ARVs did not have a mortality benefit, it did reduce disease progression<sup>[49]</sup>. Current first-line therapy for advanced AIDS-KS is liposomal anthracyclines, including pegylated liposomal doxorubicin (PLD). In a randomized control trial (RCT), PLD demonstrated superiority to previous conventional chemotherapy, bleomycin and vincristine with 58.7% vs 23.3% ( $P < 0.001$ ) response rate and a decreased adverse event rate (10.7% vs 26.7%)<sup>[50]</sup>. Another RCT of liposomal daunorubicin versus doxorubicin, bleomycin and vincristine showed no statistical difference in response rate or disease progression (25% vs 28%)<sup>[51]</sup>. When the analysis was restricted to patients receiving prior zidovudine, however, survival was improved in the liposomal daunorubicin group. Another non-randomized study showed a trend

Figure 5 SPAIR and T2 images Kaposi sarcoma on magnetic resonance imaging.

toward mortality benefit with liposomal doxorubicin as compared to bleomycin plus vinblastine, vincristine or ARV monotherapy alone, although this did not reach statistical significance<sup>[52]</sup>.

Interferon-alpha, has an array of antiviral and antiangiogenic properties with efficacy in AIDS-KS, but its use is limited due to hepatotoxicity<sup>[48]</sup>.

Paclitaxel has systemic response rates from 59%-71% and is approved as second-line treatment for KS. In randomized controls, paclitaxel does not demonstrate benefit over PLD in complete or partial remission and no mortality data were available according to KS staging<sup>[53]</sup>. Less well tolerated than doxorubicin, adverse events include peripheral neuropathies, cytopenias, and gastrointestinal upset. Third line agents for AIDS related visceral KS include etoposide, bleomycin, vinblastine, and vincristine with overall response rates ranging from 23% to 36%. The median survival times are 11 (6 to 20) mo in the bleomycin only group and 13 (7 to 36) mo in the ABV group. With extensive side effect profiles, including secondary malignancies, these treatment modalities are maintained in resource-limited settings<sup>[54,55]</sup>.

Although HAART with or without chemotherapy is the current recommended treatment, novel targets are being explored including inhibitors of angiogenesis and matrix metalloproteinases. These drugs are currently in various phases of clinical trials<sup>[56]</sup>. Inhibition of HHV-8 replication with agents such as foscarnet and ganciclovir have also been explored<sup>[57]</sup>.

Finally, it bears mentioning that treatment for HIV/AIDS in patients co-infected with HHV-8 can cause a paradoxical worsening of disease. In the KS AIDS AntiRetroviral Therapy Trial, 23/112 (21%) of co-infected patients receiving ARV therapy developed KS-IRIS, which was defined as a rapid worsening of KS beyond its natural course within 12 wk of initiating ARV therapy. Of those 23 patients, 10 died, 9 of which had visceral KS. Eighteen patients in the study overall (16%) had worsening elevation in their liver enzymes and two patients (1.8%) died of liver failure. In this study, exclusion criteria included HIV-KS patients with direct serum bilirubin > 85  $\mu\text{mol/L}$  or aspartate aminotransferase or alanine aminotransferase > 2.5

times the normal range<sup>[39]</sup>.

Biologic and targeted molecular therapies may have a supplementary or alternative role in AIDS-KS, but are currently in early stages of clinical trials. In the AIDS Malignancy Consortium, a phase II trial of imatinib with a small sample size showed a partial response in approximately one third of patients<sup>[58]</sup>. In another study focusing on patients who did not respond to chemotherapy and chimeric antigen receptor T cell therapy, bevacizumab, an anti-vascular endothelial growth-factor monoclonal antibody, had a response rate in again approximately one third of patients<sup>[59]</sup>. The cytokine, interleukin-12 had a response rate of 71% in small phase I and phase II trials. However, patients were ineligible if they had transaminitis or a history of hepatic disease<sup>[60]</sup>. Ongoing studies include a phase II trial for the utility of combined PLD and bevacizumab in the treatment of advanced AIDS-KS<sup>[61]</sup> and a phase I study for dosing and side effect profile of combination therapy with ipilimumab, a cytotoxic T-lymphocyte antigen 4 antibody and nivolumab, an antibody against programmed cell death 1 for the treatment of advanced KS solid tumors<sup>[62]</sup>. These trials show that biologic and molecular therapies may have a role in the future as alternative treatment therapy for some patients with AIDS-KS.

Currently, HHV-8 infection cannot be eradicated but long-term remission is feasible. Treatment is indicated in patients with progressive hepatic disease in the absence of other etiologies.

## CONCLUSION

Hepatic KS is a clinical presentation that disproportionately affects the HIV/AIDS population. Up to 34% of patients with AIDS and KS have hepatic involvement. It is rarely clinically significant and often diagnosed during autopsy, but can cause liver injury or even fatal liver failure, as demonstrated in the case presentation above and case series in Table 2. In an immune compromised patient with ALI or failure, a thorough skin exam in addition to abdominal imaging and biochemical testing should be pursued and a diagnosis of hepatic KS should be considered. Treatment of hepatic KS does not differ

from systemic treatment of other KS manifestations with HAART and chemotherapy, and should be considered within the context of medical comorbidities and severity of disease. Due to wide population prevalence, a lack of clinically significant disease and variable presentations, there is little clinical data or dedicated clinical trials for liver specific disease, and further investigation is warranted.

### Abstract

Treatment of patients with chronic kidney disease (CKD) and chronic hepatitis C (CHC) differs from that used in the general CHC population mostly when glomerular filtration rate (GFR) is below 30 mL/min, as sofosbuvir, the backbone of several current regimens, is officially contraindicated. Given that ribavirin free regimens are preferable in CKD, elbasvir/grazoprevir is offered in CHC patients with genotype 1 or 4 and ombitasvir/paritaprevir and dasabuvir in genotype 1b for 12 wk. Although regimens containing peginterferon with or without ribavirin are officially recommended for patients with CKD and genotype 2, 3, 5, 6, such regimens are rarely used because of their low efficacy and the poor safety and tolerance profile. In this setting, especially in the presence of advanced liver disease, sofosbuvir-based regimens are often used, despite sofosbuvir contraindication. It seems to have good overall safety with only 6% or 3.4% of CKD patients to discontinue therapy or develop serious adverse events without drug discontinuation. In addition, sustained virological response (SVR) rates with sofosbuvir based regimens in CKD patients appear to be comparable with SVR rates in patients with normal renal function. Treatment recommendations for kidney transplant recipients are the same with those for patients with CHC, taking into consideration potential drug-drug interactions and baseline GFR before treatment initiation. This review summarizes recent data on the current management

of CHC in CKD patients highlighting their strengths and weaknesses and determining their usefulness in clinical practice.

**Key words:** Chronic hepatitis C virus infection; Kidney; Renal; Kidney transplantation; Direct acting antiviral agents; Glomerular filtration rate; Hepatitis C

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Recent evidence showed very good safety and efficacy of both interferon and ribavirin-free direct acting antivirals (DAAs) regimens in patients with severe kidney disease (CKD) or kidney transplantation. Nevertheless, sofosbuvir, the backbone of most antiviral schemes is officially contraindicated in patients with CKD (creatinine clearance < 30 mL/min). Accordingly, CKD patients with genotype 1 or 4 can be currently treated with available ribavirin free DAAs regimens without sofosbuvir, while those with non-1, non-4 genotype can officially be treated with peginterferon with or without ribavirin, but they are actually treated with sofosbuvir-based regimens mostly if they have advanced liver disease.

## INTRODUCTION

The prevalence of hepatitis C virus (HCV) infection among hemodialysis (HD) patients has been reported to range from 10% to 25%<sup>[1]</sup>. Chronic hepatitis C (CHC) has been related with high morbidity and reduced survival in both patients with renal dysfunction and kidney transplant (KT) recipients<sup>[2]</sup>. HCV treatment in patients with renal dysfunction has been a complex and challenging issue in the pre-direct acting antiviral (DAAs) era. Interferon-alpha (IFN) or pegylated IFN (PEG-IFN) with or without low doses of ribavirin (RBV) (200-400 mg three times weekly) was associated with low rates of sustained virological response (SVR) and several potentially dangerous side effects<sup>[3]</sup> such as steroid resistant acute allograft rejection in KT recipients<sup>[4]</sup>.

In general, the introduction of first generation DAAs (*i.e.*, telaprevir and boceprevir) improved the SVR rates in CHC patients infected with genotype 1 but did not substantially improve the treatment of such patients with renal dysfunction or KT<sup>[5]</sup>. Initially, both telaprevir and boceprevir had to be used in combination with PEG-IFN and RBV resulting in the potential appearance of limitations, worse tolerability and safety profile of both PEG-IFN and RBV. These could account for severe anemia with both drugs, rash and pruritus with telaprevir

and dysgeusia with boceprevir<sup>[5]</sup>. Moreover, glomerular filtration rate (GFR) deterioration was reported to develop in about 5% of CHC patients who received telaprevir- or boceprevir-based therapy, particularly if they had additional risk factors for renal impairment (*e.g.*, arterial hypertension)<sup>[6,7]</sup>.

After 2014, newer DAAs have been licensed for the treatment of CHC by EMA and FDA. They include a nucleotide analogue NS5B polymerase inhibitor, sofosbuvir (tablet of 400 mg, Sovaldi<sup>®</sup>, Gilead)<sup>[8]</sup>, the NS3/4 protease inhibitor, simeprevir (tablet of 150 mg, Olysio<sup>®</sup>, Janssen)<sup>[9]</sup>, the NS5A inhibitor, daclatasvir (tablet of 60 mg, Dankliza<sup>®</sup>, Bristol-Myers Squibb)<sup>[10]</sup>, the co-formulation of a NS5A inhibitor, ledipasvir, with sofosbuvir (tablet of 90/400 mg, Harvoni<sup>®</sup>, Gilead)<sup>[11]</sup>, the co-formulation of a NS5A inhibitor, ombitasvir, with a NS3/4 protease inhibitor, paritaprevir, boosted by ritonavir (r) (tablet of 12.5/75 per 50 mg, Viekirax<sup>®</sup>, Abbvie), with a non-nucleos(t)ide analogue NS5B polymerase inhibitor, dasabuvir (tablet of 250 mg, Exviera<sup>®</sup>, Abbvie)<sup>[12]</sup>, the co-formulation of a NS5A inhibitor, elbasvir, with a NS3/4 protease inhibitor, grazoprevir (tablet of 50/100 mg, Zepatier<sup>®</sup>, Merck)<sup>[13]</sup> and the co-formulation of a NS5A inhibitor, velpatasvir, with sofosbuvir (tablet of 100/400 mg, Epclusa<sup>®</sup>, Gilead)<sup>[14]</sup> (Table 1). IFN-free and often RBV-free combinations of the newer DAAs given for 8-24 wk have been associated with very high (> 95%) SVR rates in most subgroups of CHC patients. Such combinations seem to represent the optimal choice against HCV infection in patients with chronic kidney diseases (CKD) or KT recipients, although its potential effects on renal function in all HCV patients and in HCV patients with renal impairment have just started to be evaluated. All newer DAAs are mainly eliminated through the liver, except for sofosbuvir which is eliminated through the kidney<sup>[15]</sup>. According to licensed summaries of product characteristics, daclatasvir, dasabuvir, ombitasvir/paritaprevir/r and elbasvir/grazoprevir could be administered to patients with any severity of renal impairment. However, sofosbuvir and consequently its co-formulations, ledipasvir/sofosbuvir and velpatasvir/sofosbuvir, should not be used in patients with severe renal impairment [estimated GFR (eGFR) < 30 mL/min per 1.73 m<sup>2</sup>] and/or patients requiring HD. Furthermore, caution is required when simeprevir is offered in patients with severe renal impairment and/or on HD because the knowledge of how it affects kidney function is limited<sup>[15]</sup>.

The purpose of this review is to summarize the most recent data on the impact of the recent IFN-free anti-HCV regimes on kidney function in CHC patients as well as the safety and efficacy of these regimens in CHC patients with CKD and KT recipients.

## IMPACT OF NEW DAAS ON RENAL FUNCTION

### Non transplant setting

Given that sofosbuvir represents the back-bone of many current IFN-free regimens and at the same time it is the

**Table 1** Main characteristics of the approved direct acting antivirals that are currently used for the treatment of hepatitis C

DAA (commercial name), dose	Category	Dose adjustment in renal impairment	Antiviral activity	CNIs co-administration
Sofosbuvir (Sovaldi®), tablet 400 mg, once daily	Nucleotide analogue NS5B polymerase inhibitor	Contraindicated in patients with GFR < 30 mL/min	Genotypes 1-6 High genetic barrier	No change
Simeprevir (Olysio®), tablet 150 mg, once daily with food	NS3/4A protease inhibitor	No change in renal impairment	Genotypes 1,4 Low genetic barrier	Contraindicated with cyclosporine
Daclatasvir (Daklinza®), tablet 60 mg, once daily	NS5A inhibitor	No change in renal impairment	Genotypes 1, 2, 3, 4 Low genetic barrier	No change
Ledipasvir/sofosbuvir (Harvoni®), tablet 90/400 mg, once daily	NS5A inhibitor + nucleotide analogue NS5B polymerase inhibitor	Contraindicated in patients with GFR < 30 mL/min	Genotypes 1, 4, 5, 6 High genetic barrier	No change
Ombitasvir/paritaprevir/ritonavir (Viekirax®), tablet 12.5/75/50 mg, two once daily with food	NS5A inhibitor + NS3/4A protease inhibitor boosted by ritonavir boosted	No change in renal dysfunction	Genotypes 1, 4 Genetic barrier depending on HCV genotype	Cyclosporine: 20% of pretreatment total daily dose; tacrolimus: 0.2 mg/72 h or 0.5 mg once weekly
Dasabuvir (Exviera®), tablet 250 mg, every 12 h	Non-nucleos(t)ide analogue NS5B polymerase inhibitor	No change in renal dysfunction	Genotype 1 Low genetic barrier	
Elbasvir/Grazoprevir (Zepatier®), tablet 100/50 mg, once daily	NS5A inhibitor + NS3/4A inhibitor	No change in renal dysfunction	Genotypes 1,4	Co-administration increases tacrolimus concentrations
Velpatasvir/sofosbuvir (Epclusa®), tablet 100/400 mg, once daily	NS5A inhibitor + nucleotide analogue NS5B polymerase inhibitor	Contraindicated in patients with GFR < 30 mL/min	Genotypes 1-6 High genetic barrier	No change

CNI: Calcineurin inhibitor; DAA: Direct acting antiviral; GFR: Glomerular filtration rate.

only agent with renal elimination, only sofosbuvir based regimens have been evaluated for potential effects on renal function. One study<sup>[16]</sup> assessed the rate of renal impairment in patients treated with sofosbuvir-based regimens comparing it to that of telaprevir or boceprevir based regimens, which have been previously shown to cause renal impairment in 5%-7% of treated CHC patients<sup>[7]</sup>. In total, 442 patients (50% with cirrhosis, > 95% with baseline GFR  $\geq$  60 mL/min)<sup>[16]</sup>. Renal impairment (defined as increase in serum creatinine  $\geq$  50% from baseline) was observed at similar rates in all groups: 7% of 228 patients under boceprevir/telaprevir-based regimens, 5% of 76 patients under sofosbuvir plus PEG-IFN/RBV and 4% of 152 patients under IFN-free sofosbuvir-based regimens ( $P = 0.40$ ), but the on-treatment median creatinine peak was lower in the boceprevir/telaprevir group compared to sofosbuvir containing groups (1.4 mg/dL vs 2.0 mg/dL,  $P = 0.04$ ). In multivariable analysis, only ascites [odds ratio (OR) = 3.16] and preexisting proteinuria (OR = 5.74) were significantly associated with development of renal impairment and SVR did not differ between patients who did or did not develop renal impairment (88% vs 86%,  $P = 0.90$ ). According to the authors, monitoring of renal function and standard nephroprotective measures may be useful when sofosbuvir-based regimens are applied, particularly in patients with ascites or pre-existing kidney disease. This finding was confirmed in a recent study<sup>[17]</sup>, in which 90 patients with HCV infection were treated with sofosbuvir plus ledipasvir: 17 patients had abnormal baseline renal function (GFR < 60 mL/min), while 42% had worsening GFR while on treatment. In multivariate analysis, baseline GFR < 60 mL/min was independently associated with worsening renal function on treatment ( $P$

= 0.04).

On the other hand, HCV infection may have a negative impact on renal function, and thus, HCV eradication could be associated with improvement of GFR. This was shown in a recent study<sup>[18]</sup> including 124 patients treated with DAAs (mean age 53.8 years, 67.7% treatment experienced, 83% had genotype 1 and 41% had cirrhosis). The achievement of SVR was associated with GFR improvement (baseline:  $78.55 \pm 8.96$  vs SVR at week 12:  $81.85 \pm 12.87$  mL/min,  $P = 0.037$ ). Thus, renal function may be improved after effective treatment of HCV infection with DAAs-based regimens. However, caution is still advised if sofosbuvir is administered in patients with renal impairment, as renal function may get worse in addition to more adverse events particularly if RBV is also used in combination.

Another study assessed the potential effect of sofosbuvir-based regimens on renal function in patients with HCV decompensated cirrhosis, who represent a group at high risk for renal dysfunction<sup>[19]</sup>. The on-treatment changes of serum cystatin C, as a marker of glomerular function, and of neutrophil gelatinase-associated lipocalin (NGAL), as a marker of tubular function, were evaluated in 52 patients with Child-Pugh score  $\geq 7$  treated with sofosbuvir and a NS5A inhibitor (ledipasvir or daclatasvir) and RBV for 12 wk. Half of the patients had at least one renal risk factor (e.g., hypertension, diabetes, therapy with diuretics), while 14% of the patients had eGFR < 60 mL/min. The eGFR did not change significantly during antiviral therapy, but cystatin C and NGAL levels increased from baseline to week 4 of therapy (cystatin C: 1.46 mg/L vs 1.55 mg/L,  $P < 0.01$ ; NGAL: 28.1 ng/mL vs 32.8 ng/mL,  $P < 0.01$ ) indicating transient renal dysfunction. Unfortunately, the evolution of these renal markers at

longer follow-up was not provided.

### Transplant setting

The impact of sofosbuvir-based regimens on renal function was assessed in liver transplant (LT) recipients who are at high risk for renal dysfunction for several reasons including the long-term use of calcineurin inhibitors. A recent multicenter study<sup>[20]</sup> evaluated 193 LT recipients with HCV recurrence treated with sofosbuvir-based regimens (mean age  $58.7 \pm 9.0$  years, 30.6% cirrhotics). Renal dysfunction developed in 38% of patients. The presence of a preexisting renal disease (OR = 3.49), the baseline GFR (OR = 1.02) and tacrolimus-based immunosuppressive therapy (OR = 0.43) were all three predictive factors of renal dysfunction development. The same study group<sup>[21]</sup> focused on 20 patients with combined liver-kidney transplantation (cirrhosis 25%, genotype 1 in 70%) who received sofosbuvir-based therapy for HCV recurrence. The authors reported that GFR decreased significantly from baseline value 50.9 mL/min to 41.8 mL/min at week 12 and to 42.7 mL/min at 12 wk after the end of antiviral therapy ( $P$  values always  $\leq 0.0001$ ).

Finally, 165 LT patients with HCV recurrence<sup>[22]</sup> received sofosbuvir-based regimens. A decline in renal function was observed in 22% of patients, particularly in those with baseline eGFR < 30 mL/min ( $P = 0.01$ ), cirrhosis ( $P = 0.01$ ) and prior treatment failure ( $P = 0.03$ ). Similarly to the non-LT setting<sup>[18]</sup>, renal function improvement after treatment was observed in 58% of patients and more commonly in those who achieved SVR, compared to those who did not (81% vs 19%,  $P < 0.05$ ).

## INTERFERON-FREE REGIMENS IN PATIENTS WITH CHC AND CKD

### Interferon-free antiviral schemes approved for CHC and CKD

**Ombitasvir/paritaprevir/dasabuvir based regimens:** The combination of ombitasvir/paritaprevir/r and dasabuvir, which has been abbreviated as 3D regimen, is used with or without the addition of RBV for the treatment of genotype 1a or 1b CHC patients. Moreover, the combination of ombitasvir/paritaprevir/r (2D) with RBV is administered for the treatment of genotype 4 CHC patients. The potential effect of renal impairment on the pharmacokinetics of 3D combination was evaluated in more than 2000 patients from seven phase 2/3 studies<sup>[23]</sup>. The severity of renal dysfunction was not found to affect the area under the plasma concentration curve (AUC) of 3D in 22 patients with GFR between 30 and 59 mL/min and therefore no dose-adjustments are required. However, no patients with end stage renal disease (GFR < 30 mL/min) were included in that initial evaluation. In a smaller study<sup>[24]</sup>, HCV patients with normal or mild renal impairment ( $n = 38$ ), were compared to those with stage 4 or 5 CKD patients (with or without HD) ( $n = 19$ ). During a 12-wk course with the

3D regimen, renal dysfunction did not affect significantly the pharmacokinetics of the 3D regimen. Ombitasvir and paritaprevir exposures were comparable (< 20% difference) in both groups and ritonavir and dasabuvir exposures were 33% and 37% lower, respectively. Thus, the authors concluded that no dose adjustment for the 3D regimen is required in HCV patients with severe renal impairment.

In the RUBY-I study<sup>[25]</sup>, the safety and efficacy of 3D given for 12 wk was evaluated in 20 genotype 1 treatment-naïve non-cirrhotics patients with CHC and CKD stage 4 or 5 (RBV was given at 200 mg/d in genotype 1a patients). Thirteen patients were under HD. The efficacy was high since SVR was achieved in 18 (90%) of 20 patients in the intention to treat analysis: One F3 genotype 1a patient relapsed 4 wk post-treatment, while a second patient died 14 d after the end of therapy due to left ventricular systolic dysfunction. Regarding safety profile, most adverse events were of mild to moderate severity. There were nine serious adverse events in 4 patients (including the patient who died), but none of them was considered to be related with antiviral therapy (including RBV). Four patients received erythropoietin for anemia but none required blood transfusion. No deterioration of liver or kidney function was observed during the study period.

More recently, real life data have been reported from two studies<sup>[26,27]</sup> which evaluated the safety and effectiveness of 3D with or without RBV in 69 CHC patients with stage 4 or 5 CKD (*i.e.*, GFR < 30 mL/min) or under HD. Sixty-five (94.2%) patients had genotype 1 including 29 (44.6%) cases with genotype 1a. Twenty five (75.7%) of 33 patients were treatment naïve<sup>[26]</sup> and 31 (45%) of 69 patients had cirrhosis<sup>[26,27]</sup>. 3D was given for 12 wk in all 69 patients, combined with RBV in 32 (46.3%) of them<sup>[26,27]</sup>. SVR rates at week 12 (SVR12) were 97% (65/67) [94.4% (17/18) for 3D and 94.4% (17/18) for 3D plus RBV, as provided by the study data]. In regards to safety profile, no patient discontinued 3D, two patients stopped RBV and five out of 69 patients (7.2%) developed serious adverse events requiring hospitalization (1 urinary tract infection, 2 heart failure, 1 arthritis and 1 atrial fibrillation) (Table 2).

**Elbasvir/grazoprevir:** Elbasvir/grazoprevir co-formulated in one tablet, with or without the addition of RBV, has been recently licensed by FDA and EMA for the treatment of HCV genotype 1 and 4<sup>[13]</sup>. Given that these agents are cleared by the liver, they can be a good option for patients with CKD stages 4 and 5. In the C-SURFER phase III study<sup>[28]</sup>, 224 patients with eGFR < 30 mL/min were randomized to receive elbasvir/grazoprevir ( $n = 111$ ) or placebo ( $n = 113$ ) for 12 wk. At week 16, unmasking occurred and all patients in the placebo arm received elbasvir/grazoprevir as well. Almost half (52%) of the patients had genotype 1a, 83% were HCV treatment-naïve, 6% had cirrhosis, 19% had CKD stage 4 and 81% CKD stage 5 (76% of them under HD). In the intention to treat analysis, SVR was achieved in 94%

(115/122) of patients in the active arm: 1 noncirrhotic patient relapsed during the first 12 wk after the end of treatment, while 6 patients discontinued treatment for reasons unrelated to antiviral therapy. Serious adverse events occurred in 16 (14%) and 17 (15%) patients in the elbasvir/grazoprevir and placebo arms, respectively. None and 4% of the patients in the active and placebo groups, respectively, discontinued therapy due to an adverse event. The most common adverse events in the active arm were headache, nausea and fatigue (Table 2).

### Interferon-free antiviral schemes not approved for CHC and CKD

In total, nine studies<sup>[29-37]</sup> evaluated the safety and efficacy of various antiviral schemes in 235 patients with CHC and CKD. All patients had stage 4 or 5 CKD (*i.e.*, GFR < 30 mL/min) or were under HD. The mean age was provided in 7 studies and ranged between 52.4 and 62 years<sup>[29-35]</sup>. Based on the available data,

169 (71.9%) of 235 patients had genotype 1 [67/122 (54.9%) genotype 1a]<sup>[29,32-36]</sup>. One hundred (47.6%) of 210 patients were treatment naïve<sup>[29,31,33-36]</sup> and 121 (51.4%) of 235 patients had cirrhosis<sup>[29-37]</sup>.

Sofosbuvir was given for 12-24 wk in combination with RBV in 42 (and PEG-IFN in 3)<sup>[29,31,32,35-37]</sup>, simeprevir in 87<sup>[29-31,33,35,36]</sup> (and RBV in 2, unclarified in 11)<sup>[31,36]</sup>, daclatasvir in 55 patients<sup>[30,31,33,35]</sup> and ledipasvir in 17<sup>[33,35]</sup>. The dosage of sofosbuvir was 400 mg per day in 84<sup>[29,30,33,36,37]</sup>, 200 mg per day in 33<sup>[29,32,36]</sup>, 200 mg every other day in 2<sup>[29]</sup> and unclarified in 82 patients. The dosage of PEG-IFN was not provided in the few studies including PEG-IFN containing regimens, while the dosage of RBV was 200 mg per day in 20<sup>[32,37]</sup>, variable (200 mg three times per week to 600 mg per day) in 35<sup>[31]</sup> and unknown in the remaining patients receiving RBV. The daily dosage of simeprevir was 150 mg and of daclatasvir 60 mg in all patients. The dose of ledipasvir was dependent on the dose of sofosbuvir.

The efficacy of sofosbuvir-based antiviral therapy was provided in all studies. Based on the available data, the rates of end of treatment virological response and SVR at week 12 were 100% (91/91) and 87.1% (129/148), respectively [SVR: 55.2% (16/29) for sofosbuvir plus RBV, 92.1% (35/38) for sofosbuvir plus simeprevir (with or without RBV), 100% (14/14) for ledipasvir/sofosbuvir and 85.7% (12/14) for sofosbuvir plus daclatasvir]. The SVR rates were 80.6% (25/31) for simeprevir plus daclatasvir with or without RBV.

Regarding safety profile, only 14 (5.9%) of the 235 patients discontinued therapy due to adverse events (one under combination of sofosbuvir plus RBV due to acute respiratory failure and one under sofosbuvir plus simeprevir for unclarified cause, while no details were provided for 12 patients)<sup>[33,35-37]</sup>. In addition, one patient developed pancytopenia at week 7 under therapy (no further data were given regarding antiviral therapy, but sofosbuvir was reduced from 400 mg/d to 400 mg every other day)<sup>[30]</sup>. Finally, 8 (3.4%) of 235 patients developed serious adverse events requiring hospitalization without treatment discontinuation: Hematemesis<sup>[37]</sup>, new onset encephalopathy<sup>[29]</sup>, uncontrolled diarrhea<sup>[29]</sup>, diabetic ketoacidosis or angina<sup>[32]</sup> (unclarified causes in 3 patients)<sup>[36]</sup>. Renal safety was evaluated in two studies<sup>[31,36]</sup> which reported no significant change of GFR from baseline to the end of treatment in non-haemodialysis patients under sofosbuvir-based regimens (Table 2).

Recently, the co-formulation of velpatasvir/sofosbuvir was approved for the treatment of all HCV genotypes. Its short-term safety and pharmacokinetics were evaluated in 10 subjects with eGFR < 30 mL/min<sup>[38]</sup>. A single dose of 100 mg velpatasvir was followed by a 120-h intensive blood monitoring. Records were compared to control subjects with normal renal function (eGFR ≥ 90 mL/min) matched for age, sex and body mass index. Velpatasvir was well tolerated and all adverse events were of mild severity. Only an approximately 50% increase in the velpatasvir AUC was observed in the group of patients with renal dysfunction, while the maximum velpatasvir concentrations (C<sub>max</sub>) were similar between the two groups. The authors concluded that velpatasvir could be administered without dose adjustment in patients with any GFR. However, since velpatasvir is available only in co-formulation with sofosbuvir, its use is driven by the limitations of sofosbuvir in patients with renal impairment.

## INTERFERON-FREE REGIMENS IN KT RECIPIENTS WITH CHC

In total, 10 studies<sup>[39-48]</sup> evaluated the safety and efficacy of current DAAs based regimens in 330 KT recipients with CHC for 12-24 wk. The mean age ranged from 53 to 65 years. Based on the available data, 247 out of 281 patients (87.9%) had genotype 1 CHC [54/143 (37.8%) genotype 1a]<sup>[39-46]</sup>. One hundred and fifty one out of 238 patients (63.4%)<sup>[40,42-44,46,47]</sup> were treatment naïve and 64 out of 252 patients (25.4%) had cirrhosis<sup>[39,40,43,44,46,47]</sup>.

Sofosbuvir was given in combination with RBV in 30 patients, simeprevir (± RBV) in 31, daclatasvir (± RBV) in 20 and ledipasvir (± RBV) in 230 for 12-24 wk. The 3D (or 2D) combination (± RBV) was given in 12<sup>[46,48]</sup> and the combination of simeprevir and daclatasvir (± RBV) in 7 patients<sup>[46]</sup>. The daily dosage of RBV was provided in only 2 studies<sup>[42,43]</sup> ranging from 200 mg to 1200 mg per day.

Based on the available data, the week-12 SVR rates of sofosbuvir based regimens were 94.2% (193/205): 66.7% (10/15) for sofosbuvir plus RBV [100% (4/4) for genotype 2], 88% (22/25) for sofosbuvir plus simeprevir (with or without RBV), 75% (3/4) for sofosbuvir plus daclatasvir, 98% (158/161) for sofosbuvir plus ledipasvir (with or without RBV). In addition, in one study the week-12 SVR rates were 97.8% (45/46) for various antiviral schemes<sup>[46]</sup>. No data have been available for the efficacy of 3D or simeprevir plus daclatasvir regimens<sup>[46,48]</sup>.

Regarding safety profile, 7 (2.1%) of 330 KT recipients discontinued therapy (4 under combination sofosbuvir and RBV due to pruritus, myalgia, anemia and unclarified reason; 1 under sofosbuvir plus daclatasvir due to virological failure; 2 under ledipasvir/sofosbuvir plus RBV for unclarified reasons)<sup>[39,41,44,47]</sup>, while one patient died 4 wk after the end of antiviral therapy due to bleeding from donor aorta graft<sup>[40]</sup>. In addition, 15 KT recipients developed anemia requiring RBV dose reduction and/or erythropoietin injection or blood transfusion, one patient had an episode of bradycardia requiring pacemaker placement despite on regular amiodarone treatment, 2 patients presented worsening proteinuria (> 3 g/d), 4 patients developed rejection of kidney graft, and 12 patients developed unclarified serious adverse events<sup>[47]</sup>. No dose adjustment of calcineurin inhibitors was required. Renal and liver function tests remained stable during antiviral treatment (Table 3).

## DISCUSSION

Current DAAs against HCV have very good safety profiles. However, baseline GFR and potential drug-drug interactions should be always considered before treatment initiation. Since sofosbuvir is the only DAA with renal elimination, concerns for potential nephrotoxicity have been raised mainly for this agent. There have been reports suggesting that sofosbuvir might have a negative impact on renal function in patients at high renal risk (e.g., decompensated cirrhosis, LT, proteinuria), particularly if more sensitive renal function markers are used (e.g., cystatin C or serum or urine NGAL). However, renal function decline in such high renal risk patients does not necessarily reflect drug related toxicity, as shown in uncontrolled reports. In addition, improvement in renal function after treatment has also been reported in patients who achieved SVR despite the scarcity of long follow-up data after the end of therapy. Only nephrotoxicity related to sofosbuvir has been observed but seems to be minimal given the short duration of therapy. Therefore, no definite conclusion can be drawn,

**Table 3** Studies of interferon-free regimens for treatment of hepatitis C virus positive kidney transplant recipients

while it seems reasonable to apply nephroprotective measures and careful renal monitoring during treatment with sofosbuvir-based regimens in patients at high renal risk. Anyway, eGFR monitoring is currently recommended at 4 wk of therapy and as clinically indicated for all patients receiving any regimen with DAAs<sup>[49]</sup>.

All current DAAs can be given in CHC patients with mild to moderate renal impairment (*i.e.*, eGFR ≥ 30 mL/min) without dose modification. Similarly, they could all be administered in severe renal impairment (*i.e.*, eGFR < 30 mL/min) or end-stage renal disease without dose modification as well, except for sofosbuvir. Of note, the currently recommended regimens for CHC patients with severe renal impairment or end-stage renal disease according to the AASLD and EASL are presented in Table 4<sup>[49,50]</sup>. To date, HCV therapy is only recommended for patients with high urgency for treatment of the liver disease and without KT as an immediate option. Furthermore, antiviral therapy can be given after KT or even simultaneous liver and kidney transplantation,

when patients usually have eGFR > 30 mL/min and can receive any regimen. HCV therapy with an IFN free regimen is mandatory for CHC patients with cirrhosis and severe renal impairment usually due to hepatorenal syndrome, since HCV eradication may lead to liver function stabilization and such an improvement resulting in LT elimination. But more data are required in this subgroup before the optimal regimen can be decided. Regrettably, lack of adequate supporting evidence halts a widely disseminated recommendation.

The indication of elbasvir/grazoprevir as first line treatment for CHC patients with genotype 1 or 4 and severe renal impairment, always given without RBV for 12 wk, has been based on the results of the C-SURFER trial. In contrast to genotype 1a patients with eGFR > 30 mL/min who should be tested for NS5A resistance associated variants (RAVs) before therapy and require 16 instead of 12 wk treatment period - of elbasvir/grazoprevir combined with RBV in case of NS5A RAVs presence-, there is no recommendation for such pre-

**Table 4** Recommended regimens from the American Association for the Study of Liver Diseases and European Association for the Study of the Liver for patients with chronic hepatitis C and severe renal impairment (glomerular filtration rate < 30 mL/min) who need urgent hepatitis C virus therapy and renal transplantation is not an immediate option

HCV genotype	AASLD recommended regimen	EASL recommended regimen <sup>3</sup>
1	Elbasvir/grazoprevir for 12 wk (for 1a or 1b) or ombitasvir/paritaprevir/ritonavir plus dasabuvir <sup>1</sup> (for 1b) for 12 wk	Elbasvir/grazoprevir or ombitasvir/paritaprevir plus dasabuvir (for 1a or 1b), for 12 wk (plus RBV 200 mg/d for 1a if the haemoglobin level is > 10 g/dL at baseline)
2, 3, 5 or 6	Pegylated interferon-alfa plus dose-adjusted ribavirin (200 mg daily) <sup>2</sup>	Sofosbuvir/velpatasvir or sofosbuvir plus daclatasvir (plus ribavirin if the haemoglobin level is > 10 g/dL at baseline for genotype 3) for 12 wk (or for 24 wk without ribavirin for genotype 3) <sup>4</sup>
4	Elbasvir/grazoprevir for 12 wk	Elbasvir/grazoprevir for 12 wk or ombitasvir/paritaprevir plus dasabuvir plus ribavirin (if the haemoglobin level is > 10 g/dL at baseline) for 12 wk

<sup>1</sup>For HCV genotype 1a: Ombitasvir/paritaprevir/ritonavir plus Dasabuvir plus ribavirin at reduced doses (200 mg thrice weekly to daily) may be also used; <sup>2</sup>Ribavirin should be discontinued when hemoglobin decreases by > 2 g/dL despite use of erythropoietin (or in case of severe anaemia (haemoglobin < 8.5 g/dL according to EASL guidelines); <sup>3</sup>According to EASL guidelines: (1) antiviral therapy is indicated in those without an indication for kidney transplantation otherwise after kidney transplantation may be preferred; and (2) sofosbuvir should be used with caution (no dose recommendation can currently be given for these patients) and with careful monitoring of renal function; <sup>4</sup>If treatment is urgently needed. HCV: Hepatitis C virus; AASLD: American Association for the Study of Liver Diseases; EASL: European Association for the Study of the Liver.

treatment testing in patients with genotype 1a and eGFR < 30 mL/min. The higher exposure to antiviral agents, the lower baseline HCV RNA levels in CHC patients and the severe renal impairment attribute for the previous difference. The 3D combination is considered an acceptable alternative for genotype 1 patients based on the results of the smaller RUBY I study and few real life data. The 3D combination is more attractive for patients with at least severe renal impairment and genotype 1b given for 12 wk without RBV. In contrast, the need for the addition of RBV makes it less attractive for such patients with genotype 1a. The safety and efficacy of the 2D regimen in patients with genotype 4 and CKD is currently under evaluation in the RUBY II trial.

The progress in HCV therapy seems to have been minimal for CHC patients with non-1, non-4 genotype and CKD, since current guidelines still recommend the PEG-IFN and RBV combination, which is associated with low efficacy, poor tolerance and potentially several adverse events. Therefore, several efforts have been focused on sofosbuvir based regimens despite its official contraindication in patients with stage 4 or 5 renal impairment (*i.e.*, with GFR < 30 mL/min or under HD)<sup>[51]</sup>. The package labels record that up to 20-fold accumulation of the sofosbuvir metabolite GS-331007 is expected in patients with severe renal dysfunction, but the clinical significance of GS-331007 accumulation remains unknown. Moreover, a recent prospective observational study<sup>[52]</sup> evaluated the pharmacokinetics of sofosbuvir in 2 dosing (400 mg per day or 3 times per week after HD), in HCV-infected patients under HD. No accumulation of sofosbuvir or GS-331007 was observed, while HD removed 53% of GS-331007.

Since sofosbuvir was chronologically the first licensed current DAA in most countries and is still required for the IFN-free treatment of patients with non-1, non-4 genotype, the safety and efficacy of sofosbuvir based regimens in patients with end stage renal disease (CKD stage 4 or 5) on or off HD have been reported in several

“real life” studies (Table 2). Its overall safety profile has been very good even in this setting with only 6% of patients (14/235) discontinuing therapy and 3.4% of patients (8/235) developing serious adverse events but without drug discontinuation. The SVR rates seem to be comparable with SVR rates in patients with normal renal function, although no definite conclusion can be drawn due to the suboptimal design of the studies, the suboptimal regimens used in some studies according to chronological availability, the small patient numbers and the variable sofosbuvir dosage. Provided that reduced sofosbuvir dosage reduces not only the plasma concentrations of GS-331007, but also the liver concentrations of the active sofosbuvir metabolite, GS-461203<sup>[53]</sup> and no major safety issues have been raised with the use of any sofosbuvir dosage in patients with at least severe renal impairment, the standard dose of sofosbuvir (400 mg daily) seems to be optimal even for this setting but should be linked with close clinical, biological, cardiovascular, and therapeutic drug monitoring. Nevertheless, further studies including more patients are required to provide stronger answers to all unresolved issues with sofosbuvir use in patients with CKD. In addition, further studies are needed in children and adolescents with CHC. It is estimated that the prevalence of chronic HCV infection is low (*e.g.*, < 0.5 among European children)<sup>[54]</sup> and currently no data on the efficacy and adverse effects of DAA are available in children with CHC.

For KT recipients, IFN-free, sofosbuvir based regimens are highly recommended providing that there is no severe underlying renal dysfunction because they are very effective with good tolerance, safety and minimal drug-drug interactions. Alternatively, the 3D or 2D regimens and the fixed elbasvir/grazoprevir combination could be the additional treatment options for patients with genotypes 1 and 4, but their safety and efficacy in the KT setting has not been evaluated yet. In general, the concurrent use of immunosuppressive agents has not been shown to affect the efficacy of any DAA

regimen and the main concern in transplant patients has been the potential drug interactions. Of the currently licensed DAAs, sofosbuvir, daclatasvir and ledipasvir have no interaction with the usual immunosuppressive agents and require no dosage modifications in transplant patients. On the other hand, simeprevir should not be given in patients receiving cyclosporine and initiation of 3D or 2D regimens should be given with reduced daily dose of cyclosporine (start with 20% of previous dose) or tacrolimus (start with 0.2 mg every 72 h or 0.5 mg once per week) in parallel with close level monitoring and dosage adjustment as required. Similarly, close monitoring of tacrolimus levels should be performed in patients undertaken elbasvir/grazoprevir because their co-administration results in increased tacrolimus plasma concentrations (Table 1).

In conclusion, IFN-free recent DAAs regimens offer for the first time the opportunity to treat effectively and safely most CHC special populations including those with severe renal dysfunction or KT. In particular, excellent IFN and RBV free options are already available for patients with genotypes 1 and 4 and severe renal impairment (eGFR < 30 mL/min) on or off HD such as elbasvir/grazoprevir for genotypes 1 and 4 and 3D for genotype 1b. To date, the patients with severe renal impairment and genotype 2, 3, 5 or 6 can be treated officially with PEG-IFN with or without RBV. Nevertheless, sofosbuvir-based regimens are actually applied if urgent treatment for the liver disease is required. Otherwise, such patients can wait for HCV treatment after KT or for future options with safer kidney profile, anticipated within the next few years.

### Abstract

#### AIM

To uncover the role of hepatocyte nuclear factor 4 alpha (HNF4 $\alpha$ ) in regulating hepatic expression of microRNAs.

#### METHODS

Microarray and real-time PCR were used to determine hepatic expression of microRNAs in young-adult mice lacking Hnf4 $\alpha$  expression in liver (Hnf4 $\alpha$ -LivKO). Integrative genomics viewer software was used to analyze the public chromatin immunoprecipitation-sequencing datasets for DNA-binding of HNF4 $\alpha$ , RNA polymerase- II, and histone modifications to loci of microRNAs in mouse liver and human hepatoma cells. Dual-luciferase reporter assay was conducted to determine effects of HNF4 $\alpha$  on the promoters of mouse and human microRNAs as well as effects of microRNAs on the untranslated regions (3' UTR) of two genes in human hepatoma cells.

#### RESULTS

Microarray data indicated that most microRNAs remained unaltered by Hnf4 $\alpha$  deficiency in Hnf4 $\alpha$ -LivKO mice. However, certain liver-predominant microRNAs were down-regulated similarly in young-adult male and female Hnf4 $\alpha$ -LivKO mice. The down-regulation of miR-101, miR-192, miR-193a, miR-194, miR-215, miR-802, and miR-122 as well as induction of miR-34 and miR-29 in male Hnf4 $\alpha$ -LivKO mice were confirmed by real-time

PCR. Analysis of public chromatin immunoprecipitation-sequencing data indicates that HNF4 $\alpha$  directly binds to the promoters of miR-101, miR-122, miR-194-2/miR-192 and miR-193, which is associated with histone marks of active transcription. Luciferase reporter assay showed that HNF4 $\alpha$  markedly activated the promoters of mouse and human miR-101b/miR-101-2 and the miR-194/miR-192 cluster. Additionally, miR-192 and miR-194 significantly decreased activities of luciferase reporters for the 3'UTR of histone H3F3 and chromodomain helicase DNA binding protein 1 (CHD1), respectively, suggesting that miR-192 and miR-194 might be important in chromosome remodeling through directly targeting H3F3 and CHD1.

## CONCLUSION

HNF4 $\alpha$  is essential for hepatic basal expression of a group of liver-enriched microRNAs, including miR-101, miR-192, miR-193a, miR-194 and miR-802, through which HNF4 $\alpha$  may play a major role in the post-transcriptional regulation of gene expression and maintenance of the epigenome in liver.

**Key words:** Liver; Hepatocyte nuclear factor 4 alpha; Knockout; Mice; Human; miR-122; miR-192; miR-194; miR-101; miR-802

**Core tip:** Hepatocyte nuclear factor 4 alpha (HNF4 $\alpha$ ) is a liver-enriched master regulator of liver development and function. HNF4 $\alpha$  plays a key role in regulating hepatic transcriptome and epigenome. However, little was known about the role of HNF4 $\alpha$  in regulating hepatic expression of microRNAs, essential modulators of the transcriptome and epigenome. Results from this study uncover species differences and similarities between humans and mice in the role of HNF4 $\alpha$  in regulating hepatic expression of certain important microRNAs. Such novel knowledge will help understand the role of HNF4 $\alpha$  in post-transcriptional regulation of gene expression and maintenance of the normal epigenome and physiology in mouse and human liver.

## INTRODUCTION

Hepatocyte nuclear factor 4 alpha (HNF4 $\alpha$ ) is a master regulator of liver development and function<sup>[1]</sup>. HNF4 $\alpha$  is essential for hepatocyte differentiation in fetal liver<sup>[2-4]</sup>, maintenance of liver function in adult<sup>[5,6]</sup>, and protection against liver cirrhosis and liver cancer<sup>[7,8]</sup>. HNF4 $\alpha$  is

critical in regulating hepatic metabolism of fatty acids, bile acids, and ureagenesis<sup>[5,9-11]</sup>. Moreover, HNF4 $\alpha$  is essential in regulating hepatic expression of drug processing genes, namely cytochrome P450s, phase-II conjugation enzymes, and transporters<sup>[1,12,13]</sup>.

There are very large individual variations in hepatic basal expression of HNF4 $\alpha$  in humans<sup>[14]</sup>, and mutation of HNF4 $\alpha$  causes maturity onset diabetes of young humans<sup>[15]</sup>. The expression and/or transcriptional activity of HNF4 $\alpha$  is decreased markedly in severe cirrhotic livers, alcoholic liver disease, tumor necrosis factor- $\alpha$ -induced hepatotoxicity, and hepatoma progression<sup>[16-19]</sup>. Thus, it is important to understand how HNF4 $\alpha$  deficiency affects hepatic gene expression and its underlying mechanism.

Interestingly, overexpression of HNF4 $\alpha$  in hepatocellular carcinoma (HCC) markedly decreases the stemness of gene expression and the percentage of cancer stem cells in HCC<sup>[7]</sup>; however, the underlying mechanism is unknown. Epigenetic modifications play key roles in regulating gene expression and stem cell differentiation. Our recent study demonstrates that *Hnf4 $\alpha$*  deficiency in young-adult mouse livers causes marked alteration in histone methylation and acetylation, which is associated with induction of certain key epigenetic enzymes, including enhancer of zeste homolog 2 (EZH2), G9a and DNA methyltransferase (cytosine-5) 1 (Dnmt1)<sup>[20]</sup>. EZH2 plays a key role in maintaining the stemness of stem cells<sup>[21]</sup>. Therefore, establishment and maintenance of the epigenome of differentiated hepatocytes may be a key mechanism in the regulation of gene expression and cell differentiation by HNF4 $\alpha$ .

The importance of HNF4 $\alpha$  in regulating hepatic expression of mRNAs has been well established, however, the underlying mechanism remains less clear. HNF4 $\alpha$  directly binds to a large number of gene promoters in human and mouse liver<sup>[22-24]</sup>. *Hnf4 $\alpha$*  deficiency in young-adult mouse liver caused induction of certain key epigenetic modifiers<sup>[20]</sup>. However, our analysis of published data of chromatin immunoprecipitation-sequencing (ChIP-seq) of *Hnf4 $\alpha$*  in adult mouse liver<sup>[25]</sup> revealed no binding of *Hnf4 $\alpha$*  to these epigenetic modifiers, suggesting indirect regulation of these epigenetic modifiers by *Hnf4 $\alpha$*  in liver. microRNAs are important post-transcriptional regulators of gene expression, and deregulation of microRNAs is common in human hepatocarcinogenesis<sup>[26]</sup>. Through binding to the untranslated regions (UTRs, usually the 3'UTR) of mRNAs, microRNAs affect the stability/translation of mRNAs and thus the mRNA and/or protein levels of their target genes. We hypothesized that HNF4 $\alpha$  can indirectly regulate hepatic gene expression through directly regulating hepatic expression of certain microRNAs. Thus, the purpose of this study was to uncover the role of HNF4 $\alpha$  in regulating hepatic expression of microRNAs. We used microarray and real-time PCR to determine hepatic expression of microRNAs in young-adult mice lacking *Hnf4 $\alpha$*  expression in liver (*Hnf4 $\alpha$* -LivKO). We used integrative genomics viewer (IGV) software to analyze the public ChIP-seq datasets

for DNA-binding of HNF4 $\alpha$ , RNA polymerase- II, and histone modifications to loci of microRNAs in mouse liver and human hepatoma cells. Additionally, we conducted dual-luciferase reporter assay to determine effects of HNF4 $\alpha$  on the promoters of mouse and human microRNAs as well as effects of microRNAs on the 3'UTR of two putative target genes in human hepatoma cells.

## MATERIALS AND METHODS

### Preparation of liver samples

The livers of male and female young-adult mice with liver-specific knockout of *Hnf4 $\alpha$*  (*Hnf4 $\alpha$ -LivKO*) (*Hnf4 $\alpha$*  flox/flox, Alb-cre/+) and age-matched wild-type (*Hnf4 $\alpha$*  flox/flox, Alb-cre/-) littermates at the age of 45 d were collected in the previous study<sup>[27]</sup> and stored at -80 °C until use. All animal procedures in the study were approved by the Institutional Animal Care and Use Committee of the University of Kansas Medical Center<sup>[27]</sup>.

### Microarray profiling of microRNA expression in *Hnf4 $\alpha$ -LivKO* mice

Pooled total RNAs from livers of young-adult (42-45 d old) male and female *Hnf4 $\alpha$ -LivKO* and their age-matched wild-type littermates ( $n = 5-6$ ) were used for microarray analysis of microRNAs, utilizing miRCURY™ LNA array version 11.0 (Exiqon, Denmark), which contains probes targeting all mouse microRNAs registered in the miRBASE version 13.0. Background correction was conducted utilizing normexp plus offset method with offset value 10<sup>[28]</sup>. The non-linear regression method was used for data normalization to remove certain systematic biases from microarray data, such as dye effects or intensity dependence.

### Heat map and unsupervised hierarchical clustering of microRNAs

The heat map diagram shows the result of the 2-way hierarchical clustering of microRNAs and samples<sup>[29]</sup>. Each row represents a microRNA and each column represents a pooled liver sample. The microRNA clustering tree is shown on the left, and the sample clustering tree appears at the top. The color scale shown at the bottom illustrates the relative expression level of a microRNA across all samples: Red color represents an expression level above mean, blue color represents expression lower than the mean. The clustering is performed on log<sub>2</sub>(Hy3/Hy5) ratios which passed the filtering criteria on variation across samples; LogMedianDRatios differences > 0.58, corresponding to 50% differential expression.

### Quantification of microRNAs using real-time PCR

miRCURY LNA™ Universal RT microRNA PCR (Exiqon) was used to quantify microRNAs in individual RNA samples from livers of male *Hnf4 $\alpha$ -LivKO* mice. All PCR reagents and specific LNA-modified PCR primer sets were purchased from Exiqon. The PCR primer sets for mmu-miR-19b, 26a, 29b, 34a, 122, 192, 193a-3p, 194 and

195 target both human and mouse microRNA homologs, whereas PCR primer sets for mmu-miR-101b, 215, and 802 were specific for mouse microRNAs. The relative expression of each microRNA was normalized by 5s rRNA and U6 rRNA with values of wild-type mice set at 100.

### Use of public database to analyze DNA-binding of HNF4 $\alpha$ and the chromatin status of microRNAs in mouse liver, intestine, and human hepatoma HepG2 cells

Actively transcribed genes typically remain in loosely-packed euchromatin, where DNA is more accessible to the transcriptional machinery. DNase- I hypersensitive sites (DHSs), determined by DNase-sequencing (DNase-seq), is a key determining factor of the chromatin accessibility of transcription factors. DNA-binding of RNA polymerase 2 (Pol2) is widely used as a marker of active transcription. Histone H3 trimethylation at lysine-4 (H3K4me3) is enriched around the transcription start sites (TSS) and correlates tightly with active gene transcription<sup>[30,31]</sup>, whereas H3 trimethylation at lysine-36 (H3K36me3) along the gene coding regions after TSSs correlated highly with transcription elongation<sup>[32]</sup>. Our previous study shows that alterations of H3K4me3 correlate bi-directionally with mRNA expression in HNF4 $\alpha$ -null livers<sup>[20]</sup>. Conversely, Histone H3 trimethylation at lysine-27 (H3K27me3) and at lysine-9 (H3K9me3) are well-established epigenetic signatures of gene silencing<sup>[31,33]</sup>. The public genome-wide datasets of DNase-seq (GSM1003818) as well as ChIP-seq of H3K4me3 (GSM769014), H3K36me3 (GSM1000151), H3K9me3 (GSM1087075), H3K27me3 (GSM1087069), Pol2 (GSM722763) and HNF4 $\alpha$  (GSM1390711) in wild-type mouse liver were retrieved from GEO DataSets and uploaded into the IGV software<sup>[34]</sup> to visualize the DNA-binding of HNF4 $\alpha$ , Pol2 and these epigenetic signatures in each microRNA locus in mouse liver. Similarly, the public genome-wide datasets of DNase-seq (GSM816662) as well as ChIP-seq of H3K4me3 (GSM945182), H3K36me3 (GSM945211), H3K9me3 (GSM1003519), H3K27me3 (GSM945231), Pol2 (GSM935543), and HNF4 $\alpha$  (GSM935619) in HepG2 cells were retrieved from GEO DataSets for their visualization in the IGV software. Additionally, to determine the role of tissue-specific binding of HNF4 $\alpha$  in the tissue-specific regulation of miRs, ChIP-seq data for DNA-binding of HNF4 $\alpha$  in the mouse liver (GSM1390711) and small intestinal villus cells (GSM851120) were compared using the IGV software.

### Generation of expression vectors for wildtype and mutant mouse *Hnf4 $\alpha$ 1*

The mouse *Hnf4 $\alpha$ 1* cDNA was synthesized by Integrated DNA Technologies, Inc (IDT, Coralville, IA) and cloned into the pcDNA3 backbone to generate the expression vector for wildtype *Hnf4 $\alpha$ 1*, which was named as pcDNA3-*Hnf4 $\alpha$ 1*. The expression vector for the 304 serine to aspartic acid (S304D) mutant of *Hnf4 $\alpha$ 1* was generated using pcDNA3-*Hnf4 $\alpha$ 1* and the Q5® Site-Directed Muta-

genesis Kit (New England Biolabs), and verified by sequencing.

#### **Generation of reporter constructs for the promoters of human miR-101-2 and mouse miR-101b**

miR-101 is mainly transcribed from the human miR-101-2 and mouse miR-101b loci<sup>[35]</sup> which are located in the intron8-9 of RNA terminal phosphate cyclase-like 1 (*RCL1*) gene. The first base of the pre-miR-101-2 was assigned as chr9:4840297<sup>[35]</sup>, located within intron5-6 of *RCL1*, around where prominent peaks of H3K4me3 and DNA-binding of Pol2 and HNF4 $\alpha$  were identified. Thus, we PCR cloned a 739-bp fragment of miR-101-2 proximal promoter (-926 to -190 bp), located within the intron5-6 of *RCL1*, into the KpnI/MluI sites of pGL3-Basic reporter vector, which was named as pGL3-miR-101-2. In mice, miR-101b is predominantly expressed in the liver<sup>[35]</sup>. Similar to its human ortholog miR-101-2, we found prominent peaks of HNF4 $\alpha$ , H3K4me3 and Pol2 that start at the intron5-6 of *Rcl1* and extend to intron7-8 and intron8-9 of *Rcl1*. Thus, we PCR cloned a 933-bp fragment of the miR-101b promoter, located within intron5-6 of *Rcl1* that contains the peaks of HNF4 $\alpha$  and Pol2, into the KpnI/MluI sites of pGL3-Basic reporter vector, which was named as pGL3-miR-101b.

#### **Generation of reporter constructs for the proximal and/or distal promoters of human and mouse miR-194-2/miR-192 cluster**

Mouse miR-194-1/miR-215 and miR-194-2/miR-192 forms gene clusters in chromosome 1 and 19, respectively. The miR-194-1/miR-215 loci is expressed lowly in mouse liver<sup>[36]</sup>. In mouse liver, we found prominent peaks of DHSs, HNF4 $\alpha$ , Pol2 and H3K4me3 located approximately 1.6 kb upstream of the miR-194-2. Thus, we PCR cloned a 1973 bp fragment (-1694 to + 279 bp) of the promoter of the mouse miR-194-2/miR-192 cluster into the MluI/XhoI site of pGL3-Basic reporter vector, which was named as pGL3-mmIR-194-2. The sequences of all the primers used for PCR cloning of miR promoters are listed in Supplemental Materials.

A previous study indicates that a single approximately 2.4 kb transcript contains the human pri-miR-194-2 transcript and a 5' AK092802 cDNA. In the human colon cancer Caco-2 cells, HNF1 $\alpha$  binds to a HNF1 site located between -70 and -52 bp upstream of the transcription start site (TSS) of AK092802 to activate the promoter of pri-miR-194-2<sup>[37]</sup>. The upstream genomic region close to the TSS of pri-miR-194-2 contains some highly conserved regions between humans and mice<sup>[37]</sup>. We found prominent peaks of DHSs, HNF4 $\alpha$ , Pol2 and H3K4me3 within a 350 bp fragment from -329 to +21 bp upstream of the TSS of AK092802, which was PCR cloned into the KpnI/MluI sites of pGL3-Basic reporter vector and named as pGL3-hmiR-194-2-Dist. Genomic DNA prepared from C57BL/6 mouse liver and human embryonic kidney 293 cells were used as the PCR templates. In addition to the prominent peaks of HNF4 $\alpha$  and Pol2 identified in

approximately 2 kb upstream of the human miR-194-2 loci, smaller peaks of HNF4 $\alpha$  and Pol2 were also found in the proximal promoter of human miR-194-2. A DNA fragment of 417 bp that contains 5' KpnI and 3' Hind III restriction sites as well as a wild-type and mutant 405 bp human miR-194-2 promoter (from -405 to +1) were synthesized and verified by sequencing (GenScript United States Inc., Piscataway, NJ), and ligated into the KpnI/HindIII site in the pGL3-basic vector, which was named as pGL3-hmiR-194-2-Pro and pGL3-hmiR194-2 TriM. The mutant 405-bp human miR-194-2 promoter had mutations of 3 putative HNF4-binding sites predicted by software of NHR-scan<sup>[38]</sup> and HNF4 Binding Site Scanner<sup>[39]</sup> (for DNA sequences see Supplemental Materials).

#### **Generation of reporter construct for the mouse miR-802 promoter**

We PCR cloned a 2 kb fragment of the mouse miR-802 promoter (-2004 to -1 bp) into the MluI/XhoI sites of pGL3-Basic to generate the reporter vector for mouse miR-802 promoter, which was named as pGL3-mmIR-802 Pro.

#### **Determination of effect of HNF4 $\alpha$ on the promoter activities of human and mouse miRs**

Human hepatocellular adenoma HepG2 cells were maintained in D-MEM with 5% FBS. Cells were added to 96-well plates and grown to approximately 80% confluence. Plasmid DNA including pGL3 reporter vectors, the pRL-CMV luciferase (as control for transfection efficiency), pCDNA3-HNF4 $\alpha$ 2 (Addgene), pCMV-CCAAT/enhancer-binding protein  $\alpha$  (C/EBP $\alpha$ ) (gift from Dr. Magnus Nord, Karolinska Institute), or pCDNA3 were complexed with Lipofectamine 3000 reagent (Invitrogen, Carlsbad, CA) and applied to individual wells, according to the manufacturer's protocol. Transfected cells were lysed with passive lysis buffer (Promega) 24 h after transfection. Promoter activities of cell lysates were quantified by Dual-Glo<sup>TM</sup> luciferase assay (Promega) with the control values of pGL3-Basic vs pRL-CMV set at 1.0. To study the role of SP1 in mediating the transactivation of human miR-194-2 proximal promoter by HNF4 $\alpha$ , the SP1 inhibitor mithramycin was added 1 h after transfection and cells were lysed 24 h after transfection for dual-luciferase assay.

#### **Generation of reporter construct for the 3'UTR of mouse chromodomain helicase DNA binding protein 1 (*Chd1*) and *H3f3* mRNAs**

The chromatin remodeling factor Chd1 is required to maintain the open chromatin and pluripotency of mouse embryonic stem cells<sup>[40]</sup>. DNA sequence containing 48 bp of the 3'UTR of mouse Chd1 mRNA (NM\_007690.3, 6708-6756, in bold), namely CTAGTGATTGGCTTT AATATAAAACTGTTACAGTACACACTGATTGTATATA CGCGTA, and its antisense sequence AGCTTACGCG TATATACAATCAGTGTGTACTGTAACAGTTTTTATATTTAA

GCCAATCA were synthesized by IDT. DNA sequence containing 48 bp of the 3'UTR of mouse H3f3b mRNA (NM\_008211.3, 1593-1639, in bold), namely CTAGTAA GTATCCTATTGAAGTTTTAGGTCAATTATGTATGTTGA CTAATACGCGTA, and its antisense sequence AGCTT ACGCGTATTTAGTCAACATACATAATTGACCTAAAAA CTTCAATAGGATACTTA were synthesized by IDT. The two sense and antisense oligos were annealed and ligated into the Spe I /HindIII site between the luciferase cDNA and SV40 polyA in pMIR-REPORT™ microRNA Expression Reporter Vector (Applied Biosystems/Ambion, Austin, TX), which was named pMIR-Chd1 and pMIR-H3f3, respectively. The correctness of pMIR-Chd1 and pMIR-H3f3 was verified by the unique restriction site (ACGCGT) for MluI that was introduced into the synthetic oligo.

#### **Determination of effect of miR-194 and miR-192 on the stability of mouse Chd1 and H3f3 3'-UTR using dual-luciferase assay**

HepG2 human hepatocellular adenoma cells were maintained in D-MEM with 5% FBS. Cells were added to 96-well plates and grown to approximately 80% confluence. Plasmid DNA including pmiR-Chd1 (or pmiR-H3f3), the pRL-CMV luciferase, and a synthetic mimic of miR-194/miR-192 (miScript miR-194/miR-192, QIAGEN Inc, Valencia, CA), or AllStars Negative Control siRNA (QIAGEN, as negative control for microRNAs) were co-transfected using Lipofectamine 2000 (Invitrogen, Carlsbad, CA), according to the manufacturer's protocol of DNA-RNAi co-transfection. Transfected cells were lysed with passive lysis buffer (Promega) 24 h after transfection. Promoter activities of cell lysates were quantified by Dual-Glo™ luciferase assay (Promega) with the control values of pmiR-Chd1/pmiR-H3f3 vs pRL-CMV set at 1.0.

**Animal care and use statement:** The animal protocol was designed to minimize the pain or distress to the mice. Age-matched young-adult HNF4 $\alpha$  Liv-KO mice and their wild-type control littermates were fed rodent chow (#8064, Teklad; Harlan, Indianapolis, IN). Mice were housed at an ambient temperature of 22 °C with alternating 12-h light/dark cycles and allowed water and feed *ad libitum*.

#### **Statistical analysis**

Data are presented as mean  $\pm$  SE. Differences between two groups were determined using Student's *t*-test. For multiple comparisons, analysis of variance was performed, followed by the Student-Newman-Keuls Method in SigmaPlot 12.5, with significance set at  $P < 0.05$ .

## **RESULTS**

#### **Results of microarray analysis of microRNAs in pooled young-adult male and female Hnf4 $\alpha$ -LivKO mouse livers**

Generally, there were few gender differences in hepatic expression of microRNAs in mice (Figure 1), which is similar to that in rats<sup>[41]</sup>. Hepatic expression of most microRNAs

remained unchanged ( $< 50\%$  differential expression among the 4 pooled samples) in *Hnf4 $\alpha$ -LivKO* mice (data not shown). However, *Hnf4 $\alpha$ -LivKO* mouse livers had up- or down-regulation of a small portion of microRNAs that are important in regulating cell proliferation, differentiation, and apoptosis (Figure 1). Thirty microRNAs were found to have  $\geq 50\%$  differential expression among the 4 pooled samples, namely male WT and *Hnf4 $\alpha$ -LivKO* as well as female WT and *Hnf4 $\alpha$ -LivKO* mice. Fourteen microRNAs had  $> 50\%$  lower expression in *Hnf4 $\alpha$ -LivKO* mice than in WT mice (Figure 1A). Among them, the 4 liver-predominant microRNAs miR-194, miR-192, miR-215 and miR-193 were 71%, 72%, 70% and 70% lower, respectively, in *Hnf4 $\alpha$ -LivKO* male mouse livers than WT males (WTM). miR-101a and 101b, which are expressed moderately in liver, also decreased  $> 50\%$  in male *Hnf4 $\alpha$ -LivKO* mice. Female *Hnf4 $\alpha$ -LivKO* mouse livers had very similar lower expression of these microRNAs than WT females (Figure 1A). In contrast, two microRNAs that are expressed highly in liver, namely miR-122 and miR-26a<sup>[42,43]</sup>, had less than 50% differential expression in all the groups (Supplemental Table 1).

In contrast to the down-regulation of certain liver-predominant microRNAs, hepatic expression of 16 microRNAs were  $> 50\%$  higher in *Hnf4 $\alpha$ -LivKO* mice than in WT mice (Figure 1B). The tumor-suppressor miR-34a<sup>[44]</sup> was expressed at relatively low levels in wild-type mouse liver, but was induced 2.6 fold in male *Hnf4 $\alpha$ -LivKO* mouse livers. Tumor-suppressor miR-29b and miR-195<sup>[45]</sup> were highly and modestly expressed in WT mouse livers, respectively, and were 90% and 70% higher, respectively, in male *Hnf4 $\alpha$ -LivKO* mouse livers than WTM (Figure 1B).

The oncogenic miR-17-92 locus encodes a cluster of 7 microRNAs transcribed as a single primary transcript<sup>[46]</sup>. Four miR-17-92 members, namely miR-17, 19a, 19b and 20 tended to be higher in *Hnf4 $\alpha$ -LivKO* mouse liver (Figure 1B).

#### **Verification of changes in hepatic microRNAs in male Hnf4 $\alpha$ -LivKO mice by real-time PCR**

To verify the changes in microRNAs detected by microarray in the pooled liver samples, real-time PCR was used to quantify 12 microRNAs in individual samples from *Hnf4 $\alpha$ -LivKO* mice (Figure 2). Because similar alterations of these microRNAs were found in male and female *Hnf4 $\alpha$ -LivKO* mice (Figure 1), only individual male *Hnf4 $\alpha$ -LivKO* liver samples were used in this study. The selection of these 12 microRNAs for verification was based on their relative expression levels (Supplemental Table 1) and their reported importance in cellular pathophysiology.

Compared to male WT mice, male *Hnf4 $\alpha$ -LivKO* mice had markedly lower levels of miR-101b (7% of WT values), miR-192 (24%), miR-193a (24%), miR-194 (16%), miR-215 (59%) and miR-802 (33%) (Figure 2A-B), but higher levels of miR-29b (190%) and miR-34a (244%) (Figure 2C). In contrast, hepatic levels of miR-26a and miR-195 were similar between male WT and *Hnf4 $\alpha$ -LivKO* mice (Figure 2C-D). Hepatic miR-122 was

**Figure 1** Heat map and unsupervised hierarchical clustering of hepatic microRNAs in male and female *Hnf4a*-LivKO mice. The heat map diagram shows the results of the 2-way hierarchical clustering of microRNAs and samples. Each row represents a microRNA and each column represents a pooled liver sample. The microRNA clustering tree is shown on the left, and the sample clustering tree appears at the top. The color scale shown at the top illustrates the relative expression level of a microRNA across all samples: Red color represents an expression level above mean, blue color represents expression lower than the mean. The clustering is performed on log<sub>2</sub>(Hy3/Hy5) ratios which passed the filtering criteria on variation across samples; LogMedianDRatios differences > 0.58, corresponding to 50% differential expression. WTM: Wild-type male; WTF: Wild-type female; KOM: Knockout male; KOF: Knockout female.

modestly (30%) lower in male *Hnf4a*-LivKO mice than male WT mice (Figure 2D).

#### DNA-binding of HNF4 $\alpha$ in mouse liver and small intestine as well as the chromatin status of microRNAs in mouse liver

To understand the mechanism of regulation of microRNA expression by HNF4 $\alpha$  in mouse liver, we used IGV software to analyze the published genome-wide DNase-seq and ChIP-seq data on DNA-binding of HNF4 $\alpha$  as well as the presence of DHSs, Pol2 and active (H3K4me3 and H3K36me3) and suppressing (H3K9me3 and H3K27me3) epigenetic signatures, in the loci of several microRNAs in mouse liver and/or small intestine. Consistent with their high expression in mouse liver, miR-122a, miR-194-2/miR-192 and miR-101b had large peaks of DHSs in their gene loci, which were associated with sequential prominent peaks of HNF4 $\alpha$ , Pol2, H3K4me3 and H3K36me3 downstream (Figure 3A-3C). This strongly suggests that the binding of HNF4 $\alpha$  to the promoter of these miR genes causes the recruitment of Pol2 and the introduction of H3K4me3 and H3K36me3, the active marks of transcription initiation and elongation. Consistent with the liver-specific and liver-predominant expression of miR-122a and miR-101b, respectively, no binding of HNF4 $\alpha$  to the promoters of miR-122a and miR-101b was found in mouse small intestine (Figure 3A and 3C). In contrast, large peaks of HNF4 $\alpha$  were identified in the distal and proximal promoters of the miR-194-2/miR-192 cluster, consistent with their high expression in the mouse intestine<sup>[37]</sup>.

Similarly, peaks of DHSs, HNF4 $\alpha$ , Pol2 and H3K4me3 were also found in the gene loci of miR-193 and miR-802 (Figure 3D and E); however, the peaks were smaller and less sequential compared to those in the gene loci of miR-122, miR-194-2/miR-192 and miR-101b. In contrast, no clear peaks of H3K36me3 were found in regions that encode the mature transcripts of miR-193 and miR-802 (Figure 3D and E). Interestingly, the silencing mark H3K27me3 was found to span the whole locus of miR-802, whereas a peak of H3K9me3 was found 3' downstream of the miR-802 (Figure 3E). In summary, the data suggest that these five microRNAs might be directly regulated by HNF4 $\alpha$  in mouse liver.

Much smaller peaks of HNF4 $\alpha$  were found in the gene loci of miR-194-1/miR-215, miR26a-1 and miR26a-2, and DNA-binding of HNF4 $\alpha$  was not associated with prominent peaks of Pol2 or H3K4me3 in mouse liver (Figure 4A-C). Conversely, although prominent peaks of DHSs, HNF4 $\alpha$ , Pol2 and H3K4me3 were found in the miR-26b locus, the direction of HNF4 $\alpha$ , Pol2 and H3K4me3 peaks was toward the upstream of miR-26b, rather than the transcription initiation of miR-26b (Figure 4D). These data suggest that HNF4 $\alpha$  may not have a direct and/or important role in regulating hepatic expression of miR-194-1/miR-215, miR-26a and miR-26b. In contrast, large peaks of HNF4 $\alpha$  were found in the distal and proximal promoter of the miR-194-1/miR-215 cluster in mouse small intestine (Figure 4A), suggesting that HNF4 $\alpha$  may be important in regulating the high expression of the miR-194-1/miR-215 cluster in mouse small intestine<sup>[36]</sup>.

It was reported that HNF4 $\alpha$  binds to the proximal

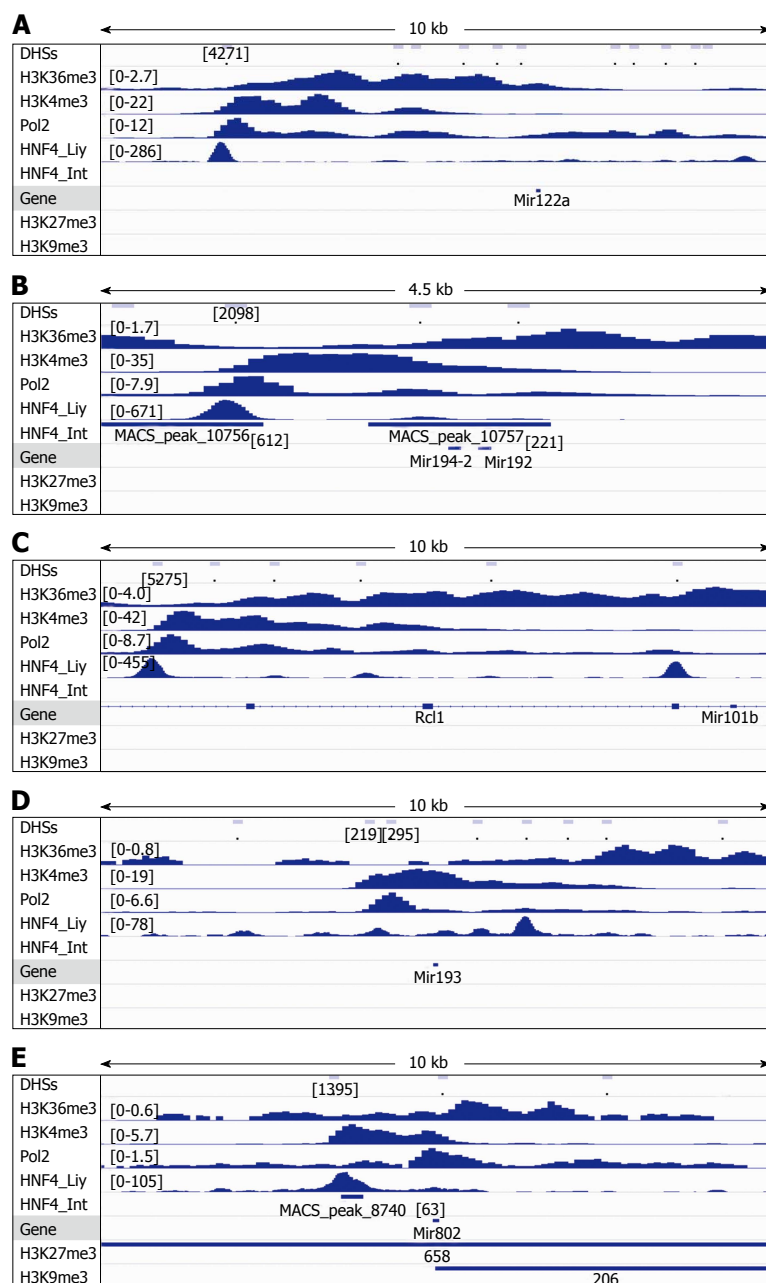

**Figure 2** Hepatic microRNA expression in young-adult male mice with liver-specific deletion of *Hnf4a* (*Hnf4a*-LivKO) (A-D). microRNAs in total RNA from livers of *Hnf4a*-LivKO and wild-type (WT) control mice ( $n = 5-6$ ) were determined by miRCURY LNA<sup>TM</sup> Universal RT microRNA PCR (Exiqon). Mean  $\pm$  SE.  $^*P < 0.05$  compared to WT control. HNF4 $\alpha$ : Hepatocyte nuclear factor 4 alpha.

promoter of miR-29 a-b cluster in cultured mouse hepatocytes, and acute loss of HNF4 $\alpha$  decreased the levels of miR-29a and miR-29b in isolated hepatocytes and livers from mice on a mixed background of SvJ129/FVB<sup>[47]</sup>. However, only a small peak of HNF4 $\alpha$  was found within 10 kb of the mouse miR-29 a-b loci in adult liver from C57BL/6 mice, and the small HNF4 $\alpha$  peak was not associated with peaks of Pol2 or H3K4me3 (Figure 5A). In contrast, a larger peak of HNF4 $\alpha$  was found in the promoter of the miR-29 a-b loci in the small intestine (Figure 5A). Thus, the role of HNF4 $\alpha$  in regulating hepatic expression of miR-29 a-b cluster in mice may be strain and/or cell-context dependent.

Recent studies indicate that HNF4 $\alpha$  directly regulates miR-124 and miR-134 in human liver, and down-regulation of HNF4 $\alpha$  is associated with reduction of miR-124 and miR-134 in human HCC<sup>[48,49]</sup>. However, our microarray data showed that miR-124 and miR-134 were expressed very lowly in mouse liver, and *Hnf4a* deficiency had no effect on hepatic expression of miR-124 and miR-134 in mice (Supplemental Table 1). Consistently, there were no clear peaks of HNF4 $\alpha$ , Pol2, or the activating signatures H3K4me3, H3K36me3 in the loci of the 3 mouse miR-124 genes, namely miR-124a-1, 124a-2 and 124a-3 in livers of C57BL/6 mice (Figure 5B-D). In contrast, large peaks of the silencing mark H3K27me3 were found

in the whole loci of miR-124a-1, 124a-2 and 124a-3, and a large peak of H3K9me3 was found in the miR-124a-1 locus (Figure 5B-D). Similarly, there were no prominent peaks of DHSs, HNF4 $\alpha$ , Pol2, H3K4me3, or H3K36me3 detected in the locus of mouse *miR-134* gene, where the silencing mark H3K9me3 was found (Figure 5E). Taken together, the very low signal of miR-124s and miR-134 in the microarray data (Supplemental Table 1) and the lack of activating epigenetic signatures but enrichment of silencing epigenetic signatures in the loci of miR-124s and miR-134 strongly indicate that miR-124 and miR-134 are expressed very lowly in adult mouse liver, and they are not HNF4 $\alpha$ -target genes in mouse liver. Thus, there appear to be species differences between humans and mice in hepatic basal expression and regulation of miR-124 and miR-134 by HNF4 $\alpha$ .

Because our data of microRNA expression and analysis of public database for ChIP-seq strongly suggest that HNF4 $\alpha$  has a critical direct role in maintaining hepatic expression of miR-194/miR-192 and miR-101b in mice, we further examined DNA-binding of HNF4 $\alpha$  and chromatin status in the gene loci of miR-194-2/miR-192 and miR-101-2 in the human hepatoma HepG2 cells using the data from public database (Figure 6). Very similar to the mouse miR-194-2/miR-192 cluster (Figure 3B), starting from approximately 2 kb upstream of the

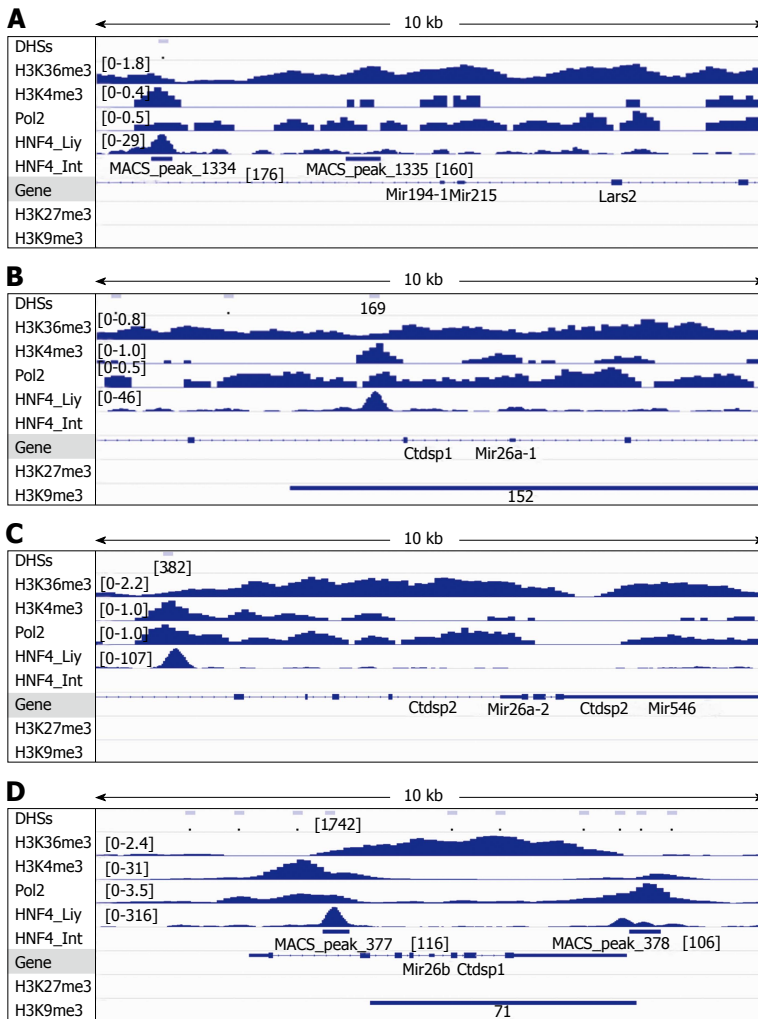

**Figure 3** Analysis of DNase-I hypersensitive sites as well as DNA-binding of HNF4 $\alpha$ , RNA polymerase II (Pol2), and methylated histones to loci of miR-122a (A), miR-194-2/miR-192 (B), miR-101b (C), miR-193 (D) and miR-802 (E) in wildtype mouse liver. DNA-binding of HNF4 $\alpha$  to these microRNA loci in the mouse small intestine (HNF4 $\alpha$ \_Int) was compared to those in the mouse liver (HNF4 $\alpha$ \_Liy). Data of DHSs (determined by DNase-seq) and DNA-binding of proteins (determined by ChIP-seq) were retrieved from the public database of GEO DataSets and visualized in the IGV software. The peak values/ranges for each mark were shown in square brackets or under the line mark. DHSs: DNase-I hypersensitive sites; HNF4 $\alpha$ : Hepatocyte nuclear factor 4 alpha; H3K36me3: H3 trimethylation at lysine-36; H3K4me3: H3 trimethylation at lysine-4; H3K27me3: H3 trimethylation at lysine-27; H3K9me3: H3 trimethylation at lysine-9; Pol2: Polymerase 2; HNF4 $\alpha$ : Hepatocyte nuclear factor 4 alpha; ChIP-seq: Chromatin immunoprecipitation-sequencing; IGV: Integrative genomics viewer.

human pri-miR-194-2, prominent sequential peaks of DHSs, HNF4 $\alpha$ , Pol2, H3K4me3 and H3K36me3 were identified in the human *miR-194-2/miR-192* gene cluster in HepG2 cells (Figure 6A). Very similar to the mouse miR-101b, the human *miR-101-2* gene body is located in the intron8-9 of the *RCL1* gene, and clear (but weaker than miR-194-2) sequential peaks of HNF4 $\alpha$ , Pol2, H3K4me3 and H3K36me3 were identified in the intron5-6 of *RCL1* (Figure 6B). These data strongly suggest that HNF4 $\alpha$  may also have a direct critical role in

regulating hepatic expression of miR-194-2/miR-192 and miR-101-2 in humans. In contrast, there were no clear peaks of HNF4 $\alpha$ , Pol2, or H3K4me3 (Figure 6C) in the miR-122 locus which is known to be silenced in HepG2 cells<sup>[42]</sup>.

#### Regulation of the mouse and human miR-194-2/miR-192 gene cluster by HNF4 $\alpha$

Hepatic expression of miR-194 is markedly down-regulated in mice null for *Hnf1 $\alpha$* <sup>[36]</sup>, a down-stream target

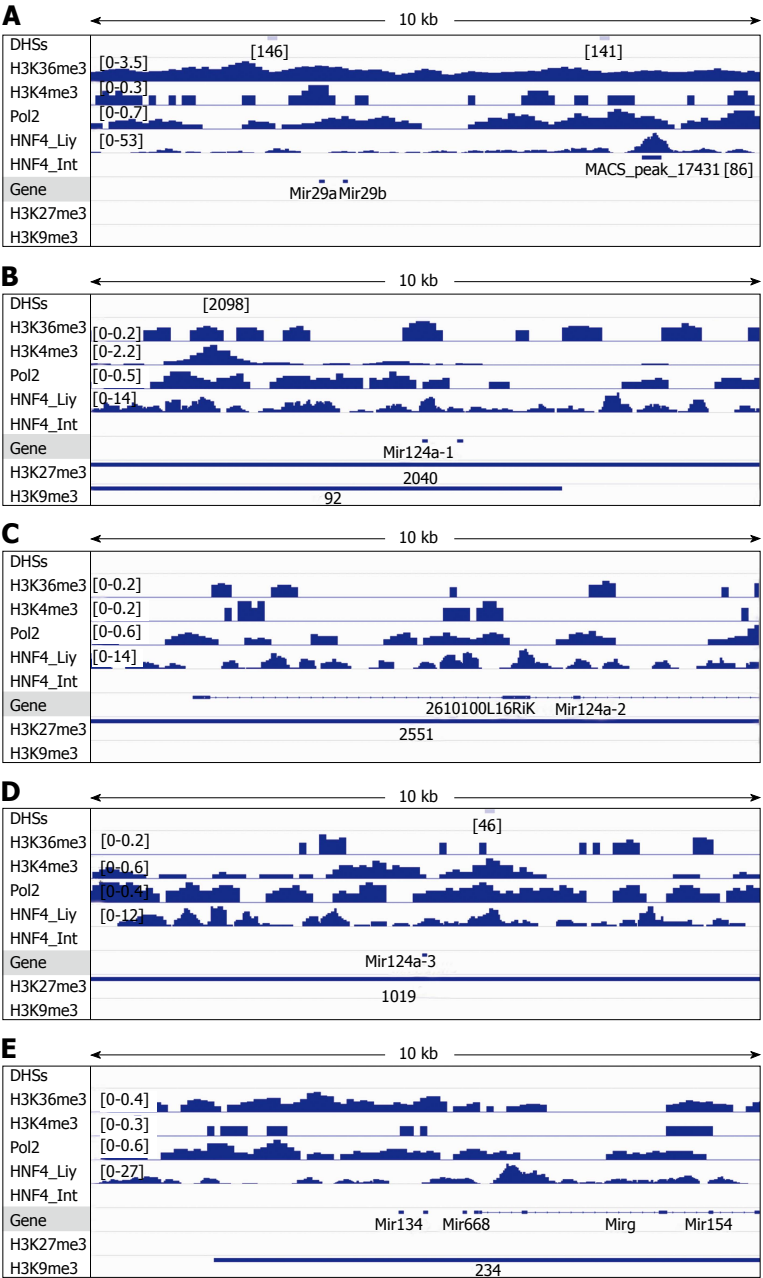

**Figure 4** Analysis of DNase-I hypersensitive sites as well as DNA-binding of HNF4 $\alpha$ , RNA polymerase II (Pol2), and methylated histones to loci of miR-194-1/miR-215 (A), miR-26a-1 (B), miR-26a-2 (C) and miR-26b (D) in wildtype mouse liver. DNA-binding of HNF4 $\alpha$  to these microRNA loci in the mouse small intestine (HNF4 $\alpha$ \_Int) was compared to those in the mouse liver (HNF4 $\alpha$ \_Liv). Data of DHSs (determined by DNase-seq) and DNA-binding of proteins (determined by ChIP-seq) were retrieved from the public database of GEO DataSets and visualized in the IGV software. The peak values/ranges for each mark were shown in square brackets or under the line mark. DHSs: DNase-I hypersensitive sites; H3K36me3: H3 trimethylation at lysine-36; H3K4me3: H3 trimethylation at lysine-4; H3K27me3: H3 trimethylation at lysine-27; H3K9me3: H3 trimethylation at lysine-9; Pol2: Polymerase 2; HNF4 $\alpha$ : Hepatocyte nuclear factor 4 alpha; ChIP-seq: Chromatin immunoprecipitation-sequencing; IGV: Integrative genomics viewer.

of HNF4 $\alpha$ . In small intestine, miR-194 is transcriptionally up-regulated by Hnf1 $\alpha$ <sup>[37]</sup>. Hepatic mRNA expression of Hnf1 $\alpha$  decreased modestly in *Hnf4 $\alpha$ -LivKO* mice<sup>[1]</sup>. We found that HNF1 $\alpha$  and HNF4 $\alpha$  modestly activated the reporter for the mouse *miR-194-2/miR-192* gene cluster 1.5 and 2.8 fold, respectively, and they synergistically activated mouse miR-194-2/miR-192 promoter 7.5 fold (Figure 7A). ChIP-seq results showed that HNF4 $\alpha$  bound strongly to the distal promoter but weakly to the proximal promoter of human miR-194-2/miR-192 cluster (Figure 6A). To determine the role of HNF4 $\alpha$  in regulating the *miR-194-2/miR-192* gene cluster in humans, we generated reporter vectors for the distal and proximal promoters of human miR-194-2/miR-192 cluster. Surprisingly, HNF4 $\alpha$  only modestly activated the distal promoter 3 fold, but very strongly activated the proximal promoter of human miR-194-2/miR-192 cluster by 200 fold (Figure 7B). To identify the critical cis-elements responsible for the very strong transactivation

of this proximal promoter by HNF4 $\alpha$ , we engineered luciferase reporter constructs for the mutated 400-bp proximal promoter of human *miR-194-2* gene cluster. Surprisingly, mutations of the 3 putative HNF4-binding sites (HNF4-RE) within the 400-bp miR-194-2 promoter had little effects on the transactivation of this promoter by HNF4 $\alpha$  (Figure 7C). HNF4 $\alpha$  can transactivate the human p21 promoter *via* physically interacting with the general transcription factor SP1, independent of DNA-binding of HNF4 $\alpha$ , because the S304D mutant of HNF4 $\alpha$  which has markedly decreased DNA-binding activity<sup>[50]</sup>, is equally active as the WT HNF4 $\alpha$  in transactivating p21<sup>[51]</sup>. Thus, we tested the hypothesis that HNF4 $\alpha$  can DNA-binding-independently transactivate the proximal human miR-194-2 promoter *via* interacting with SP1. We found that mithramycin, a widely used SP1 inhibitor<sup>[52]</sup>, dramatically suppressed the HNF4 $\alpha$ -transactivation of both the WT and HNF4RE-mutant miR-194-2 promoter by 94% and 95%, respectively (Figure 7C). Moreover,

**Figure 5** Analysis of DNase-I hypersensitive sites as well as DNA-binding of HNF4 $\alpha$ , RNA polymerase II (Pol2), and methylated histones to loci of miR-29a/miR-29b (A), miR-124a-1 (B), miR-124a-2 (C), miR-124a-3 (D) and miR-134 (E) in wildtype mouse liver. DNA-binding of HNF4 $\alpha$  to these microRNA loci in the mouse small intestine (HNF4 $\alpha$ \_Int) was compared to those in the mouse liver (HNF4 $\alpha$ \_Liv). Data of DHSs (determined by DNase-seq) and DNA-binding of proteins (determined by ChIP-seq) were retrieved from the public database of GEO DataSets and visualized in the IGV software. The peak values/ranges for each mark were shown in square brackets or under the line mark. DHSs: DNase-I hypersensitive sites; H3K36me3: H3 trimethylation at lysine-36; H3K4me3: H3 trimethylation at lysine-4; H3K27me3: H3 trimethylation at lysine-27; H3K9me3: H3 trimethylation at lysine-9; Pol2: Polymerase 2; HNF4 $\alpha$ : Hepatocyte nuclear factor 4 alpha; ChIP-seq: Chromatin immunoprecipitation-sequencing; IGV: Integrative genomics viewer.

the S304D-mutant of HNF4 $\alpha$  was equally active as the WT HNF4 $\alpha$  in transactivating the proximal human miR-194-2 promoter (Figure 7D). Taken together, these data strongly indicate that HNF4 $\alpha$  can DNA-binding-independently transactivate the proximal human miR-194-2 promoter *via* interacting with SP1.

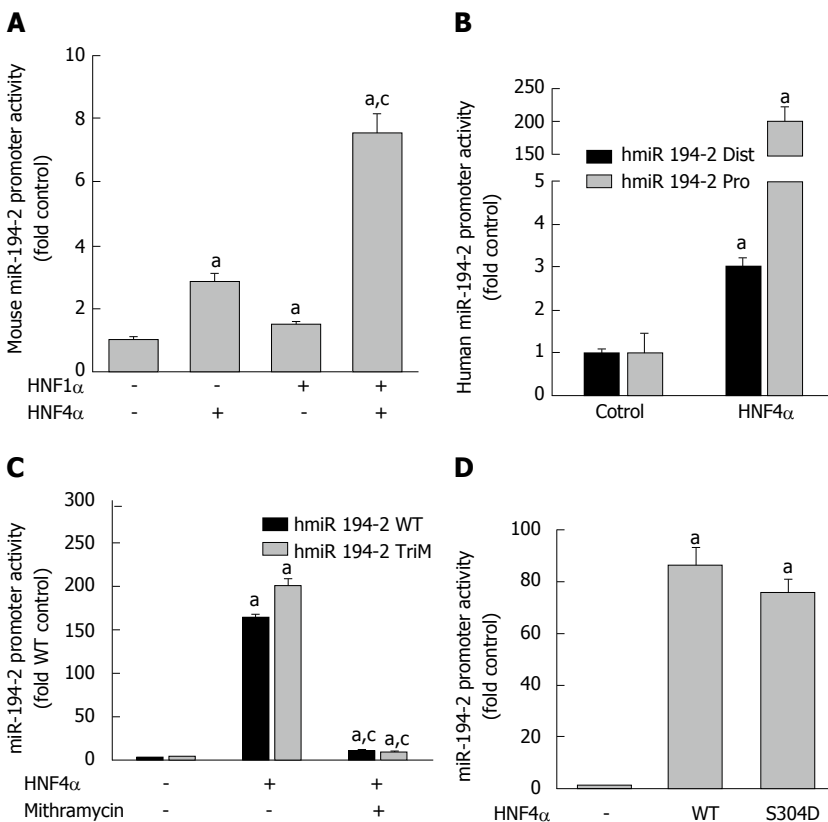

### Regulation of mouse miR-101b and human miR-101-2 promoters by HNF4 $\alpha$

The mouse miR-101b promoter was moderately active in

HepG2 cells (Figure 8A), whereas the human miR-101-2 promoter was largely inactive in HepG2 cells (Figure 8B). C/EBP $\alpha$ , a liver-enriched transcription factor, plays a key role in regulating liver-specific gene expression. The expression of C/EBP $\alpha$  is low in HepG2 cells, and re-expression of C/EBP $\alpha$  in HepG2 cells can reactivate certain liver-specific genes<sup>[53]</sup>. Our analysis of published ChIP-seq data for C/EBP $\alpha$  in mouse liver (GSM1037657) showed that C/EBP $\alpha$  bound to the miR-101b promoter, located in the Intron5-6 of Rcl1, in close proximity to

**Figure 6** Analysis of DNase-I hypersensitive sites as well as DNA-binding of HNF4 $\alpha$ , RNA polymerase II (Pol2), and methylated histones to loci of miR-194-2/miR-192 (A), miR-101-2 (B) and miR-122 (C) in human hepatoma HepG2 cells. Data of DHSs (determined by DNase-seq) and DNA-binding of proteins (determined by ChIP-seq) were retrieved from the public database of GEO DataSets and visualized in the IGV software. The peak values/ranges for each mark were shown in square brackets or under the line mark. DHSs: DNase-I hypersensitive sites; H3K36me3: H3 trimethylation at lysine-36; H3K4me3: H3 trimethylation at lysine-4; H3K27me3: H3 trimethylation at lysine-27; H3K9me3: H3 trimethylation at lysine-9; Pol2: Polymerase 2; HNF4 $\alpha$ : Hepatocyte nuclear factor 4 alpha; ChIP-seq: Chromatin immunoprecipitation-sequencing; IGV: Integrative genomics viewer.

**Figure 7** Activation of mouse (A) and human (B-D) miR-194-2/miR-192 promoter by HNF4 $\alpha$ . Human hepatoma HepG2 cells were transfected with firefly luciferase vectors containing wild-type and mutant miR-194-2 promoter, pRL-CMV, and an expression vector for HNF4 $\alpha$ /HNF1 $\alpha$ . Dual-luciferase reporter assay was conducted 24 h after transfection. The y-axis represents relative luciferase activity for microRNA promoter normalized by the renilla luciferase.  $n = 4$ , Mean  $\pm$  SE. <sup>a</sup> $P < 0.05$  compared to vector control; <sup>b</sup> $P < 0.05$  compared to HNF4 $\alpha$  alone group. HNF4 $\alpha$ : Hepatocyte nuclear factor 4 alpha.

**Figure 8** Activation of (A) mouse miR-101b, (B) human miR-101-2, and (C) mouse miR-802 promoter by HNF4 $\alpha$ . Human hepatoma HepG2 cells were transfected with firefly luciferase vectors containing microRNA promoter, pRL-CMV, and an expression vector for HNF4 $\alpha$  and/or C/EBP $\alpha$ . Dual-luciferase reporter assay was conducted 24 h after transfection. The Y-axis represents relative luciferase activity for microRNA promoter normalized by the renilla luciferase.  $n = 4$ , Mean  $\pm$  SE. <sup>a</sup> $P < 0.05$  compared to vector control; <sup>c</sup> $P < 0.05$  compared to HNF4 $\alpha$  alone group. HNF4 $\alpha$ : Hepatocyte nuclear factor 4 alpha; C/EBP $\alpha$ : CCAAT/enhancer-binding protein  $\alpha$ .

HNF4 $\alpha$ . Moreover, putative C/EBP binding sites are highly enriched in the human miR-101-2 promoter, predicted by the Alibaba2 software. We found that HNF4 $\alpha$  and C/EBP $\alpha$  activated the mouse miR-101b promoter 6.2 and 8.9 fold, respectively, and they synergistically activated the miR-101b promoter 19 fold in HepG2 cells (Figure 8A). Similarly, HNF4 $\alpha$  and C/EBP $\alpha$  activated the human miR-101-2 promoter 11 and 33 fold, respectively, and they synergistically activated the miR-101-2 promoter 65 fold in HepG2 cells (Figure 8B).

#### Regulation of mouse miR-802 promoter by HNF4 $\alpha$

Different from miR-101, HNF4 $\alpha$  had no effect on the 2 kb mouse miR-802 promoter, and HNF4 $\alpha$  did not enhance the transactivation of the miR-802 promoter by C/EBP $\alpha$  in HepG2 cells (Figure 8C).

#### Regulation of mouse Chd1 and H3f3 by miR-194 and miR-192

TargetScan was used to identify potential targets of liver-predominant microRNAs down-regulated in *Hnf4 $\alpha$* -LivKO livers. miR-192/215 and miR-194 have a perfect match (8 mer) and very high context score percentile of 96%-99% with human and mouse histone H3f3b (H3.3b) and Chd1, respectively, indicating a very high likelihood of inhibition (Table 1). Therefore, we generated luciferase reporters for the 3'UTR of H3.3 and Chd1. Results of dual luciferase assay showed that miR-194 and miR-192 significantly decreased the luciferase activity for the 3' UTR of Chd1 (Figure 9A) and H3.3 (Figure 9B) by 37% and 36%, respectively, in HepG2 cells.

## DISCUSSION

The present study demonstrates that *Hnf4 $\alpha$*  is essential for hepatic expression of certain liver-predominant microRNAs, namely miR-101, miR-192, miR-193 and miR-194. HNF4 $\alpha$  transactivates these miRs *via* direct DNA-binding to the promoters and/or interacting with the general transcription factor SP1. These miRs target essential epigenetic modifiers, such as EZH2 (by miR-101), histone H3.3 (by miR-192) and Chd1 (by miR-194) (Figure 10).

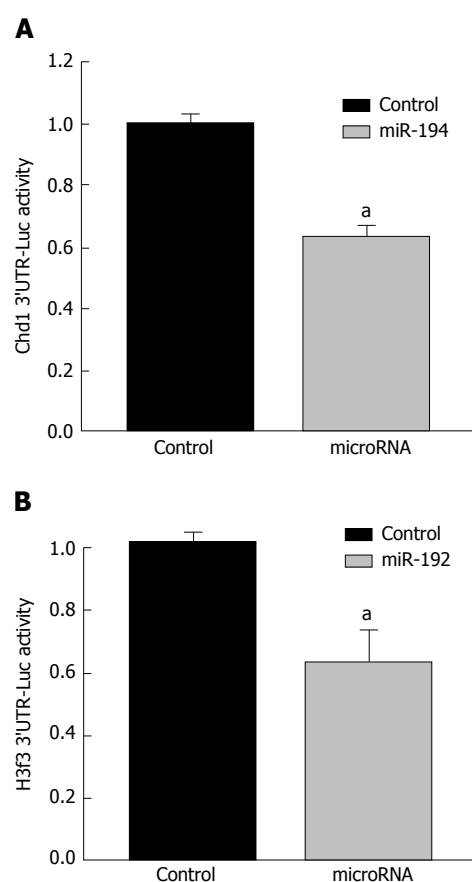

The present data provide the first evidence that HNF4 $\alpha$  is essential for hepatic expression of miR-194 in mice, and likely in humans. In both mice and humans, miR-194 is expressed highly in kidney and GI tract including liver and small intestine<sup>[37]</sup>. The tissue distribution of miR-194 parallels that of HNF4 $\alpha$ . In liver, miR-194 signals are detected in hepatocytes but not in non-parenchymal cells, and miR-194 is down-regulated during dedifferentiation of hepatocytes<sup>[54]</sup>. miR-194 inhibits the metastasis of mesenchymal-like liver cancer cells. Moreover, ChIP-seq results demonstrate direct binding of HNF4 $\alpha$  to the distal and proximal promoters of mouse and human miR-194-2 (Figure 3B and 6A). Furthermore, results of reporter assays indicate that HNF4 $\alpha$  potentially activates the promoter of mouse and human *miR-194-2/miR-192* gene cluster (Figure 7). Taken together, these data strongly indicate that HNF4 $\alpha$  plays a key role in maintaining hepatic expression of miR-194 in mice and humans.

Two recent studies of mice with inducible knockout of *Hnf4 $\alpha$*  demonstrate that acute loss of *Hnf4 $\alpha$*  in adult mouse liver triggers extensive hepatocyte proliferation, hepatomegaly, and increased HCC<sup>[55-57]</sup>. The increased intestinal cell proliferation in mice with specific loss of *Hnf4 $\alpha$*  in the adult intestinal epithelium is ascribed to the activation of the Wnt/beta-catenin system<sup>[58]</sup>. miR-194 negatively control expression of frizzled-6, which activates the beta-catenin pathway<sup>[36]</sup>. Therefore, *Hnf4 $\alpha$*  may

3'UTR: Untranslated regions.

**Figure 9 Effects of miR-194 and miR-192 on the activities of luciferase reporter vectors for the 3'UTR of mouse Chd1 and H3f3.** Human hepatoma HepG2 cells were transfected with plasmid DNA including pmir-Chd1 (or pmir-H3f3), the pRL-CMV luciferase, and a synthetic mimic of miR-194/miR-192, or AllStars Negative Control siRNA (as negative control for microRNAs) using Lipofectamine 2000. Dual-luciferase reporter assay was conducted 24 h after transfection. The Y-axis represents relative luciferase activity for the 3'UTR of Chd1 or H3f3 normalized by the renilla luciferase.  $n = 4$ , Mean  $\pm$  SE.  $^{\ast}P < 0.05$  compared to control (AllStars Negative Control siRNA). 3'UTR: Untranslated regions.

inhibit cell proliferation through the miR-194→frizzled-6→beta-catenin signaling pathway.

The chromatin remodeling factor CHD1 is required to maintain the open chromatin and pluripotency of mouse

**Figure 10** Diagram that illustrates the regulation of hepatic microRNA expression by Hnf4 $\alpha$  in mouse liver. HNF4 $\alpha$ : Hepatocyte nuclear factor 4 alpha; C/EBP $\alpha$ : CCAAT/enhancer-binding protein  $\alpha$ .

embryonic stem cells<sup>[40]</sup>. CHD1 is required for chromatin incorporation of the histone variant H3.3, which is generally associated with active genes<sup>[59]</sup>. However, CHD1 may also repress gene expression *via* association with HDACs<sup>[60]</sup>. Overexpression of HNF4 $\alpha$  in hepatoma cells dramatically decreased the “stemness” gene expression and the percentage of cancer stem cells in HCC<sup>[8]</sup>; however, the underlying mechanism is unknown. HNF4 $\alpha$ , *via* regulating miR-194, might inhibit stemness gene expression by targeting the chromatin remodeling factor CHD1, which deposits the unmodified or altered histone H3.3 into chromatin and increases the stemness of *Hnf4 $\alpha$* -LivKO hepatocytes.

The present data indicate that Hnf4 $\alpha$  is essential for hepatic expression of miR-192, and the histone variant H3.3 is a direct target of miR-192. Thus, down-regulation of miR-192 may be the underlying mechanism of hepatic induction of H3.3 in young-adult Hnf4 $\alpha$ -LivKO mice<sup>[21]</sup>. The replacement H3 variant H3.3 is encoded by two genes termed H3.3A and H3.3B, both code for the same amino acid sequence, but differ in nucleotide sequences and gene organization<sup>[61]</sup>. H3.3 is the exclusive substrate for replication-independent deposition, which provides a mechanism for the immediate activation of genes that are silenced by histone modification<sup>[62,63]</sup>, and H3.3 is important in epigenetic memory<sup>[64]</sup>. H3.3/H2A.Z double variant-containing nucleosomes mark “nucleosome-free regions” of active promoters and other regulatory

regions<sup>[65]</sup>. Deposition of H3.3 can rapidly derepress gene silencing<sup>[66]</sup>. Taken together, Hnf4 $\alpha$  directly regulates miR-192, and the down-regulation of miR-192 in *Hnf4 $\alpha$ -LivKO* livers may be the underlying mechanism of hepatic induction of H3.3, which contributes to the marked alteration of epigenome and transcriptome in *Hnf4 $\alpha$ -LivKO* livers<sup>[21]</sup>.

The present study indicates that Hnf4 $\alpha$  is required for hepatic expression of the tumor-suppressor miR-101. miR-101 is predominantly expressed in the liver<sup>[35]</sup>. miR-101 is down-regulated in HCC<sup>[67]</sup> and miR-101 directly represses EZH2<sup>[68,69]</sup>, a protooncogene that silences the expression of tumor-suppressors *via* H3K27me3. Down-regulation of miR-101 in *Hnf4 $\alpha$ -LivKO* mouse livers might be the underlying mechanism of induction of EZH2 and increased H3K27me3 observed previously<sup>[21]</sup>.

The present data indicate that Hnf4 $\alpha$  is important for hepatic basal expression of the tumor-suppressor miR-193a. miR-193a and miR-365 closely cluster in chromosome 11 in mice. The tumor-suppressor miR-193a is down-regulated in the majority of HCC in humans<sup>[70]</sup> and miR-193a prevents the resistance of HCC to 5-fluorouracil *via* repressing the expression of serine/arginine-rich splicing factor 2 (SRSF2)<sup>[71]</sup>. Through maintaining hepatic expression of miR-193a, HNF4 $\alpha$  might regulate expression of SRSF2 and the splicing of transcripts in liver. Interestingly, miR-193a also targets directly Wilms' tumor protein 1 (WT1)<sup>[72]</sup>. WT1 is overexpressed in cirrhotic liver and HCC<sup>[18,73]</sup>, and induction of WT1 down-regulates HNF4 $\alpha$  expression in liver<sup>[18]</sup>. The putative feedback regulatory loop of HNF4 $\alpha$ →miR-193a→WT1 and its significance in liver cirrhosis and carcinogenesis warrant further investigation.

The present data provide the first evidence that Hnf4 $\alpha$  is important for hepatic expression of miR-802 (Figure 2). Results of reporter assay (Figure 8C) suggest that HNF4 $\alpha$  may indirectly regulate hepatic miR-802 expression *via* C/EBP $\alpha$ , whose DNA-binding activity decreased in *Hnf4 $\alpha$ -LivKO* mice<sup>[27]</sup> and human hepatoma cells. Interestingly, the miR-802 locus is marked with both the activating signature H3K4me3 and the silencing signature H3K27me3, a feature of bivalent chromatin which allows a low basal expression but timely activation of developmentally-regulated genes<sup>[74]</sup>. Hnf1 $\beta$  is a direct target of miR-802<sup>[75]</sup>, and Hnf1 $\beta$  is overexpressed in adult *Hnf4 $\alpha$ -LivKO* mouse livers<sup>[4]</sup>. In mouse liver, miR-802 is expressed at 10-fold higher levels in hepatocytes than non-hepatocytes<sup>[75]</sup>. In contrast, Hnf1 $\beta$  is strongly expressed in cholangiocytes but weakly in hepatocytes, and Hnf1 $\beta$  plays a key role in bile-duct morphogenesis and glucose homeostasis<sup>[76]</sup>. Thus, the putative HNF4 $\alpha$ →C/EBP $\alpha$ →miR-802→HNF1 $\beta$  pathway might play a role in controlling cell-specific expression of HNF1 $\beta$  and liver morphogenesis during liver development.

The tumor-suppressor microRNAs miR-34a, miR-192, miR-215 and miR-194 are all p53-inducible microRNAs<sup>[77]</sup>. The induction of the p53-target gene p21 in *Hnf4 $\alpha$ -nul* mouse livers<sup>[13]</sup> suggests that p53 is activated by *Hnf4 $\alpha$*  deficiency, which may contribute to the induction of the p53-target miR-34a and miR-29b (Figure 2B). However,

hepatic expression of other p53-target microRNAs miR-192, miR-215 and miR-194 are markedly down-regulated in *Hnf4 $\alpha$ -LivKO* mice. It is interesting that HNF4 $\alpha$  can transactivate two p53-target genes, p21 and miR-194 (Figure 7), independent of DNA-binding of HNF4 $\alpha$  to the promoter. The AMP-activated protein kinase (AMPK) phosphorylates HNF4 $\alpha$  at S304, resulting in a marked decrease in the DNA-binding activity and decreased transactivation of apolipoprotein C3<sup>[50]</sup>. AMPK suppresses lipogenesis and carcinogenesis in liver<sup>[78,79]</sup>. The contribution of selective modulation of HNF4 $\alpha$ -target lipogenic genes and tumor-suppressors (p21 and miR-194) to the physiological and pharmacological roles of AMPK in liver diseases warrants further investigation.

miR-29 is broadly expressed at high levels in normal tissues. miR-29 sensitizes cholangiocarcinoma cells to TNF-induced cytotoxicity<sup>[80]</sup> and miR-29 activates p53<sup>[81]</sup>. miR-29 induces global DNA hypomethylation and tumor suppressor gene reexpression in lung cancer and acute myeloid leukemia by targeting directly DNMT3A and 3B and indirectly DNMT1<sup>[82,83]</sup>. miR-29 also directly inhibits Dnmt3a and Dnmt3b in mice<sup>[84]</sup>. Thus, induction of miR-29b might contribute to the lack of global changes in hepatic DNA methylation, despite an induction of Dnmt1, in the young-adult *Hnf4 $\alpha$ -LivKO* mice<sup>[21]</sup>. Currently, the mechanism of induction of miR-29 in the young-adult *Hnf4 $\alpha$ -LivKO* mice remains unknown. miR-29 can be transactivated by p53<sup>[85]</sup>. Thus, activation of p53 might contribute to hepatic induction of miR-29b in *Hnf4 $\alpha$ -LivKO* mice.

The liver-specific miR-122 is important in regulating hepatic cholesterol and lipid metabolism<sup>[86,87]</sup>, and down-regulation of miR-122 contributes to HCC malignancy<sup>[88-90]</sup>. HNF4 $\alpha$  can directly activate the expression of miR-122 in mouse liver<sup>[91]</sup>. However, knockdown of HNF4 $\alpha$  does not affect the high expression of miR-122 in a HCC cell line, although miR-122 expression correlates strongly with HNF4 $\alpha$ <sup>[88]</sup>. In contrast, hepatic miR-122 expression is regulated by Hnf1 $\alpha$ <sup>[88]</sup>. The moderate down-regulation of miR-122 in *Hnf4 $\alpha$ -LivKO* mouse livers parallels the moderate decrease of Hnf1 $\alpha$  in these mice<sup>[27]</sup>. Taken together, these data suggest that HNF4 $\alpha$  has a positive but limited role in regulating hepatic expression of miR-122.

The present study demonstrates species differences between humans and mice in hepatic basal expression and regulation of miR-124 and miR-134 by HNF4 $\alpha$ . Interleukin-6 (IL6) plays a key role in inflammation and hepatocarcinogenesis<sup>[92]</sup>. Interestingly, HNF4 $\alpha$  exerts anti-inflammatory effects in human hepatocytes *via* the miR-124-IL6R-STAT3 pathway; knockdown of HNF4 $\alpha$  in human hepatocytes leads to down-regulation of miR-124, induction of IL6R and IL6, and activation of STAT3<sup>[49]</sup>. However, there is no induction of IL-6 or activation of STAT3 in adult mice with acute loss of HNF4 $\alpha$ <sup>[56]</sup>. Thus, there may be species difference between humans and mice regarding the interaction of HNF4 $\alpha$  with miR-regulated inflammatory and carcinogenic pathways in the liver.

Our previous study found that Hnf4 $\alpha$  deficiency in

young-adult mice causes marked alteration of histone modifications, which is associated with induction of epigenetic modifiers such as Ezh2 and histone H3.3<sup>[20]</sup>. However, ChIP-seq data reveal no direct binding of Hnf4 $\alpha$  to these epigenetic modifiers in adult mouse livers, suggesting that these epigenetic modifiers may not be directly regulated by Hnf4 $\alpha$ . The present study provides the first evidence of the essential role of Hnf4 $\alpha$  in maintaining hepatic expression of certain microRNAs, including miR-101, miR-192, miR-193a, miR-194 and miR-802. These microRNAs target certain key proteins in gene regulation and epigenetic modifications, such as WT1 (by miR-193a)<sup>[72]</sup>, HNF1 $\beta$  (by miR-802)<sup>[75]</sup>, CHD1 (by miR-194) (Figure 9), EZH2 (by miR-101)<sup>[69]</sup>, SRSF2 (by miR-193a)<sup>[71]</sup>, and histone H3.3 (by miR-192) (Figure 9). Establishment and maintenance of hepatic expression of these microRNAs by HNF4 $\alpha$  may play a key role in the indirect regulation of hepatic transcriptome and epigenome by HNF4 $\alpha$  (Figure 10).

## COMMENTS

### Background

Hepatocyte nuclear factor 4 alpha (HNF4 $\alpha$ ) is a liver-enriched master regulator of liver development and function. HNF4 $\alpha$  plays a key role in regulating hepatic transcriptome and epigenome. However, little was known about the role of HNF4 $\alpha$  in regulating hepatic expression of microRNAs, essential modulators of the transcriptome and epigenome. Additionally, HNF4 $\alpha$  deficiency causes marked induction of a large number of genes in mouse liver; however, the mechanism of suppression of hepatic gene expression by HNF4 $\alpha$  remains poorly understood.

### Research frontiers

Previous studies demonstrate that HNF4 $\alpha$  regulates hepatic expression of miR-122, miR-124 and miR-29.

### Innovations and breakthroughs

This is the first study to use microarray and liver-specific knockout mice to determine the genome-wide role of HNF4 $\alpha$  in the regulation of hepatic expression of microRNAs in mice. The key changes in hepatic microRNA expression induced by HNF4 $\alpha$  deficiency were verified by real-time polymerase chain reaction. Moreover, hepatic microRNA expression were correlated with chromatin accessibility as well as DNA-binding of HNF4 $\alpha$ , RNA polymerase II, and activating/silencing epigenetic signatures to determine the role of HNF4 $\alpha$  in regulating hepatic expression of these microRNAs. The novel key role of HNF4 $\alpha$  in regulating liver-predominant expression of miR-101-2/miR-101b and the miR-194-2/miR-192 cluster was confirmed by luciferase reporter assay.

### Applications

Results from this study uncover species differences and similarities between humans and mice in the role of HNF4 $\alpha$  in regulating hepatic expression of certain important microRNAs. Such novel knowledge will help understand the role of HNF4 $\alpha$  in post-transcriptional regulation of gene expression and maintenance of the normal epigenome and physiology in mouse and human liver.

### Terminology

Epigenetic signatures/marks are modifications of the genome that do not change

the underlying DNA sequence but can switch genes on and off and thus affect how cells express genes. Typical epigenetic signatures/marks include DNA methylation and histone modifications.

## Peer-review

The study appears to be properly conducted and written. No major criticisms and/or weaknesses were noted.

### Abstract

#### AIM

To evaluate the effects of aqueous extract of Salep on Paraquat-mediated liver injury.

#### METHODS

In this experimental study, 56 adult male Wistar rats were divided randomly to 7 groups as control, sham, and 5 experimental groups. In control group, rats did not receive any substance during experiment. In Sham group, rats were given distilled water according to their body weight and in experimental groups, Paraquat alone and with different doses of Salep aqueous extract

(40, 80, 160 and 320 mg/kg) was given intraperitoneal daily for 14 d. After that, liver biochemical parameter and histologic changes were analyzed and compared in different groups.

## RESULTS

Paraquat compared to control and sham groups, significantly ( $P < 0.05$ ) increased serum level of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), bilirubin, malondialdehyde (MDA) and total oxidant capacity (TOC); while level of total protein, albumin and total antioxidant capacity (TAC) were remarkably decreased by Paraquat. Salep at doses of 80, 160 and 320 mg/kg significantly decreased serum level of ALT, AST, ALP, bilirubin, MDA and TOC and significantly increased total protein, albumin and TAC level as compared to Paraquat exposed group in dose dependent manner. Aqueous extract of Salep at doses of 40 mg/kg made no significant changes in serum level of mentioned biochemical parameters. Liver microscopic observation revealed that Paraquat could cause hepatocyte necrosis, degenerative changes, proliferation and activation of Kupffer cells (sporadically) which were reduced by Salep treatment.

## CONCLUSION

Salep possesses remarkable hepatoprotection activity against Paraquat-induced hepatic injury by having antioxidant activity and reducing lipid peroxidation and oxidative stress.

**Key words:** Salep; Paraquat; Liver injury; Antioxidant; Oxidative stress

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Oxidative stress has a key role in triggering Paraquat-mediated liver injury. Paraquat causes oxidative stress *via* modulation of redox cycling, generation of free radicals and reduction of endogenous antioxidant levels. Salep from orchid family (Orchidaceae) used in traditional medicine as a healing agent in the treatment of breast disorders, gastrointestinal disorders, tuberculosis, diarrhea, Parkinson, cancer, fever, and impotency. Salep is used in food engineering for preparation of ice cream and drinks. This study showed that Salep could have a protective effect against Paraquat-induced hepatic injury *via* reinforcing endogenous antioxidant systems, reduction of lipid peroxidation and free radical scavenging. The antioxidant and protective effect of Salep could be due to presence of flavonoids and polyphenols such as Quercetin, Ferulic Acid and Glucomannan.

## INTRODUCTION

With the increasing population of human societies, providing nourishment without the use of advanced scientific farming is impossible. In this modern agriculture, using pesticides, herbicides and chemical fertilizers for more and higher quality crop is inevitable and may be toxic to man and animals. Paraquat (1, 1'-dimethyl-4, 4'-bipyridylium-dichloride) is a widely used herbicide for broadleaf weed control<sup>[1]</sup> and is extremely poisonous for humans and animals and many cases of acute poisoning and death have been reported over the past few decades<sup>[2]</sup>.

Paraquat is a bipyridyl compound with high toxicity for lungs, kidney, brain and liver<sup>[3]</sup>. When it is given in acute dose (50 mg/kg) in mice, liver necrosis and inflammation will develop<sup>[4]</sup>. Paraquat toxicity is due to oxidative damage to cells and generation of free radicals<sup>[5]</sup>. Herbicidal activity of paraquat can be explained by its interfering with photosynthesis and intracellular electron transfer system in plants and prevention of NADP reduction to NADPH. This could disrupt important NADPH-dependent biochemical processes<sup>[6,7]</sup>. In addition, Paraquat radical forms superoxide anion in presence of oxygen which leads to production of more toxic reactive oxygen species like hydrogen peroxides and hydroxyl radical and would cause oxidative stress<sup>[1,8]</sup>. Superoxide anion may also attack unsaturated lipids of membrane to form fatty acid hydroperoxide, resulting in lipid peroxidation, membrane injury, cell death and multi-system toxicity<sup>[9]</sup>.

Due to the role of oxidative stress mechanisms in Paraquat toxicity and the lack of an effective antidote, researchers are currently focused on the importance of antioxidant in Paraquat poisoning management<sup>[10]</sup>. Many herbal compounds have antioxidant properties and can protect the liver from damaging agents like Paraquat. One of these plants is Salep from orchid family (Orchidaceae) which has different species worldwide<sup>[11]</sup>. Salep contains Quercetin, Nitrogenic materials, Ferulic acid, starch, protein, Glucomannan, Glucose, Daucosterol, Cirsilineol and steroids<sup>[11-13]</sup>. This plant is used in traditional medicine as a healing agent in the treatment of breast disorders, gastrointestinal disorders, tuberculosis, diarrhea, Parkinson, cancer, fever, and impotency. Salep is used in food engineering for preparation of ice cream and drinks<sup>[13-15]</sup>.

Polyphenols, especially flavonoids such as quercetin, are important antioxidants found in Salep<sup>[12]</sup>. These compounds have hepatoprotective effects against liver damage caused by toxins and free radicals<sup>[16]</sup> and can also protect cells against depletion of glutathione by increasing the capacity of antioxidant enzymes such as glutathione reductase, glutathione peroxide and catalase<sup>[17]</sup>. Furthermore, glucomannan can inhibit oxidative stress and

effectively reduce alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels<sup>[18]</sup>. Therefore, the aim of this survey was to evaluate the effects of aqueous extract of Salep on Paraquat - induced hepatotoxicity.

## MATERIALS AND METHODS

### Chemicals

Paraquate was purchased from Ara Shimi-Iran Company. Paraquat was dissolved in distilled water and animals were given intraperitoneal injection in each case. Malondialdehyde (MDA), total antioxidant capacity (TAC) and total oxidant capacity (TOC) measurement kits were purchased from Diametra Company (Italy), ALT, AST, alkaline phosphatase (ALP), albumin and bilirubin and total protein (TP) measurement kits were purchased from Pars Azmoon Company (Iran).

### Collection and extraction of Salep

Salep plants were obtained from farmlands around Yasouj (a city in the southwest of Iran). Salep roots were washed and dried in laboratory and mixed with Ethanol 96° in 1 to 5 proportions, mixed for 24 h at room temperature and a homogeneous mixture was obtained. Then, the uniform solution was filtered and dried for 48 h to obtain solid extract without ethanol. The final dried extract was dissolved with distilled water<sup>[12]</sup>.

### Experimental animals

Fifty-six adult male Wistar rats (180-200 g) were obtained from the Animal House of Jahrom University of Medical Sciences. The animal house temperature was maintained at 22 °C ± 2 °C with a 12 h light/dark cycle. All animals were kept for two weeks prior to experiment and had free access to food and water. All ethical points regarding working with laboratory animals were considered in this research (Ethical Code: IR.JUMS.1394.722).

### Experimental design

The rats were divided randomly to 7 groups, 8 rats each, as followed: Control group: Rats did not receive any substance during experiment; Sham group: Rats were given distilled water according to their body weight during the experiment; Experimental group 1: Rats were given Paraquat 2 mg/kg per BW; Experimental groups 2, 3, 4 and 5: Rats were given Paraquat at a dose of 2 mg/kg per BW daily and Salep at doses of 40, 80, 160 and 320 mg/kg per BW, respectively. Salep doses were selected based on previous studies done on this herbal treatment<sup>[12]</sup>; Paraquat and Salep aqueous extract were administered intraperitoneally daily for 14 d in all 5 groups.

### Blood sampling and liver function evaluation

At the end of the study (day 15) after weighing the animals, blood sample were taken directly from their

hearts using 5 cc syringes (rats were anesthetized by barbiturate) and blood serum was collected after centrifugation (15 min, 3000 rpm) and stored at -20 °C until they were tested. Biochemical measurement kits (made in Iran and Italy) using the colorimetric method and an autoanalyzer machine (Selectera XL model made in Holland) were used for assessment of biochemical factors including ALT, AST, ALP, TP, albumin, bilirubin, MDA, TOC and TAC.

### Histological examination

After drawing the blood, for histological examination a small part of liver was separated, fixed by 10% formalin and embedded in paraffin wax. Paraffin sections with thickness of 5 µm were prepared, stained employing the haematoxylin and eosin and Masson Trichrome stain methods and histological and pathological changes were studied using a light microscope. Furthermore, The Degree of inflammation in the portal zone, liver necrosis and inflammatory cell infiltration were evaluated in the form of semiquantitative scale, double-blind, according to the method described by Frei *et al.*<sup>[19]</sup> in 1984. Severity of damage were ranked from zero to four (zero: No damage, 1: Minimum damage, 2: Mild damage, 3: Average damage, 4: Severe damage). Scoring was performed in five microscopic fields of each cut, randomly, with magnification of × 100.

### Statistical analysis

All values were given as mean ± SEM. Statistical analysis was carried out using SPSS 21, One-way analysis of variance followed by Duncan *post hoc* test. Statistical *P*-value less than 0.05 was considered significant.

## RESULTS

### Biochemical measurement

Paraquat compared to control and sham groups significantly (*P* < 0.05) increased serum level of liver factors including ALT, AST and ALP, Bilirubin, MDA and TOC; while serum level of Total Protein, Albumin and TAC were considerably lower in group receiving Paraquat (Tables 1 and 2).

Paraquat treatment groups with aqueous extract of Salep at doses of 80, 160 and 320 mg/kg significantly decreased serum level of ALT, AST, ALP, Bilirubin, MDA and TOC and significantly increased elevated Total Protein, Albumin and TAC serum level as compared to Paraquat treatment group alone (Tables 1 and 2). Aqueous extract of Salep at doses of 40 mg/kg made no significant changes in serum level of mentioned biochemical parameters while the greatest effect is related to the dose of 320 mg/kg of Salep.

### Histopathological examination

Microscopic examination of liver tissue of control and sham groups showed that liver tissue structure was normal and healthy (normal structure of lobules with

normal central venous, sinusoids and Kupffer cells and normal distribution of glycogen and lack of lymphocytic infiltration and congestion in the blood vessels) (Figure 1A-D).

In study group 3 (rats were given Paraquat alone), microscopic observation revealed hepatocyte necrosis, degenerative changes, proliferation and activation of Kupffer cells (sporadically), increased infiltration of inflammatory cells around the portal vein and in sinusoid space, formation of fibrotic inflamed bridges between liver lobules, and sever cellular ballooning and blood congestion in the sinusoids. In this group, progressive liver fibrosis had occurred as evidenced by presence of collagen fibers in the liver parenchyma, the portal space and around the central vein in the centrilobular region (Figure 1E-J).

Treatment with aqueous extract of Salep reduced the damaging effect of Paraquat on liver tissue. This reduction in destructive effect of Paraquat on liver tissue was mild with Salep at doses of 80 mg/kg, moderate at doses of 160 mg/kg and highest at doses of 320 mg/kg as compared to study group that received Paraquat alone (Figure 1K-R). A microscopic observation of liver tissue of rats under study have been brought to a quantitatively in Table 3.

## DISCUSSION

Oxidative stress has a key role in triggering Paraquat-mediated liver injury<sup>[20]</sup>. Paraquat causes oxidative stress *via* modulation of redox cycling, generation of free radicals and reduction of endogenous antioxidant levels<sup>[21-23]</sup>. Furthermore, generation of nitric oxide and reactive oxygen species like superoxide also play a crucial role in Paraquat - induced hepatotoxicity<sup>[24]</sup>. Salep could have protective effect against chemical induced liver injury *via* reinforcing endogenous antioxidant systems and free radical scavenging<sup>[12,16]</sup>. As liver is one of the major sites of Paraquat toxicity, this study was done in order to evaluate protective potential of Salep against Paraquat- induced liver injury.

Remarkable increase of ALT, AST, ALP and bilirubin and significant decrease of total protein and Albumin levels were observed in Paraquat - exposed group in comparison with control group, which confirmed the hepatotoxic potential of Paraquat. These results were in concurrence with previous studies on evaluation of Paraquat induced liver toxicity, which showed increase in serum level of liver enzymes<sup>[21,25]</sup>. Significant reduction of increased level of ALT, AST, ALP and bilirubin and marked increased in level of Albumin and Total Protein in Paraquat + Salep treated groups showed that Salep

Zero: No damage; 1: Minimum damage; 2: Mild damage; 3: Average damage; 4: Severe damage. Scoring was performed in five microscopic fields of each cut, randomly, with magnification of  $\times 100$ .

could have protective effect against Paraquat-mediated hepatic injury in dose dependent manner. These results are supported by a previous report which also revealed the protective effect of Salep on liver function<sup>[12]</sup>.

Liver pathological examination showed hepatocyte necrosis, proliferation and activation of Kupffer cells, increased infiltration of inflammatory cells around the portal vein and in sinusoid space, formation of fibrotic inflamed bridges between liver lobules, and sever cellular ballooning and blood congestion in the sinusoids in Paraquat - exposed group, which was in accordance with previous reports<sup>[3,20]</sup>. Remarkable recovery toward normal liver histology in Paraquat + Salep treated groups also favored the protective activity of Salep against Paraquat-induced liver injury.

As oxidative stress has a crucial role in Paraquat-induced liver injury, in this study we evaluated serum level of TOC, which precisely shows the oxidant status of blood, and TAC, as indicator of blood, cells and tissues defense system against free radicals, measures the antioxidant capacity of all antioxidants in a biological sample and not just the antioxidant capacity of a single compound. Measurement of TAC can provide information on overall antioxidant status, which may include those antioxidants not yet recognized or not easily measured<sup>[20,26]</sup>. Significant augmentation of TOC and reduction of TAC were observed in Paraquat-exposed groups, which confirmed the role of free radical generation and attenuation of antioxidant level in Paraquat-mediated hepatic injury. Significant reduction of TOC and marked increased of TAC in Paraquat + Salep treated groups demonstrated that Salep could have protective effects against Paraquat toxicity by possessing antioxidant activity. These results were supported by a previous study done by Pourahmad

*et al*<sup>[12]</sup>. The antioxidant effect of Salep could be due to the presence of flavonoids and polyphenols such as Quercetin, Ferulic Acid and Glucomannan<sup>[11,16,18]</sup>. The two latter components of Salep could also reduce serum level of liver enzymes such as ALT and AST<sup>[27,28]</sup>. Zhang *et al*<sup>[16]</sup> showed that Quercetin could have hepatoprotective and antioxidant activity by decreasing lipooxygenase, free radical scavenging, enhancing the expression of antioxidant transcription factor and antioxidant enzyme such as Thioredoxin and Peroxiredoxin.

Furthermore, part of Paraquat hepatotoxicity is related to lipid peroxidation due to free radical generation including Oxygen Reactive Species<sup>[24]</sup>. MDA works as an indicator of lipid peroxidation and oxidative stress assessment<sup>[29]</sup>. MDA level was significantly augmented in Paraquat - exposed group which was in accordance with previous studies<sup>[6]</sup>. Serum level of MDA was substantially decreased in Paraquat + Salep treated groups as compared with Paraquat - exposed group in dose dependent manner. This result also supported the protective activity of Salep against oxidative stress and lipid peroxidation caused by Paraquat.

In conclusion, based on our results, it could be concluded that Salep possesses remarkable hepatoprotection activity against Paraquat-induced liver injury and could reduce the damaging effect of Paraquat on liver by having antioxidant activity and reducing lipid peroxidation and oxidative stress. Further studies are required to evaluate protective and antioxidant effect of Salep in human.

## ACKNOWLEDGMENTS

We would like to thank the Vice Chancellor of Research of Jahrom University of Medical Sciences.

## COMMENTS

### Background

Paraquat is a common herbicide used in agriculture and could cause severe damage to the lungs, liver and other tissues in mammals. Oxidative stress has a key role in triggering Paraquat-mediated hepatotoxicity. Salep could have protective effect against chemical induced hepatotoxicity via reinforcing endogenous antioxidant systems and free radical scavenging.

### Research frontiers

In the present study, the authors found that Salep possesses remarkable hepatoprotection activity against Paraquat-induced liver injury and could reduce damaging effect of Paraquat on liver by having antioxidant activity and reducing lipid peroxidation and oxidative stress.

### Innovations and breakthroughs

This is the first study evaluating the effect of Salep on Paraquat-induced liver injury. This study investigates the protective and antioxidant effect of salep on liver damage caused by Paraquat. The results of current study demonstrated that Salep could ameliorate paraquate-mediated liver injury by having antioxidant activity and reducing lipid peroxidation and oxidative stress.

### Applications

Salep aqueous extract could reduce damaging effect of Paraquat on liver tissue by having significant antioxidant activity. Therefore, the results of this study showed that Salep can be introduced as an alternative to chemical agents as potential therapeutic strategies for Paraquate-induced liver injury.

### Terminology

Oxidative stress is essentially an disturbance in balance between the production of free radicals and the ability of the body to counteract or detoxify their harmful effects through neutralization by antioxidant which could cause tissue damage including liver. Lipid peroxidation is a crucial step in the pathogenesis of several disease states in adult and infant patients. Lipid peroxidation is a process mainly caused by the effect of reactive oxygen species including hydroxyl radical and hydrogen peroxide. These reactive oxygen species readily attack the polyunsaturated fatty acids of the cell membrane, initiating a self-propagating chain reaction. The destruction of membrane lipids and the end-products of such lipid peroxidation reactions are dangerous for the viability of cells, even tissues.

### Peer-review

The paper by Atashpour *et al* has an interesting rationale and a good background. The results presented are consistent with the effects of the different components of the Salep.

## Abstract

### AIM

To evaluate efficacy/safety of hepatitis C virus (HCV) protease inhibitor boceprevir with pegylated interferon (PEG-IFN) alfa and weight-based ribavirin (RBV) in a phase 3 trial.

### METHODS

A prospective, multicenter, phase 3, open-label, single-arm study of PEG-IFN alfa, weight-based RBV, and boceprevir, with a PEG-IFN/RBV lead-in phase was performed. The HCV/human immunodeficiency virus coinfecting study population included treatment naïve (TN) and treatment experienced (TE) patients. Treatment duration ranged from 28 to 48 wk dependent upon response-guided criteria. All patients had HCV Genotype 1 with a viral load > 10000 IU/mL. Compensated cirrhosis was allowed. Sample size was determined to establish superiority to historical (PEG-IFN plus RBV) rates in sustained viral response (SVR).

### RESULTS

A total of 257 enrolled participants were analyzed (135 TN and 122 TE). In the TN group, 81.5% were male and 54.1% were black. In the TE group, 76.2% were male and 47.5% were white. Overall SVR12 rates (HCV RNA < lower limit of quantification, target not detected, target not detected) were 35.6% in TN and 30.3% in TE. Response rates at SVR24 were 28% in TN and 10% in TE, and exceeded those in historical controls. The highest rate was observed in TN non-cirrhotic participants (36.8% and the lowest in TE cirrhotics (26.3%). Cirrhotic TN participants had a 27.8% SVR12 rate and 32.1% of TE non-cirrhotics achieved SVR12. Significantly lower response rates were observed among black participants; in the TE, SVR12 was 39.7% in white participants but only 13.2% of black subjects ( $P = 0.002$ ). Among the TN, SVR12 was 42.1% among whites and 27.4% among blacks ( $P = 0.09$ ).

### CONCLUSION

The trial met its hypothesis of improved SVR compared to historical controls but overall SVR rates were low. All-oral HCV treatments will mitigate these difficulties.

**Key words:** Human immunodeficiency virus; Hepatitis C virus; Boceprevir; Pegylated interferon alfa; Ribavirin

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Approval of first generation hepatitis C virus (HCV) protease inhibitors has initiated a change in care of HCV infected patients. Phase 2 trials in HCV/human immunodeficiency virus coinfecting patients have suggested improved efficacy and tolerability for regimens that combined pegylated interferon (PEG-IFN) + ribavirin (RBV) with either boceprevir or telaprevir. We evaluated an HCV treatment regimen using a first generation HCV protease inhibitor (boceprevir) with PEG-IFN, and weight-based RBV in a phase 3 treatment trial, including HCV

treatment-naïve and treatment-experienced coinfecting subjects. While sustained viral response rates were low overall they did exceed historical PEG-IFN/RBV rates. Use of new interferon-free direct acting antiviral agents modalities in this population is indicated.

## INTRODUCTION

Hepatitis C virus (HCV) coinfection is a major cause of morbidity and mortality among those with human immunodeficiency virus (HIV) infection<sup>[1-4]</sup>. Prior to the emergence of new HCV targeted direct acting antiviral agents (DAAs) in 2011, response to standard therapy with pegylated interferon (PEG-IFN) and ribavirin (RBV) was poor, both in terms of efficacy and medication tolerability<sup>[5]</sup>. The approvals of first generation serine protease inhibitors of HCV replication initiated a revolution in terms of the care and management of HCV infected patients. Phase 2 trials in HCV/HIV coinfecting patients suggested improved efficacy with moderate drug tolerability for treatment regimens that combined either boceprevir or telaprevir with PEG-IFN + RBV<sup>[6,7]</sup>. In an effort to define treatment efficacy with response- and cirrhosis-guided regimens in HCV/HIV coinfecting, we conducted a prospective, multicenter, open-label Phase 3 trial in both HCV treatment naïve and treatment experienced participants with comparison to historical controls in the same clinical trials network.

## MATERIALS AND METHODS

The study was performed in the NIH AIDS Clinical Trials Group network (ACTG, National Institutes of Health Registration number NCT01482767) with enrollment of participants at 42 sites across the United States. All participants provided informed consent and the study was conducted with approval of Institutional Review Boards at each site. The study was monitored by an independent, NIH-chartered data safety and monitoring board.

The overall study design is shown in Figure 1. Briefly, treatment naïve (TN) participants (Group A) were treated with PEG-IFN alfa 2b 1.5 µg/kg subcutaneously with weight-based ribavirin (800-1400 mg/d) for 4 wk (lead-in). Then boceprevir 800 mg tid was added to the treatment regimen. Cirrhotic participants received 44 wk of triple therapy. Among non-cirrhotics, the week 8 serum HCV RNA was used to determine total duration of therapy. Those who had undetectable HCV RNA at week

**Figure 1 Overall study design.** Group A refers to treatment naïve participants while Group B refers to treatment experienced participants. PEG/WBR treatment is pegylated-interferon alpha 2b (PEG-IFN) and weight-based ribavirin (WBR). <sup>1</sup>Cirrhotic participants received 44 wk of triple therapy. SVR12: HCV RNA < LLOQ, target not detected at 12 wk post treatment discontinuation; BOC: Boceprevir; SVR: Sustained viral response; HCV: Hepatitis C virus; LLOQ: Lower limit of quantification.

8 completed therapy at week 28. Those with detectable HCV RNA at week 8 received 32 wk of triple therapy followed by 12 additional weeks of double-drug therapy with PEG-IFN/RBV. Treatment experienced participants (TE) (Group B) also had lead-in followed by 32 wk of triple therapy and 12 wk of PEG-IFN/RBV double therapy if non-cirrhotic, or by 44 wk of triple therapy if cirrhotic. Treatment was to be discontinued due to failure if: (1) HCV RNA  $\geq 100$  IU/mL at week 12; (2) detectable HCV RNA at week 24; or (3) confirmed HCV RNA > 1000 IU/mL any time after week 12. HCV RNA was determined to be undetectable if below the lower limit of quantification (LLOQ) and target not detected (TND) by Roche COBAS<sup>®</sup> TaqMan<sup>®</sup> HCV Test v2.0.

Key inclusion criteria included HCV genotype 1 with HCV RNA  $\geq 10000$  IU/mL. All participants underwent either liver biopsy or non-invasive marker (FibroSure<sup>®</sup>) testing to determine whether or not cirrhosis was present. Cirrhotics were confirmed to have stage A Child-Pugh disease. HIV RNA viral load was required to be < 50000 copies/mL for participants not on antiretroviral therapy, or less than 50 copies/mL for those on an approved antiretroviral regimen. A CD4<sup>+</sup> T-cell count of > 200 cells/mm<sup>3</sup> was also required within 42 d of study entry. Approved regimens included efavirenz, raltegravir, lopinavir/ritonavir, atazanavir/ritonavir or darunavir/ritonavir plus a dual nucleoside reverse transcriptase inhibitor backbone that did not include zidovudine or didanosine. Key exclusion criteria were those with mixed HCV genotypes, prior use of HCV protease or polymerase inhibitors or the presence of decompensated liver disease. Also excluded were other known causes of significant liver disease including HBV, HAV, hemochromatosis, or alpha-1 antitrypsin deficiency.

Data were centrally submitted and analyzed using SAS 9.4 (SAS Institute, Cary, NC, United States). The key outcome measure was sustained viral response in each study group and how the estimates compared to those in historical controls from a prior study of PEG-IFN plus RBV therapy (ACTG 5178). The study was powered

to conclude that sustained viral response (SVR) is greater than 28% in TN and 10% in treatment experienced participants, based on A5178 results on HCV genotype 1 participants. The SVR proportions were estimated with two-sided 95% Wilson confidence intervals (CI), and Fisher's exact tests were conducted for comparisons between groups. The analyses included all participants who met the eligibility criteria and initiated the study treatment.

## RESULTS

The baseline characteristics of the TN and TE participants as well as the historical controls are shown in Table 1. A total of 257 enrolled participants were analyzed: 135 TN (Group A) and 122 TE (Group B). The study included primarily middle-age males. There was a high representation of black/African-American participants, and this was accompanied by a similarly high percentage of IL28b genotypes carrying the "T" allele. Median CD4 counts were above 600 cell/mm<sup>3</sup> in both groups, corresponding to the high rate of active antiretroviral therapy (> 95%). There were more participants with cirrhosis in TE than in TN, in both A5294 and historical controls.

Overall SVR12 (HCV RNA < LLOQ, TND (target not detected) at 12 wk post treatment discontinuation) rates were 35.6% (95%CI: 28.0-43.9%) in TN and 30.3% (95%CI: 22.9%-39.0%) in TE (Table 2). Rates of response exceeded SVR24 in historical controls: 28% in TN and 10% in TE. The highest rate was observed in TN non-cirrhotic participants (36.8%, 95%CI: 28.6%-45.8%) and the lowest in TE cirrhotic participants (26.3%, 95%CI: 15.0%-42.0%). Cirrhotic TN participants had a 27.8% (95%CI: 12.5%-50.9%) SVR12 rate and 32.1% (95%CI: 23.1%-42.7%) of TE non-cirrhotics achieved SVR12. Race was a significant factor in treatment outcome. Indeed, among TE, SVR12 was noted to occur in 39.7% of white participants but in only 13.2% of those identified as black ( $P = 0.002$ ). Among TN, SVR12 was 42.1% among whites and 27.4% among blacks ( $P =$

0.09). Treatment discontinuation rates were high in all groups and were attributed to a mix of treatment failure per HCV viral load criteria or due to adverse events. Among TN, there was one death unrelated to the study, 42 (31%) treatment failures leading to early discontinuation, and additional 22 (16%) premature treatment discontinuations due to adverse events. In TE, there were 52 treatment failures (43%), additional 16 (13%) premature treatment discontinuations due to adverse events, and no deaths. The most commonly

reported adverse events of grade 3 or higher included hematologic laboratory events (44% in TN and 48% in TE), and general body (chills, fatigue, pain, weight loss; 23% in TN and 22% in TE), gastrointestinal (4% in TN and in 3% TE) and neurologic (7% in TN and 5% in TE) symptoms. HIV breakthrough was rare and only two study participants (both on raltegravir regimen) met predetermined criteria for this event.

Among TN, the highest SVR rates were observed among participants whose cART regimen included rito-

**Table 2 Sustained viral response rates**

A5294 participants (n = 257)	% SVR12
Treatment naïve (n = 135)	35.6
Non-cirrhotic (n = 117)	36.8
Cirrhotic (n = 18)	27.8
Treatment experienced (n = 122)	30.3
Non-cirrhotic (n = 84)	32.1
Cirrhotic (n = 38)	26.3

navir - boosted atazanavir with a 2 nucleoside/nucleotide backbone. Overall SVR12 rate in this group (n = 18) was 61.1% (95%CI: 38.6%-79.7%) which was significantly higher than SVR12 rates among participants receiving other cART regimens combined (P = 0.018) in a post-hoc analysis. However, we note that this was an exploratory analysis on a small subset not adjusted for baseline co-variables, and this effect was not observed in TE.

## DISCUSSION

HCV/HIV coinfection remains a serious medical problem characterized by a high global disease burden (4-5 million) of patients who are at risk for increased fibrotic progression, cirrhosis, and hepatocellular carcinoma<sup>[8]</sup>. Coinfected patients also have significant non-hepatic complications including increased cardiovascular risk<sup>[9]</sup>. Therefore, HCV cure is a priority in the management of coinfecting HCV/HIV patients. The emergence of new DAAs for HCV has been a rapid and turbulent process which followed years of stagnation in the field. It is not surprising that new therapeutic regimens have been under investigation, even as earlier regimens were entering confirmatory clinical trials. The primary Phase 2 trial for boceprevir/PEG-IFN/RBV was initiated in 2010 and results were reported in July 2013<sup>[6]</sup>. Planning for the Phase 3 trial reported in this publication began in 2011, and the study completed in early 2015. During this brief interlude, even more effective, shorter duration regimens were studied and brought to the marketplace.

Despite this rapid advancement in therapy, the Phase 3 trial met its primary goals and moved the field forward in a number of key aspects. First, it again demonstrated the importance of Phase 3 trials which often reveal efficacy levels that fall short of their Phase 2 predecessors. The Phase 2 HCV/HIV coinfection trial of the boceprevir/PEG-IFN/RBV regimen yielded an SVR rate of 63%. This is significantly higher than what we observed in the Phase 3 trial which enrolled a population more representative of the United States HCV/HIV population at large in terms of racial distribution. Indeed, the proportion of black participants in this study (49%) is higher than the imputed racial distribution of HCV/HIV coinfecting patients in United States (23%-33%) based upon a 2002 analysis<sup>[10]</sup>. It also exceeds the black representation in the previously reported Phase 2 trial<sup>[6]</sup>. Our treatment population was more male, more non-white, with a higher representation of the IL28b T allele and with more advanced fibrosis/cirrhosis than the population enrolled

in the previously reported Phase 2 study. Our findings of a lower SVR in this population is similar to that reported in "real world" analyses using first generation protease inhibitors<sup>[11]</sup>.

Interestingly, we observed a higher SVR12 among treatment-naïve subjects whose cART regimen consisted of ritonavir boosted atazanavir + a dual NRTI backbone. Pharmacokinetic data indicates that boceprevir AUC was reduced 32% when administered with ritonavir-boosted darunavir while atazanavir AUC decreased only 5%<sup>[12]</sup>. While we cannot categorically state that this difference affected overall SVR, we suspect it represents an important factor in treatment outcomes among treatment naïve patients. The lack of this finding in treatment experienced participants may represent the overall decreased effectiveness of the PEG-IFN component in that group which masks more subtle effects related to HCV protease inhibitor pharmacokinetics.

Interferon-based therapy is difficult to tolerate and this is clearly demonstrated by the high drop-out rate seen in our study cohort. Though some guidelines and insurers still encourage use of PEG-IFN in some treatment groups, this approach may be particularly detrimental in the HIV-infected patient where tolerability to interferon-based regimens seems to be lower than that observed in comparable Phase 3 trials in monoinfected patients.

Though the treatments utilized in this Phase 3 multicenter trial will not be utilized in general practice, our study provided several important principles and observations that may guide future trials in the field. First, we provide additional support to the concept that Phase 3 trials represent a more accurate representation of true response rates compared to Phase 2 trials. We also note that outcomes in HCV/HIV coinfecting patients may be related to the background HIV antiretroviral regimen and that this effect may be a drug effect rather than a class effect. Finally, we note the systematic delays in initiation of clinical trials for those with underlying HIV infection vs those without HIV. Phase 3 trials of first generation HCV protease inhibitors lagged significantly behind drug approvals in HCV monoinfected patients. More recent drug development programs have attempted to remedy this situation, but the HIV research community should remain vigilant to reduce this bias going forward, particularly in rapidly moving developmental fields.

## COMMENTS

### Background

Hepatitis C virus (HCV) coinfection is a major cause of morbidity and mortality among those with human immunodeficiency virus (HIV) infection. Prior to the emergence of new HCV targeted direct acting antiviral agents in 2011, response to standard therapy with pegylated interferon (PEG-IFN) and ribavirin (RBV) was poor, both in terms of efficacy and medication tolerability. The approvals of first generation serine protease inhibitors of HCV replication initiated a revolution in terms of the care and management of HCV infected patients. Phase 2 trials in HCV/HIV coinfecting patients suggested improved efficacy with moderate drug tolerability for treatment regimens that combined either boceprevir or telaprevir with PEG-IFN + RBV. In an effort to define treatment efficacy with response- and cirrhosis- guided regimens in HCV/HIV coinfecting, the authors conducted a prospective, multicenter, open-label Phase 3 trial in both HCV treatment naïve and treatment experienced participants with comparison to historical controls in the same clinical trials network.

### Research frontiers

The treatment of hepatitis C is a rapidly moving and dynamic field. Introduction of new agents has led to expansion of indications prior to completion of comprehensive Phase 3 trials in some cases. This study provides data regarding a large Phase 3 trial of a first generation protease inhibitor of HCV which was utilized in combination with PEG-IFN and RBV in HCV/HIV coinfecting patients.

### Innovations and breakthroughs

This is the largest study to investigate the efficacy and safety of this first generation protease inhibitor therapy in HCV/HIV coinfecting patients. The treatment was not optimal, but it did meet criteria for treatment success compared to historical controls treated with PEG-IFN plus RBV.

### Applications

While this study demonstrates efficacy of a first generation HCV protease inhibitor in the treatment of HCV/HIV coinfecting patients, the regimen is unlikely to be widely used due to rapid development of all-oral regimens that have supplanted the use of PEG-IFN-based regimens. The importance of conducting Phase 3 trials was emphasized by the lower rates of efficacy than were observed in Phase 2 trials that included highly selected patients.

### Terminology

Treatment naïve patients are those who have never been treated with a hepatitis C active agent while treatment experienced are those who may have been exposed to interferon or PEG-IFN with or without RBV in the past. Therapies for HIV are collectively called cART which includes combinations of drugs used for antiretroviral therapy.

## Peer-review

The authors report data on efficacy and safety of HCV protease inhibitor boceprevir with PEG-IFN alfa and weight-based RBV in a phase 3 trial in patients with HCV plus HIV. The result, in terms of RBV, is similar to that reported by other studies in the real world and reflects the limits of this treatment. The authors, correctly, described the chronology of their trial, born before the entry in the clinical practice of the new treatments.

### Abstract

The role of minimally invasive liver surgery as a bridge to transplantation is very promising but still underestimated. However, it should be noted that surgical approach for hepatocellular carcinomas (HCC) is not merely a technical or technological issue. Nowadays, the epidemiology of HCC is evolving due to the increasing role of non-alcoholic fatty-liver-disease, and the emerging concerns on direct-acting antivirals against hepatitis C virus in terms of HCC incidence. Therefore, a fully multidisciplinary study of the cirrhotic patient is currently more important than ever before, and the management of those patients should be reserved to tertiary referral hepatobiliary centers. In particular, minimally invasive approach to the liver showed several advantages compared to the classical open procedure, in terms of: (1) the small impact on abdominal wall; (2) the gentle manipulation on the liver; (3) the limited surgical trauma; and (4) the respect of venous shunts. Therefore, more direct indications should be outlined also in the Barcelona Clinic Liver Cancer model. We believe that treatment of HCC in cirrhotic patients should be reserved to tertiary referral hepatobiliary centers, that should offer patient-tailored approaches to the liver disease, in order to provide the best care for each case, according to the individual comorbidities, risk factors, and personal quality of life expectations.

## TO THE EDITOR

We read with great interest the paper by Memeo *et al.*<sup>[1]</sup>, recently published on *World Journal of Hepatology* and titled "Innovative surgical approaches for hepatocellular carcinoma". In their well written and complete analysis of surgical planning and treatment for hepatocellular carcinomas (HCC), the authors affirm that the well-known advantages of minimally invasive liver surgery (MLS) compared to the classic "open" approach (OLS) may result in an easier access to the abdomen in case of future liver transplantation (LT). We completely agree and compliment them for highlighting this issue, which is currently underestimated. In July 2014 we started a robotic program at University of Modena and Reggio Emilia and in a period of two years 69 procedures have been performed. A total of 47 robotic liver procedures were ruled out, and among those 24 resection for HCC in cirrhotic patients. In this cohort of patients there were no conversions to laparotomy, mean operative time was 318 min (docking time included), and the mean in-hospital stay was 5.1 d. No readmission nor recurrences were observed. Our robotic cohort of HCC patients is included in an ongoing study funded by "Regione Emilia Romagna" (Regional Public Health System) that aims to investigate the role of robotic surgery in bridging patients with HCC to LT. Up to now, in our Institution two patients successfully underwent LT after MLS and four are on the waiting list.

The robotic platform is expanding its field of application on liver surgery for HCC including the so-called "difficult segments", and should be considered as a valuable tool for bridging patients to LT<sup>[2-6]</sup>. Although OLS has been classically limited to a strictly selected population of patients, several studies demonstrated that MLS is safe, feasible and particularly effective for parenchyma-sparing procedures, as needed in cirrhotic patients<sup>[7]</sup>. However, it should be noted that surgical approach for HCC is not merely a technical or technological issue. Nowadays, the epidemiology of HCC is evolving due to the increasing role of non-alcoholic fatty-liver-disease and direct-acting antivirals against

hepatitis C virus<sup>[8]</sup>. Therefore, a fully multidisciplinary study of the cirrhotic patient is currently more important than ever before, and the management of those patients should be reserved to tertiary referral hepatobiliary centers. Moreover, it should be taken into account that the intraoperative management as well is not only a matter of individual ability to perform certain procedures. MLS seems more effective than OLS in patients affected by HCC within a cirrhotic liver due to several reasons. First of all, in a setting of reduced liver function and reduced functional reserve, we can benefit from less impact on the abdominal wall, gentle manipulation on the liver, respect of the venous shunts and limited surgical trauma. In addition, the perioperative perspiration is consistently less with MLS compared to OLS: Consequently, fluids administration can be more conservative since generous substitutions are not needed. Finally, a better control of post-operative pain and early mobilization of the patient after MLS reduce respiratory complications by enhancing respiratory movements<sup>[9]</sup>. Currently, there is no formal evidence of the superiority of robotic approach vs conventional laparoscopy and also oncological results are similar<sup>[10]</sup>. The correct timing and criteria for choosing between liver resection or LT is still debated, and optimizing organ allocation is still our priority<sup>[11]</sup>. MLS offers an opportunity to safely treat HCC patients even with a Child A-B cirrhotic liver, with lower rates of overall morbidity when compared to OLR, and lower incidence of local recurrence when compared to radiofrequency ablation<sup>[12]</sup>. In conclusion, minimally invasive liver procedures can be considered as an independent field of surgery, with particular indication for Child A and B patients and parenchyma-sparing procedures, that should be better classified in the classical Barcelona Clinic Liver Cancer model<sup>[13-15]</sup>.

We compliment again the Authors for their work and their effort as a referral center of technological innovation to improve both surgical performances and patients' safety. We believe that a modern hepatobiliary center should offer patient-tailored approaches to the liver disease, in order to provide the best care for each case, according to the individual comorbidities, risk factors and personal quality of life expectations.

**REVIEW**

- 227 Adverse effects of oral antiviral therapy in chronic hepatitis B  
*Kayaaslan B, Guner R*
- 242 Role of surgical resection for non-colorectal non-neuroendocrine liver metastases  
*Takemura N, Saiura A*

**ORIGINAL ARTICLE****Retrospective Study**

- 252 Efficacy and safety of telaprevir- and simeprevir-based triple therapies for older patients with chronic hepatitis C  
*Yamagiwa S, Ishikawa T, Waguri N, Sugitani S, Wakabayashi H, Ohkoshi S, Tsukishiro T, Takahashi T, Watanabe T, Terai S*

**Observational Study**

- 263 Malnutrition negatively impacts the quality of life of patients with cirrhosis: An observational study  
*Rojas-Loureiro G, Servín-Caamaño A, Pérez-Reyes E, Servín-Abad L, Higuera-de la Tijera F*
- 270 Addition of simvastatin to carvedilol non responders: A new pharmacological therapy for treatment of portal hypertension  
*Wani ZA, Mohapatra S, Khan AA, Mohapatra A, Yatoo GN*

**SYSTEMATIC REVIEWS**

- 278 Influence of vitamin D on liver fibrosis in chronic hepatitis C: A systematic review and meta-analysis of the pooled clinical trials data  
*Dadabhai AS, Saberi B, Lobner K, Shinohara RT, Mullin GE*

**META-ANALYSIS**

- 288 Is it time to rethink combined liver-kidney transplant in hepatitis C patients with advanced fibrosis?  
*Shah NJ, Russo MW*

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Dr. Kun-Ming Chan, MD, Associate Professor, Head, Surgeon, Department of General Surgery, Division of Liver and Transplantation Surgery, Chang Gung Memorial Hospital at Linkou, Chang Gung University College of Medicine, Taoyuan city 33305, Taiwan

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Oral nucleoside/nucleotide analogues (NAs) are currently the backbone of chronic hepatitis B (CHB) infection treatment. They are generally well-tolerated by patients

and safe to use. To date, a significant number of patients have been treated with NAs. Safety data has accumulated over the years. The aim of this article is to review and update the adverse effects of oral NAs. NAs can cause class adverse effects (*i.e.*, myopathy, neuropathy, lactic acidosis) and dissimilar adverse effects. All NAs carry a "Black Box" warning because of the potential risk for mitochondrial dysfunction. However, these adverse effects are rarely reported. The majority of cases are associated with lamivudine and telbivudine. Adefovir can lead to dose- and time-dependent nephrotoxicity, even at low doses. Tenofovir has significant renal and bone toxicity in patients with human immunodeficiency virus (HIV) infection. However, bone and renal toxicity in patients with CHB are not as prominent as in HIV infection. Entecavir and lamivudine are not generally associated with renal adverse events. Entecavir has been claimed to increase the risk of lactic acidosis in decompensated liver disease and high Model for End-Stage Liver Disease scores. However, current studies reported that entecavir could be safely used in decompensated cirrhosis. An increase in fetal adverse events has not been reported with lamivudine, telbivudine and tenofovir use in pregnant women, while there is no adequate data regarding entecavir and adefovir. Further long-term experience is required to highlight the adverse effects of NAs, especially in special patient populations, including pregnant women, elderly and patients with renal impairment.

**Key words:** Nucleoside/nucleotide analogues; Adverse events; Lamivudine; Chronic hepatitis B; Side effects; Safety; Telbivudine; Hepatitis B infection; Adefovir; Entecavir; Adverse effects; Tenofovir; Hepatitis B virus

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Extrahepatic effects of nucleotide analogues (*i.e.*, myopathy, nephropathy, bone disorders) are more commonly indicated in current reports. Some of these adverse events can be attributed to their effect of causing mitochondrial dysfunction. These adverse events are named as "class effects" and mostly associated

with lamivudine and telbivudine treatment. Adefovir is a well-known nephrotoxic agent. Nephrotoxic and bone density loss effects of tenofovir in patients with chronic hepatitis B (CHB) are not as clear as in those with human immunodeficiency virus infection. Serum creatinine, phosphorus and creatine kinase levels should be monitored. Safety profile is a major issue that should not be ignored in the treatment of CHB.

Kayaaslan B, Guner R. Adverse effects of oral antiviral therapy in chronic hepatitis B. *World J Hepatol* 2017; 9(5): 227-241 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i5/227.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i5.227>

## INTRODUCTION

Chronic hepatitis B (CHB) infection is one of the major causes of chronic liver diseases and affects an estimated 350 to 400 million people worldwide<sup>[1]</sup>. Up to 15%-40% of patients with CHB are at risk of developing complications including cirrhosis, hepatic decompensation and hepatocellular carcinoma (HCC)<sup>[2]</sup>. Prevention of disease progression and disease-related complications is the main goal of treatment in CHB and achieved by suppression of hepatitis B virus (HBV) DNA replication<sup>[2]</sup>. Because CHB requires long-term treatment in the majority of patients, the safety profiles of drugs become important in addition to their antiviral activities. Two different groups of antiviral agents have been approved for the treatment of CHB: Conventional or pegylated interferons (IFN or Peg-IFN), and oral nucleoside/nucleotide analogues (NAs)<sup>[2-4]</sup>. IFN/Peg-IFNs have some disadvantages, including severe side effects, aggravation of decompensated cirrhosis and autoimmune diseases. NAs have become currently the backbone of CHB treatment because they have been well tolerated by patients for decades without severe side effects<sup>[5]</sup>. There are currently five NAs approved for the treatment of CHB and they are classified into two groups: Nucleoside analogues (lamivudine, telbivudine and entecavir) and nucleotide analogues (adefovir dipivoxil and tenofovir dipivoxil fumarate)<sup>[6]</sup>. To date, a significant number of patients have been treated with NAs. Therefore, experience with the efficacy, resistance and safety profile of NAs has increased over the years. The aim of this article is to provide a review of the adverse effects of oral NAs in light of the current data.

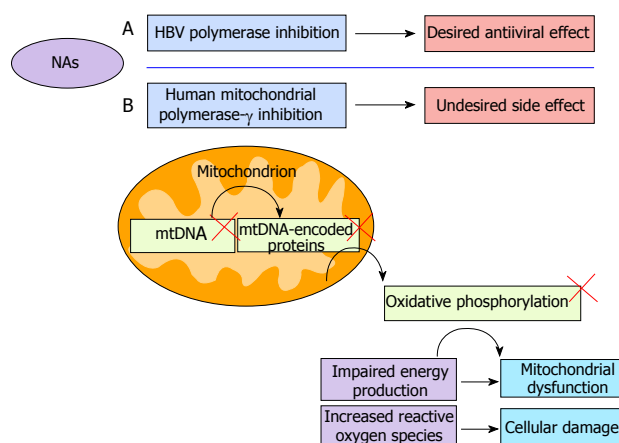

All five NAs have a favorable safety profile<sup>[7]</sup>. However, undesired extrahepatic adverse events may occur during the treatment of CHB infection. The most common extrahepatic adverse events are renal dysfunction, decreased bone mineral density and some neurological findings. Because hepatitis B infection itself may lead to extrahepatic organ involvement<sup>[5]</sup>, determining the source of extrahepatic manifestations may be difficult sometimes during the treatment of CHB. Extrahepatic adverse events may result from mitochondrial toxic effect

of NAs. These adverse effects are generally named as "class effects"<sup>[8]</sup>.

## CLASS EFFECTS OF NAs

NAs suppress viral replication by the inhibition of the HBV polymerase enzyme. As NAs structures were similar to natural nucleosides, some of these agents can also inhibit human mitochondrial polymerase- $\gamma$  and cause mitochondrial toxicity<sup>[3,5,9]</sup>. Mitochondrial toxicity was first noticed during human immunodeficiency virus (HIV) treatment with antiretroviral therapy. Nucleos(t)ide reverse transcriptase inhibitors (NRTIs) are activated by phosphorylation in the cell, and then inhibit HIV reverse transcriptase. Additionally, these drugs also inhibit a human polymerase- $\gamma$  enzyme, which is responsible for the production of mitochondrial DNA (mtDNA) content. mtDNA-encoded proteins are present in multiple copies in each mitochondrion and responsible for encoding enzyme subunits of the respiratory chain function. Respiratory chain function is required for numerous metabolic pathways, including oxidative synthesis of ATP and synthesis of DNA. The depletion of mtDNA-encoded proteins results in mitochondrial dysfunction that causes impaired oxidative phosphorylation. The other result of human mitochondrial polymerase- $\gamma$  inhibition is increased reactive oxygen species that cause cellular damage (Figure 1)<sup>[5,8,10]</sup>. The close relation between NRTIs and mitochondrial toxicity have been described in many reports<sup>[5,8,11]</sup>. Because NAs lead to a minimal mitochondrial polymerase- $\gamma$  inhibition, NAs-associated mitochondrial toxicity cases have been rarely reported. All NAs carry a warning of mitochondrial toxicity as part of their prescribing information<sup>[5,8]</sup>. The clinical manifestations of mitochondrial toxicity include hematologic disorders, peripheral neuropathy, skeletal and cardiac myopathy, pancreatitis, hepatic failure and lactic acidosis<sup>[8,11]</sup>.

The most remarkable examples of mitochondrial toxicity were reported with clevudine therapy. Clevudine is a thymidine-nucleoside analogue approved in South Korea and the Philippines for the treatment of CHB. Although no mitochondrial dysfunction findings had been detected in preclinical studies, multi-center international phase III studies were terminated due to the emergence of clevudine-associated myopathy cases. Clevudine had been shown to be peripherally phosphorylated by mitochondrial thymidine kinase and to accumulate in cells rich in mitochondria<sup>[5]</sup>. South Korea revoked its approval because of indirect adverse effects<sup>[12-14]</sup>. The emergence of an association between clevudine and myopathy served as a reminder that all NAs have a potential risk for mitochondrial toxicity. Among the NAs, lamivudine and telbivudine are the agents most frequently reported to be associated with myopathy and peripheral neuropathy (Table 1). Long-peripheral neurons were more susceptible to mitochondrial toxic effect of NAs due to length-dependent effect<sup>[15]</sup>. Xu *et al*<sup>[16]</sup> performed muscle and nerve biopsy in the 6 cases

**Figure 1 Effects of nucleos(t)ide analogues.** A: NAs show antiviral effect by inhibition of hepatitis B virus (HBV) polymerase; B: NAs also inhibits human mitochondrial polymerase- $\gamma$  enzyme. Thus, mitochondrial DNA (mtDNA) can not be synthesized. Oxidative phosphorylation is impaired. There are two consequences of this: Impaired energy production and increased reactive oxygen species that cause cellular damage. NAs: Nucleos(t)ide analogues.

of NAs-associated myopathy or neuropathy and revealed similar changes in all the muscle and nerve biopsy samples of the patients in light or electronic microscopy and showed the decrease of the mitochondrial DNA by the quantitative real-time PCR in the affected muscle. Although an association between telbivudine and mitochondrial toxicity was not detected *in vitro* studies<sup>[12]</sup>, telbivudine-associated myopathy and creatine kinase (CK) elevations have been reported repeatedly in real-life patients after phase studies. Myopathy may be accompanied by neuropathy in some of patients given telbivudine or lamivudine for the treatment of CHB infection. In one study, 3 of 6 patients with lamivudine or telbivudine-associated myopathy had a complaint of numbness in the distal end of limbs, suggesting peripheral neuropathy. The presence of neuropathy was confirmed by the electrophysiological studies and nerve biopsies by the study team<sup>[16]</sup>. Neuropathy cases have been reported more commonly in patients who have been treated with a combination therapy of telbivudine and Peg-IFN alfa-2a. Combination therapy provided a rapid reduction in HBV DNA level compared to telbivudine or Peg-IFN alfa-2a monotherapy. However, the risk of peripheral neuropathy has been reported to increase up to 20% in combination with Peg-IFN<sup>[10,12,15,17]</sup>.

Myopathy is characterized by CK elevation alongside muscle pain and weakness. CK elevations are among the well-described adverse effects of NAs, but they are not specific for myopathy and may be associated with strenuous exercise and many other illnesses. CK elevations may occur in patients treated with all approved NAs for CHB. However, the incidence of myopathy is very low during the treatment with adefovir, entecavir and tenofovir, and similar to comparative groups. The causal relationship has not been elucidated as of yet<sup>[3,18]</sup>. Myopathy cases can be seen in every age group (25–82 years). There is no difference between male and female

patients in terms of myopathy incidence. The mean onset time of myopathy from the initiation of NAs was reported as 6.4 mo, but it can occur even if in the 5<sup>th</sup> year of treatment. Myopathy cases had been mostly reported from the South Korea and China, but the association between myopathy and race remains unclear<sup>[19]</sup>.

## LAMIVUDINE

Lamivudine is the first oral NA approved by the United States Food and Drug Administration (FDA) for the treatment of CHB in 1998 at a dose of 100 mg/d. It is an analogue of cytidine [2',3'-dideoxy-3'thiacytidine (3TC)] and phosphorylated to its active triphosphates form by intracellular deoxycytidine kinase enzyme. The active anabolite prevents HBV replication by competitively inhibiting viral reverse transcriptase and terminating proviral DNA chain extension<sup>[20]</sup>. Lamivudine has been the most experienced oral antiviral in CHB patients<sup>[8,20]</sup>. It can be used effectively in a broad range of patients, with minimal adverse effects<sup>[21]</sup>. However, long-term treatment of lamivudine is associated with high rates of drug resistance, which lead to virological relapse and biochemical flare<sup>[1-3,8]</sup>. Therefore, lamivudine is recommended as a second-line therapy for the treatment of CHB<sup>[1,2]</sup>.

Long-term lamivudine treatment was generally well-tolerated by CHB patients<sup>[21,22]</sup>. In the GLOBE trial, a large, multi-center phase III study, of the 1367 CHB patients who received telbivudine and lamivudine, adverse events were reported in 23% of the lamivudine recipients, similar to the findings for the telbivudine recipients (29%). The most common adverse events were upper respiratory tract infection (16.2%), nasopharyngitis (13.1%), headache (13.4%) and fatigue (12.1%). Of the patients, 6% (44) experienced serious adverse events<sup>[23]</sup>. The primary adverse event was reported as hepatic flares due to emergence of lamivudine-resistant HBV with prolonged treatment. After 4 years, hepatic decompensation and other severe adverse effects increased among patients with lamivudine resistance<sup>[24]</sup>. In an Asian study by Leung *et al.*<sup>[22]</sup>, 12% ( $n = 7$ ) of patients treated with lamivudine experienced severe side effects. Most of these were increased transaminase and CK levels, and resolved spontaneously. Increased alanine aminotransferase (ALT) levels were generally associated with emergence of YMDD mutant strains and had no clinical importance. In another study conducted among 998 patients with hepatitis B e antigen (HBeAg)-positive compensated liver disease who were treated with lamivudine for up to 6 years, lamivudine demonstrated a good safety profile, with only a 5% rate of severe adverse events<sup>[24]</sup>. Similarly, lamivudine has been found to be effective in HBV DNA decrease, ALT normalization and histological improvement, and it was well-tolerated by patients with cirrhosis. Lamivudine had been used in patients with acute or fulminant hepatitis without any adverse event, and led to fast recovery and increased

**Table 1** Characteristics of approved oral antiviral drugs for chronic hepatitis B treatment

NAs (approval year)	Class effect	Renal effect	Most common adverse events	Laboratory monitoring	Rare severe adverse reactions	Pregnancy category	Detection in breastfeeding
Lamivudine (1998)	Myopathy and neuropathy cases were reported	No significant effect	Upper respiratory tract infection, nasopharyngitis, headache and fatigue ALT flairs CK elevation may occur (usually not requiring cessation of drug)	Serum ALT and bilirubin	Rhabdomyolysis, acute dystonia, pancreatitis Rare lactic acidosis	C	Yes
Telbivudine (2006)	Myopathy and neuropathy cases were reported (especially in combination with Peg- IFN)	Nephroprotective effect Increase in GFR	Upper respiratory tract infection, nasopharyngitis, headache and fatigue Increased incidence of CK elevation (usually asymptomatic and self-limiting, not required cessation of drug)	CK level Serum lactate	Lactic acidosis	B	Yes
Adefovir (2002)	Very rare, No increased incidence of myopathy compared to placebo	Clinically significant nephrotoxicity Decrease in GFR	Pharyngitis, asteni, headache, abdominal pain, flu-like symptoms and nausea	Serum creatinine and phosphate level	Hypophosphatemia Fanconi syndrome	C	Unknown, not recommend for use
Entecavir (2005)	Very rare, No increased incidence of mitochondrial toxicity in combination of entecavir with other NAs and IFN	No decrease in GFR	Headache, upper respiratory tract infection, cough, nasopharyngitis, fatigue, dizziness, upper abdominal pain and nausea	Serum lactate	Lactic acidosis	C	Unknown, not recommend for use
Tenofovir (2008)	Very rare, No increased incidence of myopathy compared to placebo	May decrease GFR, clinically insignificant Nephrotoxic in HIV patients Hypophosphatemia	Headache, nasopharyngitis, back pain, nausea Bone mineral density loss (more prominent in HIV patients)	Serum creatinine and phosphate level BMD		B	Yes

NAs: Nucleos(t)ide analogues; ALT: Alanine aminotransferase; CK: Creatine kinase; IFN: Interferon; GFR: Glomerular filtration rate; HIV: Human immunodeficiency virus; BMD: Bone mineral density.

survival<sup>[25]</sup>.

Lamivudine has a good safety profile in different patient populations having some comorbid diseases. It is the most experienced drug for preemptive treatment of hepatitis B infection in solid-organ recipient and immunosuppressive patients<sup>[1]</sup>. There are limited data for experiences with the other NAs<sup>[26]</sup>. Although highly potent oral NAs with high genetic barriers to antiviral resistance, such as entecavir and tenofovir, have become the current preferred regimen, lamivudine remains a therapeutic option for hepatitis B prophylaxis since it is the most cost-effective choice for these patients<sup>[27,28]</sup>. Lamivudine has been well tolerated by patients receiving immunosuppressive treatment. In a systematic review investigating the preventive effect of lamivudine on chemotherapy - induced hepatitis B-related morbidity and mortality in hepatitis B surface antigen (HBsAg)-positive patients with cancer, none of the eight studies that recorded safety profile of lamivudine reported any significant adverse events<sup>[29]</sup>. Lamivudine has also been

used safely in children without any serious side effects. In one study, only slight and transient increase of ALT levels were reported in 6.8% of children with CHB, without any complaint or clinical findings<sup>[30]</sup>.

Serious adverse events have rarely been reported with lamivudine treatment<sup>[31,32]</sup>. Lamivudine-induced rhabdomyolysis is one of them and characterized by a triad of muscle weakness, myalgia and abnormal laboratory findings including CK elevation, increased urine and blood myoglobin level, and acute renal injury. Tubular damage and obstruction is considered the main reason underlying pathogenesis<sup>[31-33]</sup>. Clinical and laboratory findings improve generally within a few days after cessation of the drug. However, in one case, rhabdomyolysis relapsed after readministration of lamivudine for HBV infection prophylaxis and resolved completely after discontinuation of the drug again<sup>[34]</sup>. The mortality rate was reported to be high in patients who developed rhabdomyolysis and may be reduced by the early recognition of the disease and fluid resuscitations<sup>[31]</sup>.

Lamivudine-induced acute dystonic reaction was reported in 2 patients, and the acute dystonia resolved after discontinuing the lamivudine therapy<sup>[35]</sup>. Lamivudine-associated ichthyosiform eruptions and pancreatitis cases have been reported in the literature<sup>[25,36-38]</sup>.

## TELIVUDINE

Telbivudine is a thymidine nucleoside analogue which selectively inhibits HBV DNA synthesis. It was approved in 2006 for the treatment of CHB patients at a dose of 600 mg/d. Telbivudine is a more potent NA against HBV compared to lamivudine and adefovir<sup>[3,39]</sup>. However, high resistance rates limit the use of telbivudine as the firstline therapy<sup>[2,3]</sup>. Upper respiratory tract infection, nasopharyngitis, fatigue and headache were reported as the most frequent adverse events associated with telbivudine use. Adverse events' frequencies were found to be similar in lamivudine and telbivudine groups. However, Grade 3/4 increase in CK level occurred more commonly in patients given telbivudine (12.9% vs 4.1%), but these were not associated with musculoskeletal adverse events and no rhabdomyolysis cases were detected during the study period<sup>[23]</sup>. CK elevations were generally self-limiting and asymptomatic. Discontinuation of telbivudine was not required in most of the cases. Telbivudine-associated myopathy and CK elevations have been reported in several studies<sup>[12,40-42]</sup>. Zou *et al.*<sup>[41]</sup> conducted a prospective study to investigate clinical features and risk factors of telbivudine-associated myopathy and CK elevations. The serum CK levels of 200 patients treated with telbivudine were analyzed. The 3-year cumulative incidence of CK elevations was considerably high (84.3%). Nine patients (5%) experienced myopathy and were required to discontinue telbivudine therapy in 3 of those. None of the patients developed rhabdomyolysis. CK elevations were reported to occur in males more often than in females and in those with HBeAg negativit and aged < 45 years. In another study in which 105 patients given telbivudine were evaluated for adverse reactions, 5 presented serious adverse events. There was nervous system damage in 3 of the cases and cardiac arrhythmia in 1 case. All 5 patients had elevated CK enzymes. Therefore, it is recommended that CHB patients treated with telbivudine should be monitored closely for musculoskeletal symptoms and CK enzyme levels<sup>[3]</sup>.

Some infrequent but serious side effects were reported in previous studies. Lactic acidosis is one of them and it was reported also in patients treated with all the other nucleos(t)ide analogues<sup>[43]</sup>. It results from mitochondrial dysfunction or loss due to the inhibitor activity of telbivudine on human mitochondrial DNA polymerase- $\gamma$ . A few lactic acidosis cases depending on telbivudine therapy were reported in the literature. The symptoms of patients were anorexia, nausea, vomiting, muscle pain and weakness in upper and lower extremities. The laboratory tests revealed elevated serum CK levels and hyperlactatemia<sup>[43]</sup>. One patient's complaints

continued even after the withdrawal of telbivudine treatment, and the patient recovered after venovenous hemodiafiltration. To diagnose hyperlactatemia, the patients should be monitored by periodic (3-6 mo interval) lactate measurements, in addition to the CK monitoring.

The mechanism of adverse events associated with telbivudine use has not yet been defined. Because adverse events may occur in multiple organs including muscles, nervous and cardiac systems, Zhang *et al.*<sup>[42]</sup> suggested that the mechanism is associated with cell energy metabolism. Deficiency in manufacture of the energy molecule ATP and, therefore, inadequate supplementation of substrate for oxidative phosphorylation causes mitochondrial damage. Highly energy-dependent organs such as nerves, heart and muscles are the most susceptible to mitochondrial dysfunction. Telbivudine leads to adverse events in these organs. However, to establish a link between adverse events and mitochondrial disease, muscle biopsy and DNA studies should be done<sup>[42]</sup>.

Synergistic effect can occur in case of simultaneous use of two drugs. A study comparing telbivudine and lamivudine combination and lamivudine monotherapy reported that the addition of telbivudine to lamivudine treatment did not increase the toxic adverse effects<sup>[44]</sup>. However, the combination of telbivudine with Peg-IFN caused peripheral neuropathy in 17.0% of patients. For this reason, telbivudine should not be recommended in combination with Peg-IFN<sup>[8]</sup>.

## ADEFOVIR DIPIVOXIL

Adefovir dipivoxil is an oral prodrug of the nucleotide analogue adefovir, approved for CHB treatment at 10 mg/d dose in 2002. It was used initially in patients with HIV infection, but its use was abandoned due to the fact that higher doses of adefovir led to nephrotoxicity<sup>[8]</sup>. Adefovir improves histological, biochemical and virological outcomes in CHB patients with lamivudine resistance. The rates of adverse events in patients given adefovir are similar to those given placebo<sup>[45-48]</sup>. The most common adverse events were pharyngitis, asteni, headache, abdominal pain, flu-like symptoms and nausea<sup>[45]</sup>. In a randomized controlled study, adverse events were similar in two groups, but headache and abdominal pain occurred more frequently in the adefovir group than in the placebo group. However, these adverse events did not lead to discontinuation of the study drug<sup>[48]</sup>. Adefovir is associated with dose-dependent renal toxicity. The nephrotoxic effect of adefovir was discussed in the section below on "Renal Safety of NAs".

Myopathy cases were reported in CHB patients given adefovir treatment, but its incidence was similar to patients receiving placebo<sup>[12]</sup>. Adefovir-related lactic acidosis may occur when combined with other NAs<sup>[49]</sup>. The development of resistance to adefovir therapy is another undesirable event. Drug resistance was reported in 26% of CHB patients treated with adefovir, after

5 years<sup>[8]</sup>. The resistance rate of adefovir in patients with lamivudine resistance who were given adefovir add-on lamivudine rescue therapy was 6% at the end of 5 years<sup>[50]</sup>. To optimize therapy in lamivudine-resistant patients, it is recommended not to discontinue lamivudine therapy for a while after initiating adefovir<sup>[8]</sup>.

## ENTECAVIR

Entecavir is a highly selective guanosine nucleoside analogue, approved by the FDA at a dose 0.5 mg in treatment naive and 1 mg/d in lamivudine-resistant CHB patients in 2005<sup>[3,51]</sup>. It inhibits three steps of viral replication, which involves HBV polymerase priming, reverse transcription of the pre-genomic messenger RNA and synthesis of the positive-stranded HBV DNA<sup>[3]</sup>. Entecavir is a well-tolerated antiviral agent in CHB patients, with rates of adverse events similar to placebo or lamivudine therapy. In a comparative study, the adverse event rate was found to be similar in patients given entecavir monotherapy to those given combination of entecavir and IFN<sup>[52]</sup>. Long-term use was reported to be associated with a very low rate of side effects. Adverse events were not dose-related; their frequencies were similar between 0.5 or 1 mg doses of entecavir<sup>[51,53]</sup>. The most frequent adverse events in clinical trials were headache (17%-23%), upper respiratory tract infection (18%-20%), cough (12%-15%), nasopharyngitis (9%-5%), fatigue (10%-13%), dizziness (9%), upper abdominal pain (9%) and nausea (6%-8%). Most of these adverse effects were mild or moderate severity and did not require discontinuation of the drug<sup>[51,54]</sup>. Severe adverse events accounted for 7%-10% and discontinuation of therapy accounted for 1%-2% of patients<sup>[51]</sup>. In a randomized controlled study, severe adverse events occurred in 4.7% of pediatric patients ( $n = 8$ ), and only one of them discontinued entecavir due to headache. This adverse event was not attributed to the study drug<sup>[54]</sup>. Although preclinical data reported an association between long-term entecavir use and carcinogenicity, to date, no evidence has been detected regarding occurrence of cancer due to entecavir therapy<sup>[55]</sup>.

The FDA requires all approved NAs to include a "Black Box" warning in their product label regarding potential mitochondrial toxicity<sup>[56]</sup>. Entecavir is the most innocent antiviral agent leading to mitochondrial toxicity among the effective therapies in CHB treatments. In long-term cell culture studies, entecavir has been observed to have very low potential for mitochondrial toxicity in *in vitro* cultures studies at the highest levels tested, 300  $\mu\text{mol/L}$ . Combination of entecavir with the other NAs also did not cause an increase in the risk of other drugs<sup>[8,57]</sup>. Entecavir-associated myopathy and peripheral neuropathy cases were very rarely reported in the literature<sup>[3,15,19]</sup>. Although a study reported similar CK elevation rates with both telbivudine and entecavir therapy, there were not many studies supporting this<sup>[58]</sup>. In a meta-analysis, six randomized controlled trials involving

555 patients treated with telbivudine and entecavir for 24 or 52 wk were evaluated. Both drugs had similar antiviral and biochemical effects. However, the entecavir group was reported have greater safety than the telbivudine group, in terms of adverse events<sup>[59]</sup>. In another meta-analysis comparing the effects of telbivudine and entecavir in HBeAg-positive CHB patients, thirteen trials (3925 patients in total) were evaluated. Adverse effects were reported in 10 trials and CK elevations in 5 trials. The rates of increased CK were found to be statistically higher in the telbivudine group than in the entecavir group<sup>[60]</sup>.

Lactic acidosis can also occur during treatment with NAs as a result of mitochondrial toxicity. US prescribing information for entecavir and the other NAs carries a warning regarding the risk of lactic acidosis in CHB patients treated with NAs<sup>[61-64]</sup>. Entecavir is a good option for the treatment of CHB patients with decompensated cirrhosis because of the rapid effect on HBV decline and low resistance rates. However, it was suggested that a high Model for End-Stage Liver Disease (MELD) score that is used to detect highly impaired liver function can be associated with lactic acidosis in patients receiving entecavir<sup>[49]</sup>. One retrospective study identified 5 cases of lactic acidosis among 16 entecavir-recipient CHB patients with cirrhosis. One of them died, and the lactic acidosis resolved within 4-5 d after withdrawal of entecavir in the remaining 4 cases. All patients who developed lactic acidosis had a MELD score of at least 20 (22-38), whereas the patients who did not develop lactic acidosis had a MELD score below 18. A significant ( $P = 0.002$ ) correlation was seen between the MELD score and the development of lactic acidosis<sup>[49]</sup>. However, a small retrospective study did not find an increased risk of lactic acidosis in the CHB patients with decompensated liver disease and high MELD scores during entecavir treatment, compared to those who have non-HBV-related decompensated liver disease and similar clinical features<sup>[65,66]</sup>. Entecavir has been reported to have a high safety profile in decompensated patients and recommended as one of the first-line treatment choices of CHB patients with decompensated liver disease in an Asian-Pacific consensus statement<sup>[67,68]</sup>. Nevertheless, the patients should be monitored cautiously for the risk of lactic acidosis during the treatment and entecavir should be suspended in the case of suspected lactic acidosis<sup>[49,66]</sup>.

Patients with severe acidosis complained of nausea, dyspnea and weakness, and showed a reduced general physical condition, impaired consciousness and tachypnea. In addition, 2 of 3 patients with severe acidosis suffered from paresthesia and the remaining 1 patient developed hepatic steatosis typical for mitochondrial toxicity. ALT flares, potentially leading to decompensated hepatic disease, can be another serious health problem in a patient given entecavir for CHB. In clinical trials, ALT flare had been reported to occur in a small percentage of patients treated with entecavir and to resolve even if the treatment continued. In an open-label study evaluating

the safety and tolerability of entecavir, Grade 3 and 4 adverse events were detected in 19% of the patients, with only 4% of them possibly related to entecavir. These Grade 3 and 4 adverse events were myalgia, neuropathy, increased lipase, increased creatinine and lactate, CK elevation, decreased bicarbonate and pancreatitis. Entecavir treatment was discontinued in only 1% of cases due to adverse events. ALT flares were reported in 3% of the patients during the treatment, and were associated with inhibition of viral replication, at least 2 log<sub>10</sub> decrease of HBV DNA<sup>[68]</sup>. In a multicenter European study investigating the incidence and outcome of ALT flares during long-term entecavir in CHB, 729 patients treated with entecavir for a median of 3.5 years were evaluated. Flares were classified as host-induced (preceded by HBV DNA decline), virus-induced (HBV DNA increase) or indeterminate (stable HBV DNA). A total cumulative incidence of ALT flare was 6.3% (30) at year 5. Of them, 12 were host-induced and associated with biochemical remission. HBeAg and HBsAg seroconversion was observed in only these host-induced flares. Virus-induced flares were reported to be associated with entecavir resistance and non-compliance to the therapy<sup>[69]</sup>. Therefore, long-term use of entecavir is generally safe and associated with low rates of serious adverse events, and discontinuation of the treatment is rarely required. ALT flares were low in patients receiving entecavir and generally associated with the improvement of liver disease. In current guidelines, entecavir is also recommended as treatment and prophylaxis of CHB infection in patients with renal transplant due to being an agent without signs of nephrotoxicity<sup>[2]</sup>.

## TENOFOVIR

Tenofovir disoproxil fumarate (TDF) is a prodrug of tenofovir that has been approved as a nucleotide analogue by the United States FDA for use in HIV infection in 2001 and in CHB infection in 2008 at a dose of 300 mg<sup>[8]</sup>. TDF is converted to tenofovir by hydrolysis and then phosphorylated by cellular enzymes to tenofovir diphosphate. It inhibits (potentially) HBV DNA polymerase and reverse transcriptase. Tenofovir, one of the main components in antiretroviral regimens, plays a key role in HIV treatment. It is also a highly potent inhibitor of HBV DNA replication and recommended as a first-line treatment choice in CHB by the current clinical guidelines due to the absence of resistance to the drug<sup>[1,70]</sup>. The molecular structure and general safety profile of tenofovir is similar to adefovir, but nephrotoxicity has not been a major problem with tenofovir at therapeutic doses. Therefore, it can be used at higher doses compared to adefovir and leads to more effective responses in HBV DNA decline. The nephrotoxic effect of tenofovir is discussed in detail in the below section on "Renal Safety of NAs".

In phase III studies of tenofovir, the adverse event profiles were similar to those in the comparative arm of adefovir. The most frequent adverse events were head-

ache, nasopharyngitis, back pain and nausea. Treatment-related adverse events were detected in 6% of patients, serious adverse events in 4% and adverse events that required discontinuation of tenofovir in less than 1%<sup>[8,55]</sup>. A 3-year, prospective real-world study (Vireal group) reported 68 adverse events in 41 (9.3%) patients among a total of 440 patients receiving tenofovir. Adverse events occurring in more than one patient were renal disorders ( $n = 11$ ), abdominal pain ( $n = 8$ ), asthenia ( $n = 7$ ), nausea ( $n = 6$ ), vomiting ( $n = 5$ ) and diarrhea ( $n = 5$ ). Nine of the 16 serious side effects were reported to be tenofovir-related (visual impairment, nausea, asthenia gait disturbance, weight loss, depression, muscular weakness, muscular pain and psoriasis)<sup>[71]</sup>.

Osteomalacia can occur during long-term tenofovir treatment. In randomized clinical trials, a great loss of bone mineral density (BMD) had been well-described in patients with HIV infection treated with tenofovir<sup>[55,72-74]</sup>. However, tenofovir-related bone fractures were not reported in patients with HBV mono-infection<sup>[55]</sup>. During the 3-year prospective follow-up, fractures were observed in 1% of 375 HBeAg-negative and 266 HBeAg-positive patients, but none were related to tenofovir<sup>[75]</sup>. The primary responsible mechanism for bone density loss is believed to be related with inhibitory effects of HIV proteins or immune status in osteoblasts and an increased osteoclastic activity. Modifying effects of tenofovir on osteoblast gene expression and function was the other mechanism defined in recent reports<sup>[72]</sup>. The exact mechanism of bone toxicity in CHB is not clear. Possibly, proximal tubular damage caused by TDF therapy leads to hypophosphatemia and, indirectly, to inadequate mineralization of bone matrix<sup>[3]</sup>. There have been case reports regarding tenofovir-associated osteomalacia. A recent study including 170 patients with CHB infection compared patients treated with tenofovir ( $n = 122$ ) and control patients ( $n = 48$ ) in terms of bone health<sup>[72]</sup>. The prevalence of BMD loss in patients receiving tenofovir was similar to those who were not exposed to tenofovir. Tenofovir was reported to be associated with a lower T score only in the hips. Additionally, in the study, there was no significant correlation between duration of exposure to tenofovir and reduction in BMD at any side. The risk factors for reduction in BMD other than tenofovir exposure were the known classical factors including advancing age, lower body mass index and smoking<sup>[72-74]</sup>. A large retrospective study including 53500 subjects in Hong Kong (46454 untreated and 7046 treated) investigated renal and bone events in CHB patients with and without NAs. The patients treated with NAs had similar risk of hip fracture, spine fracture and all fracture, compared to untreated CHB patients. Treatment with nucleotide analogues, compared to nucleoside analogues, was found to increase only the risk of hip fracture but not the other side fracture, and the overall fracture rate was low<sup>[76]</sup>. Additionally, BMD reduction was demonstrated to remain constant on a plateau from year 4 through year 7 of tenofovir treatment, for both hip and lumbar spine<sup>[77]</sup>. Thus, we may conclude that

BMD reduction is not a progressive event and is detected in the first years of treatment<sup>[78]</sup>. These are important findings due to CHB infection requiring lifelong treatment in the majority of patients because the discontinuation of NAs after sustained viral response have a high risk of relapse. Tenofovir can be preferred and used safely in CHB patients in the long-term. Nevertheless, BMD should be periodically performed in patients with CHB infection treated with tenofovir<sup>[79]</sup>. Osteoporotic patients, especially with advanced age and smoking history, should be monitored more closely and, if required, consulted with a physical rehabilitation specialist.

## RENAL SAFETY OF NAs

The adverse effect of NAs on renal function is an important issue that should be carefully evaluated, since HBV infection alone carries an increased risk of renal impairment<sup>[80]</sup>. All NAs are excreted through kidneys in unchanged forms and some of them are associated with dose-dependent nephrotoxicity<sup>[3]</sup>. Nephrotoxicity results from proximal tubular damage and presents with elevated serum creatinine, proteinuria, nephrogenic diabetes insipidus, hypophosphatemia or the more severe form, Fanconi syndrome<sup>[15]</sup>. Mauss *et al.*<sup>[81]</sup> reported a milder decrease in renal function with CHB therapy irrespective of medications. Comorbidities such as diabetes, hypertension and underlying chronic renal disease may also contribute to the nephrotoxic effect of NAs and aggravate renal dysfunction. In a study analyzing effects of NAs and comorbidities on renal function in 4178 CHB patients, age, diabetes, chronic renal disease, renal transplantation and simultaneous administration of diuretics were found to be independent risk factors for the rapid progression of renal disease<sup>[81]</sup>.

Renal toxicity is the most noticeable side effect of adefovir. It is generally dose- and time-dependent, and reversible with dose-adjustment or discontinuation of the drug<sup>[15,45,82-84]</sup>. In the majority of studies, nephrotoxicity was defined as an increase  $\geq 0.5$  mg/dL from baseline in serum creatinine or a serum phosphorus value of  $< 1.5$  mg/dL on two consecutive occasions<sup>[83]</sup>. In previous studies, including randomized controlled ones, adefovir at 30 mg/d was reported to be nephrotoxic, but adefovir at 10 mg/d was well tolerated and did not lead to an increase in renal dysfunction compared to placebo<sup>[45,85]</sup>. In a study including a total of 515 patients with CHB, three groups who were treated placebo ( $n = 170$ ), adefovir dipivoxil at 10 mg ( $n = 172$ ) or adefovir dipivoxil at 30 mg ( $n = 173$ ) were compared in terms of response to the treatment and adverse events rates<sup>[45]</sup>. The safety profile was similar in two groups, the placebo group and the adefovir dipivoxil at 10 mg per day group. There was no significant change in median serum creatinine level at wk 48 of the treatment in these groups. However, 8% of the 30-mg group experienced an increase from baseline of 0.5 mg/dL (44  $\mu$ mol/L) or greater in the serum creatinine level. The prolonged use of adefovir carries an extra risk of renal dysfunction. The incidences

of increased creatinine level and hypophosphatemia were reported to be increased with longer usage of adefovir, even in patients receiving standard low-dose drug.

In recent years, Fanconi syndrome cases due to long-term use of adefovir have been increasingly reported, especially in East Asian populations<sup>[83]</sup>. Fanconi syndrome is defined as hypophosphatemia and a slight increase in serum creatinine, resulting in proximal renal tubular dysfunction. Additionally, osteomalacia may develop secondary to hypophosphatemia. The patient's main symptoms can be muscular weakness and bone pain involving the knees, ankles and ribs. Clinicians should be aware of this potential complication and monitor periodically the renal function and serum phosphate level in any patient receiving adefovir<sup>[83,86]</sup>. In a current meta-analysis, including seven randomized controlled trials, four cohort studies and six single-arm studies, adefovir treatment was not found to be associated with increased nephrotoxicity in the randomized controlled trials. However, the cohort studies showed an increased nephrotoxicity risk in patients given adefovir, and the single-arm studies revealed an approximately 1.7-fold increased risk of renal dysfunction in patients given adefovir compared to those treated with all other NAs<sup>[82]</sup>. The authors drew attention to the differences between the risk of nephrotoxicity in randomized controlled trials and cohort studies and emphasized that since the randomized controlled trials were small-sized and short observational studies, the safety data may be inadequate and that these studies may have underestimated the adverse events. Current evidence indicated an increased risk of nephrotoxicity in CHB patients treated with adefovir.

The mechanism of adefovir nephrotoxicity was poorly understood. Nephrotoxicity may result from the apoptotic or mitochondrial toxic effect of adefovir in the renal tubular epithelium. The deterioration of the balance between the active adefovir uptake from blood into proximal tubular cells, the secretion into urine, and accumulation in proximal tubular cells represent the primary mechanism of tubular toxicity.

Fanconi syndrome is a rare but serious adverse effect of adefovir treatment. Fanconi syndrome is characterized by proximal renal tubular toxicity and leads to increased urinary excretion of amino acids, uric acid, bicarbonate, glucose and phosphate, and impaired re-absorption of these solutes. Clinical manifestations in adults include polyuria, polydipsia, dehydration and osteomalacia<sup>[87]</sup>. There are a significant number of cases of adefovir-associated Fanconi syndrome in the literature. Most cases occurred after prolonged use of the drug and resolved after cessation of adefovir or switching to another NA. The lowest dose of adefovir (10 mg) can also lead to Fanconi syndrome<sup>[88]</sup>. Normalization of creatinine level may require more than 1 year. In a retrospective case series study including 35 patients with Fanconi syndrome, hypophosphatemia, increased urinary phosphate excretion and elevated alkaline phosphatase were detected in all patients.

Although serum phosphate levels rapidly increased, especially within the 4 wk after adefovir discontinuation, serum creatinine levels did not decrease to normal range even 1 year after discontinuation of therapy<sup>[88]</sup>. Fanconi syndrome was rare in CHB patients treated with tenofovir; it has been reported especially in cases of HIV-HBV coinfection<sup>[87,89-91]</sup>.

Despite tenofovir being a higher dose preparation (300 mg/d) that has similar molecular structure with adefovir, renal toxicity has been less commonly detected<sup>[3]</sup>. In animal studies, tenofovir was reported to be associated with renal dysfunction<sup>[3,84]</sup>. The mechanism of nephrotoxicity is poorly understood, but it may involve proximal tubular damage, mitochondrial toxicity and apoptosis<sup>[8,92]</sup>.

Tenofovir has been shown to have a potential nephrotoxic effect in patients with HIV infection who were treated for an especially extended period. However, in clinical trials, nephrotoxicity does not seem to be a major problem in HBV monoinfection<sup>[3,55,93]</sup>. Increases in serum creatinine of > 0.5 mg/dL were reported to be detected in 1% of patients and remained stable over 4 years in less than 1% of patients, with increased serum creatinine levels of 0.5 mg/dL<sup>[93]</sup>. Nevertheless, renal functions and serum phosphate should be monitored regularly in patients treated with tenofovir<sup>[3]</sup>.

In a study conducted by the Vireal group, a slight decrease of mean glomerular filtration rate (GFR) was reported during tenofovir therapy. Median change in creatinine clearance and serum creatinine level remained stable over time. Of the patients, 15% ( $n = 65$ ) had a decline in GFR of  $\geq 20\%$  and 6% ( $n = 26$ ) had a decline in GFR of  $\geq 30\%$  compared to baseline. Tenofovir treatment was discontinued in 23 patients due to adverse events. Seven of them were associated with renal disorders ( $n = 3$ , renal failures;  $n = 2$ , renal impairments;  $n = 2$ , renal tubular disorders)<sup>[71]</sup>. Patients who have an underlying renal impairment or HIV coinfection and those who receive a nephrotoxic drug are at increased risk of nephrotoxicity. In a study comparing tenofovir and entecavir in the same number of patients, diabetes and transplantation but not tenofovir treatment were found to be associated with increased risk of renal impairment<sup>[94]</sup>. A significant number of studies reported that tenofovir did not lead to clinically relevant changes in renal function<sup>[79,95]</sup>.

In a prospective open-label study, conducted by Heathcote *et al.*<sup>[75]</sup>, creatinine and creatinine clearance were reported to remain stable during a 3-year period, with a change in creatinine of 0.02 mg/dL at week 144. Two patients experienced a 0.5 mg/dL increase in creatinine and 4 patients a reduction in serum phosphorus < 2 mg/dL. All patients remained in the study and continued the tenofovir therapy. The long-term follow-up results of tenofovir therapy support the previous data. At year 6, less than 1.5% experienced impairment in renal function ( $\geq 0.5$  mg/dL increase in serum creatinine from baseline, phosphorus < 2 mg/dL, or CrCL < 50 mL/min) with tenofovir treatment<sup>[55]</sup>. Recently, Buti

*et al.*<sup>[77]</sup> reported 7<sup>th</sup> year results of tenofovir treatment for CHB. Of 585 patients, 21 (3.6%) experienced renal function impairment. A serum creatinine increase  $\geq 0.5$  mg/dL above baseline were confirmed in only 10 patients (1.7%). The patients who did and did not develop renal insufficiency were statistically different in terms of mean age (47 years vs 40 years;  $P = 0.003$ ), baseline mean creatinine clearance (98.5 mL/min vs 117.4 mL/min;  $P = 0.003$ ) and main serum phosphate (2.8 mg/dL vs 3.3 mg/dL;  $P = 0.002$ ). Despite the absence of significant evidence that tenofovir is a nephrotoxic agent, possible proximal tubular damage should still be kept in mind<sup>[3]</sup>. The patients with normal renal function or mild renal impairment who have no increased risk for renal toxicity should be monitored every 6 mo for serum creatinine and phosphorus. The patients with impaired renal function or underlying comorbidities that show increased renal failure may be monitored more frequently<sup>[96]</sup>. Dose-adjustment should be made according to the renal impairment<sup>[3]</sup>.

Tenofovir safety was also similar in elderly and younger patients<sup>[59]</sup>. There is little experience with tenofovir treatment in renal transplantation. One study reported 7 HBV-positive organ transplant recipients ( $n = 3$ , kidney;  $n = 1$ , liver;  $n = 3$ , hearts) who were safely and effectively treated with tenofovir. No adverse events or kidney rejection were observed. There were no statistically significant changes in renal functions<sup>[97]</sup>.

In contrast to the nucleotide analogues, nucleoside analogues are not generally associated with renal adverse events. Increase in serum creatinine was reported in less than 1% of patients treated with entecavir<sup>[49]</sup>. In the study of Tsai *et al.*<sup>[98]</sup>, entecavir and telbivudine were found to be associated with GFR improvement. Despite the absence of strong evidence, the current guidelines recommend entecavir as the best option in renal transplant recipients due to lack of data demonstrating a major renal toxicity with entecavir<sup>[2,99-101]</sup>.

Interestingly, telbivudine improves renal functions<sup>[3,8,81]</sup>. Several real-life studies have shown that treatment with telbivudine increases GFR in CHB patients. The GLOBE study and long-term extension studies had revealed that long-term telbivudine treatment was associated with a sustained improvement in renal function in patients with compensated and decompensated cirrhosis who had an increased risk of renal impairment<sup>[23,102]</sup>. Gane *et al.*<sup>[102]</sup> indicated an improvement in renal function with telbivudine treatment by the calculation of GFR using the Modification of Diet in Renal Disease, Chronic Kidney Disease Epidemiology Collaboration, and Cockcroft-Gault methods. The increment of GFR was also shown in patients at increased risk for renal impairment: +17.2% in patients with baseline GFR of 60-89 mL/min per 1.73 m<sup>2</sup>, +11.4% in patients older than 50 years and +7.2% in cirrhotic patients. Additionally, improved renal function has been reported to be maintained for 4-6 years. In a study investigating the renoprotective effect of telbivudine on patients receiving adefovir-based combination therapy, combination of adefovir

and telbivudine was found to have a more protective effect on renal functions than the combination of adefovir and entecavir, combination of adefovir and lamivudine, adefovir alone or entecavir alone<sup>[79]</sup>. Preemptive telbivudine use was reported to prevent renal deterioration caused by cisplatin-based chemotherapy in patients with advanced HCC<sup>[103]</sup>. Additionally, telbivudine is recommended in the prophylactic treatment of CHB in patients with renal transplant due to its renoprotective effect on transplanted patients<sup>[2]</sup>. Telbivudine is a good option, especially in patients with renal impairment or in those with risk factors for renal disease.

All NAs are cleared by kidneys and their dosage should be adjusted in patients with creatinine clearance below 50 mL/min<sup>[104]</sup>. To minimize the risk of nephrotoxicity, simultaneous administration of the other nephrotoxic drugs should be avoided. Secondly, all patients with CHB infection who are treated with adefovir or tenofovir should be regularly monitored for serum creatinine and phosphate levels and drug dose should be modified if creatinine increases by more than 0.5 mg/dL above baseline or phosphate level decreases below 2.0 mg/dL, to the needed dose<sup>[8]</sup>.

## SAFETY IN PREGNANCY

Mother-to-child-transmission remains the main route of hepatitis B acquisition, especially in endemic countries<sup>[105]</sup>. Despite postnatal use of immune globulin and vaccine, mother-to-child transmission of HBV infection still occurs. Intrauterine transmission is considered the main reason underlying immunoprophylaxis failures<sup>[2,106]</sup>. High HBV DNA levels and HBeAg-positive status are the most important risk factors for perinatal HBV transmission. Thus, reducing maternal HBV DNA level has become the main preventive measure of perinatal mother-to-child transmission<sup>[106]</sup>. Current guidelines recommend initiating NAs in pregnant females with high HBV DNA levels (above  $> 10^{6-7}$  IU/mL) at 28-32 wk of gestation and cessation of NAs after delivery or 4-12 wk after delivery in females who do not have a risk for ALT flares and pre-existing advanced liver fibrosis/cirrhosis<sup>[2,105]</sup>.

Two of five NAs approved for the treatment of CHB, telbivudine and tenofovir, are classified as category B in the United States FDA Pregnancy Categories (meaning that no risk was observed in animal studies; however, there are no adequate and well-controlled studies performed in pregnant women). The other three NAs, lamivudine, entecavir and adefovir, are classified as category C (meaning that an adverse effect on the fetus have been shown in animal studies, but there are no adequate studies in humans)<sup>[107]</sup> (Table 1). Prospective studies have revealed that fetal abnormality rates in mothers treated with NAs is low, and similar to those in the general population<sup>[3]</sup>. Lamivudine is the most experienced NA in pregnancy and it has been used safely in preventing mother-to-child transmission of HIV infection for 2 decades<sup>[2]</sup>. In randomized controlled studies, lamivudine has been shown to be effective in

preventing mother-to-child-transmission when used in the third trimester of pregnancy and early postnatal period. There was no significant difference in the incidence of fetal adverse effects between lamivudine and placebo groups<sup>[108,109]</sup>. The Antiretroviral Pregnancy Registry (APR) provides updated fetal safety data on various drugs used in pregnancy, and includes data from January 1989 to date. Up to 31 July 2015, APR reported newborn defect rates as 3.1% during the first trimester of 4566 pregnant women and 2.9% during the second/third trimester of 7263 pregnant women who were exposed to lamivudine. These rates were not different from those reported in the general population<sup>[110]</sup>. However, lamivudine administration, even if for short-term use such as during pregnancy, has a risk of selecting resistant strains due to poor antiviral activity<sup>[106]</sup>. Current guidelines do not recommend lamivudine as first-line therapy for the treatment of CHB infection in pregnant women<sup>[1,2]</sup>.

Tenofovir is recommended in current guidelines for preventing mother-to-child transmission in pregnant women with high viremia based on its potent antiviral activity, high barrier to resistance and being safe<sup>[1,2]</sup>. Data on tenofovir safety has been usually obtained from patients with HIV infection. It has been safely used in pregnant women with HIV infection for a relatively long time. APR reported newborn defect rates as 2.3% during the first trimester of 2608 pregnant women and 2.1% during the second/third trimester of 1258 pregnant women, which is similar to the rates in the general population. In a retrospective study, conducted in 45 HBeAg-positive pregnant women with high HBV DNA levels, tenofovir was found to be effective in preventing vertical transmission and no significant fetal adverse events were observed<sup>[111]</sup>. The other multi-center prospective observational study reported tenofovir to be more effective than lamivudine in preventing vertical transmission<sup>[112]</sup>. These data are supported by other studies<sup>[113]</sup>.

Telbivudine has greater potency than lamivudine in decreasing HBV DNA level and it is recommended by current guidelines in the prevention of mother-to-child transmission of HBV infection. Use of telbivudine during the second/third trimester of pregnancy was reported to be effective and safe. Compared to placebo, no serious adverse events were found in telbivudine-treated mothers and their infants<sup>[3,12]</sup>. Despite the relatively low resistance rate compared to lamivudine, telbivudine resistance may occur during therapy<sup>[105]</sup>. There are no adequate and well-controlled studies on the safety profile of entecavir and adefovir in pregnant women infected with CHB<sup>[15]</sup>.

Breast-feeding is discouraged during maternal NAs treatment due to the uncertain safety on infants<sup>[1,2]</sup>. Lamivudine is concentrated in breast milk. However, its amount in infants exposed to lamivudine during breast-feeding is accepted to be insignificant (approximately 2% of the recommended daily treatment dose)<sup>[114]</sup>. Similarly, tenofovir concentrations in breast milk have

been reported, but infants are exposed to a small amount because its oral bioavailability is limited<sup>[1]</sup>. There is no adequate evidence to recommend the use of entecavir and adefovir during the breast-feeding period<sup>[110,111]</sup>. Lamivudine or tenofovir is regarded as the choice in breastfeeding mothers who needed to receive treatment for HBV infection.

## CONCLUSION

In light of the current data, the treatment of CHB seems to be a life-long therapy. Thus, the long-term safety of the drugs is one of the main factors that influence treatment decision. To date, five oral NAs have been approved for the treatment of CHB. All NAs are generally safe and well-tolerated by CHB patients. All NAs carry a "Black Box" warning about mitochondrial dysfunction. The majority of mitochondrial toxicity cases are associated with lamivudine and telbivudine and generally present as myopathy, neuropathy or lactic acidosis. No increased incidence of myopathy was reported with adefovir, tenofovir and entecavir treatment, compared to placebo. Adefovir is a well-known nephrotoxic agent and may cause renal proximal tubular dysfunction. Fanconi syndrome cases have been increasingly reported in long-term adefovir therapy. Tenofovir has potential nephrotoxic and bone density loss effects, especially in patients with HIV coinfection. Entecavir and lamivudine are not generally associated with renal adverse events. Interestingly, telbivudine has the effect of improving renal function. Serum creatinine, phosphorus and CK levels should be monitored, especially in patients treated with adefovir and tenofovir. Since BMD reduction may occur during tenofovir treatment, BMD measurements should be periodically performed. Although entecavir is suggested to be associated with lactic acidosis in CHB patients with high MELD scores, its use in compensated and decompensated cirrhotic patients were reported to be safe. Safety profile is a major issue that should not be ignored in the treatment of CHB. Further studies should be done to clarify the adverse effects of NAs and determine follow-up timing and frequency, especially in selected patient populations including those with HIV-coinfection or renal impairment, and pregnant or breastfeeding women.

Prolonged treatment experience can still reveal some unknown adverse effects of drugs. Clinical trial data in different patient populations continue to accumulate in the literature. This review contains updated comprehensive data about the safety profile of NAs used in CHB.

### Abstract

It is widely accepted that the indications for hepatec-

tomy in colorectal cancer liver metastases and liver metastases of neuro-endocrine tumors result in relatively better prognoses, whereas, the indications and prognoses of hepatectomy for non-colorectal non-neuroendocrine liver metastases (NCNNLM) remain controversial owing to the limited number of cases and the heterogeneity of the primary diseases. There have been many publications on NCNNLM; however, its background heterogeneity makes it difficult to reach a specific conclusion. This heterogeneous disease group should be discussed in the order from its general to specific aspect. The present review paper describes the general prognosis and risk factors associated with NCNNLM while specifically focusing on the liver metastases of each primary disease. A multidisciplinary approach that takes into consideration appropriate timing for hepatectomy combined with chemotherapy may prolong survival and/or contribute to the improvement of the quality of life while giving respite from systemic chemotherapy.

**Key words:** Non-colorectal non-neuroendocrine liver metastasis; Metastatic liver tumor; Hepatectomy; Gastric cancer liver metastasis; Gastrointestinal stromal tumor liver metastasis; Breast cancer liver metastasis; Melanoma liver metastasis; Sarcoma liver metastasis; Renal cell carcinoma liver metastasis; Ovarian cancer liver metastasis

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Previous studies reported that the results of hepatectomy for non-colorectal, non-neuroendocrine liver metastasis (NCNNLM) showed an acceptable prognosis in the heterogeneous disease group. However, considering the indication of hepatectomy for NCNNLM, it is important to define the features of each primary disease. The present review paper describes the general prognosis and risk factors associated with NCNNLM, specifically focuses on liver metastasis associated with each primary disease. A multidisciplinary

approach that takes appropriate timing for hepatectomy combined with chemotherapy into consideration may prolong survival and/or contribute to the improvement of the quality of life, while taking time off from systemic chemotherapy.

## INTRODUCTION

Metastatic disease from solid organ tumors occurs frequently in the liver. Presently, surgical resection has been widely accepted as a treatment for colorectal cancer liver metastases<sup>[1,2]</sup> and liver metastases of neuro-endocrine tumors<sup>[3,4]</sup>, providing a relatively better prognosis, whereas, the indications and prognosis of hepatectomy for non-colorectal non-neuroendocrine liver metastases (NCNNLM) remain controversial owing to the rarity of the disease. The biological behavior of NCNNLM varies depending on its primary origin. Discussion of this heterogeneous disease group should be performed in the order from its general to specific aspects. To date, no prospective randomized study has been conducted in this limited field; therefore, in this report we provide a general review of large cohort retrospective studies on hepatectomy for NCNNLM and a more specific review on hepatectomy for liver metastases from different primaries.

## LITERATURE AND RESEARCH

In this report, we reviewed the literature reporting NCNNLM in a large number of patients and their specific primaries. More precisely, we reviewed articles in the English literature that included  $\geq 100$  cases with NCNNLM and relatively large case series for the specific primary (for liver metastases from gastric cancer, breast cancer, and melanoma, reports that included  $\geq 40$  cases were reviewed because of the limited availability of cases in many studies). Using the results reported in the selected literature, the survival outcomes and statistically significant risk factors that impacted survival by multivariate analysis (univariate analysis for some report) were evaluated.

### **Prognosis and risk factors after hepatectomy for NCNNLM**

Along with increased evidence of prolonged survival by hepatectomy in patients with colorectal and neuro-endocrine liver metastases, Schwartz *et al*<sup>[5]</sup> initially categorized NCNNLM and reviewed the literatures in 1995, followed by the analysis of prognosis in a large cohort study by Harrison *et al*<sup>[6]</sup> in 1997. Many validation studies were performed in other patient cohorts that are

summarized in Table 1<sup>[7-16]</sup>. In the present report, we reviewed the 10 largest studies, each with  $\geq 100$  patients who underwent hepatectomy for NCNNLM. In this cohort, the 3- and 5-year overall survival rates were reported as 34%-57% and 19%-42%, respectively, with median survival times of 23-49 mo. The 3- and 5-year disease-free survival rates were 21%-37% and 18%-29%, respectively, with median disease-free survival times of 10-21 mo. The postoperative mortality and morbidity rates were reported 0%-5% and 18%-33%, respectively. In these cohort studies, the reported negative risk factors for survival were the margin status in six studies<sup>[8-11,15,16]</sup>; primary tumor type in four<sup>[8,10,11,15]</sup>; shorter disease-free interval between primary tumor resection and hepatectomy<sup>[8,10,15]</sup> and extrahepatic disease<sup>[10,12,16]</sup> in three; postoperative complications<sup>[14,16]</sup>, larger hepatic metastasis in diameter<sup>[12,13]</sup>, and squamous cell histology<sup>[10,15]</sup> in two; and age<sup>[10]</sup>, major hepatectomy<sup>[10]</sup>, minor hepatectomy<sup>[15]</sup>, synchronous metastasis<sup>[11]</sup>, lymphovascular invasion<sup>[13]</sup>, stromal tumor histology<sup>[15]</sup> and  $> 3$  liver metastases<sup>[16]</sup> in one (Table 1). Negative risk factors for recurrence were extrahepatic disease<sup>[12,16]</sup> in two studies; and primary tumor<sup>[8]</sup>, disease-free interval<sup>[8]</sup>, larger hepatic metastasis in diameter<sup>[12]</sup>, blood transfusion<sup>[14]</sup>, preoperative chemotherapy<sup>[14]</sup>,  $> 3$  liver metastases<sup>[16]</sup>, and residual tumor<sup>[16]</sup> in one. Patients with liver metastases from breast cancer showed significantly better survival in three studies<sup>[10,11,15]</sup>, whereas those with liver metastases from genitourinary tumor liver showed better survival in one<sup>[11]</sup>, and patients with liver metastases from melanoma showed poorer survival compared to other primaries in two studies<sup>[10,15]</sup> (Table 2).

As previously mentioned, the type of primary origin was one of the greatest predictors of survival in patients with this heterogeneous disease. Among the 10 largest studies, the most dominant primary origin was the breast<sup>[7,10,13,15]</sup> and genitourinary<sup>[8,11,12,16]</sup> in four studies and gastrointestinal tract in two<sup>[9,14]</sup>. Elias *et al*<sup>[7]</sup> and Yedibela *et al*<sup>[9]</sup> commented that the resection of liver metastases from gastrointestinal adenocarcinoma correlated with a poor prognosis; however, a more recent report by Takemura *et al*<sup>[14]</sup> showed acceptable prognosis after resection of liver metastases from gastrointestinal carcinoma in their largest cohort with a median survival time of 33.5 mo after hepatectomy. As Yedibela *et al*<sup>[9]</sup> and Groeschl *et al*<sup>[13]</sup> reported that in the more recent years, patients undergoing hepatectomy for NCNNLM appeared to have longer survival compared to previous years, advances in chemotherapy regimens might contribute to prolong survival after the resection of NCNNLM. Adam *et al*<sup>[10]</sup> developed a risk model based on their results of multivariate prognostic factor analysis, which was validated by Lendoire *et al*<sup>[11]</sup>. Their risk model can efficiently stratify the patients into groups; however, the prognosis of each group differed between the two studies depending on the heterogeneous backgrounds of the patient. To facilitate discussion, the prognosis of each primary disease after hepatectomy for NCNNLM has been discussed separately in following section.

## LIVER METASTASES FROM GASTROINTESTINAL PRIMARY TUMORS

### Gastric cancer liver metastases

In the present report, we reviewed the largest 8 studies, each with  $\geq 40$  patients who underwent hepatectomy for liver metastases from gastric cancer. In this series, the 3- and 5-year overall survival rates were reported as 14%-51% and 9%-42%, respectively, with median survival times of 12-41 mo (Table 3)<sup>[10,17-23]</sup>. Among these studies, the negative risk factors for survival were multiple liver metastases in three studies<sup>[18,20,23]</sup>; larger hepatic metastasis in diameter<sup>[19,21]</sup> and serosal invasion

of primary gastric cancer<sup>[19,21]</sup> in two; and synchronous hepatic metastases<sup>[17]</sup>,  $> 3$  liver metastases<sup>[21]</sup> and  $> 2$  positive regional lymph node metastases of primary gastric cancer<sup>[23]</sup> in one (Table 3). The results of hepatectomy for liver metastasis from gastric cancer are influenced by the statuses of both the primary cancer and liver metastasis. The recent meta-analysis of gastric cancer liver metastases revealed that the surgical resection of liver metastases from gastric cancer was associated with a significantly improved survival and among the patients who underwent surgical resection, patients with solitary hepatic metastasis demonstrated a significantly prolonged survival compared to patients with

multiple hepatic metastases<sup>[24]</sup>. Compared to colorectal liver metastasis, reports on aggressive repeat hepatectomy have been highly limited<sup>[25]</sup>, which might be owing to the frequent occurrence of extrahepatic recurrence such as peritoneal seeding and lymph node recurrence. However, advancements in effective chemotherapy regimens can expand not only the prognosis but also the surgical indications for hepatectomy in patients with liver metastasis from gastric cancer and colorectal liver metastases alike.

#### Gastrointestinal stromal tumors liver metastases

The 7 largest studies on the hepatectomy for liver metastases from gastrointestinal stromal tumors (GIST) reported 50%-90% and 30%-76% overall 3- and 5-year survival rates, respectively, with median survival times of 33-96 mo (Table 4)<sup>[26-32]</sup>. Non-surgical therapy<sup>[28,31]</sup>, positive resection margin<sup>[30,32]</sup>, and extrahepatic disease<sup>[29,30]</sup> in two studies each and a disease free interval  $\leq 24$  mo<sup>[26]</sup>, absence of tyrosine kinase inhibitor (TKI) therapy<sup>[29]</sup>, male patients<sup>[30]</sup> and progression disease to

TKI therapy at the time of surgery<sup>[30]</sup> were the factors associated with worse survival (Table 4). Different from other NCNNLMs, the emergence of TKI dramatically changed the treatment and prognoses of patients with advanced GIST. The role of surgical resection in the treatment of metastatic GIST had remained unclear in the initial era of treatment with TKI<sup>[33]</sup>; however, recent reports showed evidence that surgical resection combined with TKI offered better prognosis than TKI monotherapy<sup>[29,31,32]</sup>. As Bauer *et al*<sup>[30]</sup> reported progression disease to TKI therapy at the time of surgery, an urgent issue to debate is the appropriate duration of preoperative therapy to minimize the risk of acquiring secondary mutations responsible for TKI resistance<sup>[26,29]</sup>.

#### Other gastro-intestinal primary tumor liver metastases

Pertaining to reports of liver resection for other gastrointestinal primary liver metastases that rarely indicated hepatectomy, esophagus and pancreas cancer liver metastasis showed dismal prognosis with a median overall survival time of 7-20 mo<sup>[10,16,34,35]</sup>. In the mean-

<sup>3</sup>Comparison to the non-operation group; <sup>4</sup>Comparison including patients without hepatectomy. MST: Median survival time; yrs: Year survival rate; NR: Not reported.

while, intestinal type primary tumors such as duodenal, ampullary and small intestinal cancer showed relatively better prognosis with median survival times of 23-58 mo<sup>[10,34]</sup> (Table 5).

## LIVER METASTASES FROM BREAST CANCER

The largest 10 studies, each with  $\geq 40$  patients who underwent hepatectomy for liver metastases from breast cancer were reviewed. In this series, the 3- and 5-year overall survival rates were 49%-68% and 27%-53%, respectively, with median survival times of 41-115 mo (Table 6)<sup>[10,13,15,36-42]</sup>. The negative prognostic predictive factors were short disease-free interval<sup>[36,39]</sup>, negative expression of hormone receptors<sup>[37,40]</sup>, poor response to systemic chemotherapy before surgery<sup>[38,40]</sup>, and positive hepatic resection margin<sup>[38,39]</sup> in two studies; and the absence of repeat hepatectomy<sup>[38]</sup>, non-hepatectomy<sup>[41]</sup>, bone metastasis<sup>[41]</sup>, lymph node metastasis in the primary tumor<sup>[42]</sup>, absence of trastuzumab therapy<sup>[42]</sup>, and multiple liver metastases<sup>[42]</sup> in one (Table 6). Some prognostic factors of liver metastases from breast

cancer are unique and different from other NCNNLMs, which could indicate that the presence of hormone receptors and HER2 overexpression requires the use of chemotherapy and/or hormone therapy and influences patient survival. Neuman *et al*<sup>[43]</sup> suggested that the impact of local control for liver metastases from breast cancer was greatest in the presence of effective targeted therapy. Similar to other NCNNLMs, surgical resection before progression of disease even with chemotherapy might result in better outcomes of selected patients with liver metastases from breast cancer<sup>[40]</sup>. As Sadot *et al*<sup>[42]</sup> advocated in their study, hepatic resection for liver metastases from breast cancer might not confer a survival advantages; however, might allow time off from systemic chemotherapy.

## LIVER METASTASES FROM MELANOMA

The largest four studies, each with  $\geq 40$  patients who underwent liver resection for liver metastases from melanoma, reported an overall 5-year survival rate of approximately 7%-20% with a median survival time of 14-28 mo (Table 7)<sup>[10,44-46]</sup>. Short disease-free interval from the diagnosis of primary tumor<sup>[45]</sup>, positive resection

Pawlik <i>et al</i> <sup>[49]</sup>	2006	1996-2005	53 (35Hx, 18RF + Hx, and 13RF), (including 36 GISTs)	47 <sup>2</sup>	65 <sup>2</sup>	27 <sup>2</sup>	Primary leiomyosarcoma
Marudanayagam <i>et al</i> <sup>[50]</sup>	2011	1997-2009	36 <sup>1</sup> (including 5 GISTs)	24	48	32	NR
Groeschl <i>et al</i> <sup>[13]</sup>	2012	1990-2009	98	72	60	32	Interval from primary tumor diagnosis $\leq 24$ mo, extrahepatic disease, positive margins
Zhang <i>et al</i> <sup>[51]</sup>	2015	2000-2009	27	NR	NR	46	

<sup>1</sup>Including some patients with GIST before 1993, GISTs were considered as leiomyosarcomas; <sup>2</sup>Including results of RF and patients with GIST; <sup>3</sup>As a part of the report of on-colorectal non-neuroendocrine liver metastases. GIST: Gastrointestinal stromal tumor; MST: Median survival time; ysr: Year survival rate; NR: Not reported; Hx: Hepatectomy; RF: Radiofrequency ablation.

margin<sup>[45]</sup>,  $> 4$  liver metastases<sup>[45]</sup>, miliary disease of the primary melanoma<sup>[45]</sup>, cutaneous melanoma<sup>[46]</sup>, and no preoperative chemotherapy were the risk factors predicting poor patients survival (Table 7). The metastatic pathway of ocular and cutaneous melanomas is different. Ocular melanoma often spreads hematogenously to the liver because there are no lymphatics in the uveal tract. In contrast, cutaneous melanomas potentially spread to the lung, lymph node and soft tissue, and infrequently to the liver<sup>[47]</sup>. Liver metastases from ocular melanoma often recur within the liver, whereas cutaneous melanoma is more likely to develop extrahepatic recurrence<sup>[44]</sup>. Surgical resection should be performed concomitantly with system in chemotherapy as part of a multidisciplinary approach because recurrent disease frequently develops after hepatectomy.

## LIVER METASTASES FROM SARCOMA

The six largest studies on the resection of liver metastases from sarcoma reported 50%-65% and 13%-46% overall 3- and 5-year survival rates, respectively, with median survival times of 24-72 mo (Table 8)<sup>[13,26,48-51]</sup>.

Negative risk factors for overall survival in this cohort were a time of  $< 24$  mo from the diagnosis of primary tumor to the time of liver metastasis<sup>[26,51]</sup>, non-GIST<sup>[49]</sup>, leiomyosarcoma<sup>[50]</sup>, extrahepatic disease<sup>[51]</sup>, and positive resection margins<sup>[51]</sup> (Table 8). These studies included some GIST patients particularly in the early study periods because GIST had been considered as leiomyosarcoma before around 1993. Repeat hepatic resection was reported in four studies. Lang *et al*<sup>[48]</sup> reported 9 second and 2 third cases of hepatectomy for intrahepatic recurrent sarcoma. Less sensitivity to chemotherapy might prompt the surgeon to conduct a repeat hepatectomy with R0 resection, resulting in a favorable outcome<sup>[48]</sup>.

## LIVER METASTASES FROM GENITOURINARY TUMORS

Genitourinary tumors mainly comprise renal cell carcinoma, gynecological carcinoma most commonly with ovarian cancer, and testicular cancer. In the present report, we have reviewed 6 studies pertaining to liver metastases from the renal cell carcinoma which reported

**Table 9** Summary of studies with relatively large cohort of the patients who underwent hepatectomy for liver metastasis from genitourinary primary tumor

Disease	Ref.	Year	Period	No. of patients	MST (mo)	3-yr (%)	5-yr (%)	Factors associated with worse overall survival

Testicular cancer	Hahn <i>et al</i> <sup>[63]</sup>	1999	1974-1996	57	NR	97 (2-yr)	NR	NR
	Adam <i>et al</i> <sup>[10]</sup>	2006	1983-2004	78	82	NR	51	NR

<sup>1</sup>As a part of the report of on-colorectal non-neuroendocrine liver metastases; <sup>2</sup>As a part of debulking surgery; <sup>3</sup>Hepatectomy as secondary cytoreduction; <sup>4</sup>Including 2<sup>nd</sup> ( $n = 15$ ), 3<sup>rd</sup> (3) and 4<sup>th</sup> (2) cytoreduction operations; <sup>5</sup>Only risk factors that included patients undergoing palliative treatment were reported. MST: Median survival time; yr: Year survival rate; NR: Not reported.

overall 3- and 5-year survival rate of 54%-68% and 38%-62%, respectively, with median survival times of 33-142 mo (Table 9)<sup>[10,16,52-55]</sup>. The negative prognostic risk factors were the resection margin<sup>[52,54]</sup>, high-grade tumor<sup>[53]</sup>, poor performance status<sup>[53]</sup>, lymph node metastasis<sup>[53]</sup>, synchronous metastasis<sup>[54]</sup>, short disease-free interval<sup>[55]</sup>, and extra hepatic disease<sup>[55]</sup> (Table 9). Staehler *et al*<sup>[53]</sup> is the first to advocate a favorable prognosis for hepatectomy in patients who underwent resection of liver metastases from renal cell carcinoma over the prognosis of patients who refused to undergo hepatectomy for metastatic renal cell carcinoma, albeit the requirement for further systemic treatment.

The nine largest studies pertaining to gynecological primary cancers, particularly with ovarian cancer, reported 5-year overall survival rates of 30%-51% with median survival times of 26-98 mo (Table 9)<sup>[10,16,56-62]</sup>. Factors associated with worse survival were shorter interval from the diagnosis of primary disease to metastasis<sup>[56,61]</sup>, residual tumor measuring > 1 cm<sup>[56,61]</sup>, hematogenous liver metastasis<sup>[57]</sup>, positive resection margins<sup>[59,60]</sup>, pre-operative ascites<sup>[59]</sup>, and bi-lobular hepatic metastasis<sup>[59]</sup> (Table 9). Owing to the unique features of ovarian cancer, hepatectomy was regarded as a part of cytoreductive surgery and concomitant chemotherapy, which has been accepted as the standard treatment for advanced ovarian cancer. In contrast to

other NCNNLMs, the resection of liver metastases from the peritoneal seeding showed better prognosis than resection of hematogenous liver metastases<sup>[57]</sup>.

Chemotherapy is highly effective in the treatment of testicular carcinoma; however, one-third of the patients either did not achieve complete responses or experienced relapses<sup>[63]</sup>. The limited studies involving treatment with sensitive chemotherapy and subsequent hepatectomy for testicular carcinoma have sufficiently demonstrated a favorable prognosis in patients who underwent this treatment regimen<sup>[63]</sup>.

## CONCLUSION

The clinical evidence accumulated with regards to NCNNLM has indicated the possibility of a chemotherapy-free period and a few studies have demonstrated a curing potential; however, almost all studies reviewed in the present report were conducted retrospectively in selected patients who underwent hepatic resection, which makes determining the absolute indications for hepatectomy in patients with NCNNLM challenging. Indications of hepatectomy for NCNNLM change according to the development of chemotherapy regimens. Strong and highly effective chemotherapy regimens might either expand the indications for hepatectomy or replace hepatectomy in this field. A multidisciplinary approach is

required for the treatment of patients with diseases that are otherwise difficult to treat.

**Author contributions:** Yamagiwa S, Ishikawa T, Waguri N and Terai S contributed to study conception and design; Yamagiwa S, Sugitani S, Wakabayashi H, Ohkoshi S, Tsukishiro T, Takahashi T and Watanabe T contributed to data acquisition, data analysis and interpretation; Yamagiwa S and Terai S contributed to drafting the article; all authors contributed to making critical revisions related to important intellectual content of the manuscript; all authors contributed to final approval of the version of the article to be published.

**Supported by** Grants-in-Aid for Scientific Research (C) (to Yamagiwa S) from Japan Society for the Promotion of Science (JSPS), No. 15K08991.

**Institutional review board statement:** The study was reviewed and approved by Niigata University Medical and Dental Hospital Institutional Review Board.

**Informed consent statement:** Written informed consent under institutional review board-approved protocols (approval no. 1474) at Niigata University Medical and Dental Hospital was appropriately obtained from all the individuals enrolled in the study.

**Conflict-of-interest statement:** We have no financial relationships to disclose.

**Data sharing statement:** No additional data are available.

**Open-Access:** This article is an open-access article which was selected by an in-house editor and fully peer-reviewed by external reviewers. It is distributed in accordance with the Creative Commons Attribution Non Commercial (CC BY-NC 4.0) license, which permits others to distribute, remix, adapt, build upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited and the use is non-commercial. ## Abstract

### AIM

To evaluate and compare the efficacy and safety of telaprevir (TVR)- and simeprevir (SMV)-based triple therapies in elderly patients, specifically patients aged 66 years or older.

### METHODS

The present study enrolled 112 and 76 Japanese patients with chronic hepatitis C virus genotype 1b infection who were treated with a 12-wk TVR-based or SMV-based triple therapy, respectively, followed by a dual therapy that included pegylated interferon  $\alpha$  and ribavirin (RBV) for 12 wk. The patients were categorized into two groups according to age as follows: A younger group of patients aged  $\leq 65$  years old and an older group of patients aged  $> 65$  years old. Among the patients treated with TVR-based triple therapy, 34 patients were included in the older group. The median ages were 56 years (range: 28–65 years) in the younger group and 69 years (range: 66–81 years) in the older group. Among the patients treated with SMV-based triple therapy, 39 patients were included in the older group. The median ages were 59 years (range: 36–65 years) in the younger group and 71 years (range: 66–86 years) in the older group. The clinical, biochemical and virological data were analyzed before and during treatment.

### RESULTS

Among the patients treated with the TVR-based triple therapy, no significant difference in the sustained virological response (SVR) was found between the younger (80.8%) and older (88.2%) groups. The SVR rates for patients with the interleukin 28B (IL28B) (rs8099917) TG/GG-genotypes (73.9% and 60.0% in the younger and older groups, respectively) were significantly lower than for patients with the IL28B TT-genotype (86.3% and 92.9%, respectively). The cumulative exposure to RBV for the entire 24-wk treatment period (as a percentage of the target dose) was significantly higher in the younger group than in the older group (91.7% *vs* 66.7%, respectively,  $P < 0.01$ ), but the cumulative exposure to TVR was not significantly different between the younger and older groups (91.6% *vs* 81.9%, respectively). A multivariate analysis identified the TT-genotype of IL28B (OR = 8.160; 95%CI: 1.593–41.804,  $P = 0.012$ ) and the adherence of RBV ( $> 60\%$ ) (OR = 11.052; 95%CI: 1.160–105.273,  $P = 0.037$ ) as independent factors associated with the SVR. Adverse events resulted in discontinuation of the treatment in 11.3% and 14.7% of the younger and older groups, respectively. Among the patients treated with the SMV-based triple therapy, no significant difference in the SVR rate was found between the younger (81.1%) and older (82.1%) groups. The SVR rates for patients with the IL28B TG/GG-genotypes (77.8% and 64.7% in the younger and older groups, respectively) were significantly lower than for patients with the IL28B TT-genotype (88.2% and 100%, respectively). A multivariate analysis identified the TT-genotype of IL28B as an independent factor associated with the SVR (OR = 9.677; 95%CI:

1.114–84.087,  $P = 0.040$ ). Adverse events resulted in discontinuation of the treatment in 7.0% and 14.3% of patients in the younger and older groups, respectively.

### CONCLUSION

Both TVR- and SMV-based triple therapies can be successfully used to treat patients aged 66 years or older with genotype 1b chronic hepatitis C. Genotyping of the IL28B indicates a potential to achieve SVR in these difficult-to-treat elderly patients.

**Key words:** Telaprevir; Aged patients; Hepatitis C virus genotype 1b; Interleukin 28B; Simeprevir

**Core tip:** We evaluated the efficacy and safety of telaprevir (TVR)- and simeprevir (SMV)-based triple therapies for elderly patients with chronic hepatitis C, especially patients aged 66 years or older, in a real-world clinical setting. In both the TVR and SMV groups, no significant differences in the SVR and adverse events resulting in treatment discontinuation were found between the younger (aged  $\leq 65$ ) and older (aged  $> 65$ ) patients. Both the TVR- and SMV-based triple therapies can be successfully used to treat patients aged 66 years or older with chronic hepatitis C virus genotype 1b infection. Genotyping of the interleukin-28B indicates a potential to achieve SVR in these difficult-to-treat elderly patients.

Efficacy and safety of telaprevir- and simeprevir-based triple therapies for older patients with chronic hepatitis C. *World J Hepatol* 2017; 9(5): 252–262 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i5/252.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i5.252>

## INTRODUCTION

Chronic hepatitis C virus (HCV) infections affect approximately 130–170 million people worldwide and are associated with an increased risk of developing liver cirrhosis and hepatocellular carcinoma (HCC)<sup>[1,2]</sup>. In Japan, an estimated 1.5–2 million people are infected with HCV<sup>[3]</sup>. Most of infected patients in Japan are infected with genotype 1 HCV and are older than the infected patients in Europe and the United States<sup>[4]</sup>. Although older patients with chronic HCV infection have a higher risk of developing HCC than younger patients even at the same liver fibrosis stage<sup>[5]</sup>, older patients have been reported to show poor virological responses to antiviral treatments, especially postmenopausal women<sup>[6–8]</sup>. Because older patients often have reduced cardiovascular, pulmonary, and renal function and a decreased blood count, they are usually more susceptible to the toxic effects of antiviral treatments, which may lead to a

higher rate and severity of adverse events and a poor adherence to the treatment<sup>[4]</sup>. Therefore, an evaluation of the safety and efficacy of antiviral treatments, especially in elderly patients with chronic HCV infections, is still necessary.

Before the introduction of direct-acting antiviral agents (DAA), pegylated interferon (PegIFN)  $\alpha$  and ribavirin (RBV) were the standard of care for HCV genotype 1 infections. However, with the approval of telaprevir (TVR) that is an HCV non-structural (NS) 3/4A protease inhibitor, the optimum treatment regimen for chronic HCV genotype 1 infections was changed to a triple therapy with a protease inhibitor plus PegIFN  $\alpha$  and RBV for 24 wk<sup>[9]</sup>. The TVR-based triple therapy has achieved an improved sustained virological response (SVR) rate compared to PegIFN monotherapy or PegIFN  $\alpha$  plus RBV dual therapy<sup>[10,11]</sup>. However, the TVR-based triple therapy is associated with an increased rate and severity of adverse events, including pruritus, skin rash, anemia, and anorectal diseases, as well as increased rates of treatment discontinuation compared to patients receiving PegIFN  $\alpha$  plus RBV dual therapy<sup>[10,11]</sup>. Because of the increased risk and severity of adverse events associated with the TVR-based triple therapy, it is difficult to use this therapy in older patients, and, therefore, reports describing the safety and efficacy of TVR-based triple therapy in elderly patients are limited<sup>[4]</sup>.

Simeprevir (SMV) is a second-generation oral HCV NS3/4A protease inhibitor with antiviral activity against HCV genotype 1, 2, 4, 5 and 6 infections<sup>[12]</sup>. The QUEST 1 and QUEST 2 phase 3 clinical trials demonstrated the SVR rates of 80% and 81%, respectively, in patients treated with SMV-based triple therapy combined with PegIFN  $\alpha$  and RBV<sup>[13]</sup>. In Japan, 4 phase 3 clinical trials (CONCERTO) were conducted, and the SVR rates were 88.6% and 91.7% for treatment-naïve patients; 35.8%, 50.9% and 38.5% for non-responders; and 89.8% and 96.6% for patients that relapsed<sup>[14-16]</sup>. Although the SMV-based triple therapy shows a favorable efficacy without inducing severe dermatologic and hematologic toxicities, the safety and efficacy of the SMV-based triple therapy for elderly patients has not yet been fully evaluated. Therefore, in the present study, we aimed to assess the efficacy and safety of TVR- and SMV-based triple therapies in elderly patients, specifically patients aged 66 years or older, in a real-world clinical setting.

## MATERIALS AND METHODS

### Patients

This prospective and multicenter study enrolled 112 and 76 HCV genotype 1b Japanese patients who received 12 wk of TVR-based and SMV-based triple therapies, respectively, followed by a dual therapy that included PegIFN  $\alpha$  and RBV for 12 wk. Nine hospitals in Niigata, Japan, including Niigata University Hospital, participated in this study. The patients were categorized into two groups according to age as follows: A younger group

of patients aged  $\leq 65$  years old and an older group of patients aged  $> 65$  years old. Among the patients treated with the TVR-based triple therapy, 34 patients were included in the older group. The median ages were 56 years (range: 28-65 years) in the younger group and 69 years (range: 66-81 years) in the older group. Among the patients treated with the SMV-based triple therapy, the older group consists of 39 patients. The median ages were 59 years (range: 36-65 years) in the younger group and 71 years (range: 66-86 years) in the older group. Liver biopsy samples were obtained from 34 (30.6%) and 42 patients (55.2%) in the TVR and SMV groups, respectively. For each sample, the fibrosis stage (F0-4) and activity grade (A0-3) were evaluated according to the Metavir score<sup>[17]</sup>.

According to responses to prior treatments, relapse was defined as undetectable HCV during and at the end of treatment with positive HCV RNA detecting later on. Non-responder was defined as detectable HCV RNA for more than 24 wk. Patients with decompensated liver cirrhosis, hepatocellular carcinoma, co-infection with hepatitis B virus or human immunodeficiency virus, autoimmune hepatitis, primary biliary cirrhosis, hemochromatosis, or Wilson's disease were excluded. Patients with uncontrollable diabetes mellitus, chronic renal failure, depression, and those with a history of alcohol abuse, were also excluded. Information regarding patient profiles was shown in Tables 1 and 2.

### Study design

All patients received a 12-wk triple therapy that included either TVR [1500 or 2250 mg/d; the initial dose of TVR was determined by each attending physician based on each patient's baseline characteristics such as bodyweight (BW)] (the dose of TVR was also reduced by each attending physician based on each patient's adverse events such as anemia, malaise, and anorexia) (Telavic; Mitsubishi Tanabe Pharma, Osaka, Japan) or SMV (100 mg/d) (Sovriad; Janssen Pharmaceutical K.K., Tokyo, Japan) combined with PegIFN  $\alpha$ 2a (180  $\mu$ g/wk) (Pegasys; Chugai Pharmaceutical Co., Ltd., Tokyo, Japan) or PegIFN  $\alpha$ 2b (1.5  $\mu$ g/BW kg per week) (Peg-Intron; MSD, Tokyo, Japan) and RBV (600-1000 mg/d according to BW as follows:  $< 60$  kg: 600 mg/d; 60-80 kg: 800 mg/d;  $> 80$  kg: 1000 mg/d; if the patient's hemoglobin was  $< 13$  g/dL at the start of therapy, RBV was reduced by 200 mg) (Rebetol; MSD or Copegus; Chugai Pharmaceutical Co., Ltd.), followed by dual therapy of PegIFN  $\alpha$ 2a or PegIFN  $\alpha$ 2b with RBV for 12 wk.

This study was conducted in accordance with the Declaration of Helsinki. The study was reviewed and approved by the Niigata University Medical and Dental Hospital Institutional Review Board. Written informed consent was appropriately obtained from all of the individuals who enrolled in the study according to the institutional review board's approved protocols (approval No. 1474) at the Niigata University Medical and Dental Hospital.

GFR: Glomerular filtration rate; IL28B SNP: Interleukin-28B single nucleotide polymorphism; ND: Not determined; ISDR: Interferon sensitivity-determining region; HCV core 70 or 91: At position 70 or 91 of the HCV core protein; HCV: Hepatitis C virus; AST: Aspartate transaminase; ALT: Alanine aminotransferase; γ-GTP: γ-glutamyl-transpeptidase.

### Laboratory and safety assessments

Laboratory and safety assessments were performed at initiation of treatment; at treatment weeks 2, 4, 8, 12, 16, 20 and 24; at the end of treatment; and at 12 and 24 wk after the end of treatment. Data on adverse events were collected, and physical examinations were

performed at each visit, if clinically indicated.

### Detection of HCV markers

The detection of HCV viremia was performed using a real-time polymerase chain reaction assay (COBAS TaqMan HCV test, Roche Diagnostic, Tokyo, Japan) with

**Figure 1** Rates of virological responses to telaprevir and simeprevir by age. Percentages indicate the proportion of patients with undetectable serum hepatitis C virus (HCV) RNA levels. Patient numbers are shown in parenthesis. TVR: Telaprevir; SMV: Simeprevir; RVR: Rapid virological response; cEVR: Complete early virological response; EOT: End of treatment response; SVR24: Sustained virological response defined as undetectable serum HCV RNA at 24 wk after the end of treatment.

a lower limit of quantitation of 15 IU/mL and a linear dynamic range of 1.2–7.8 log IU/mL. The number of amino acid substitutions in the interferon sensitivity-determining region (in the range of 2209–2248 in the HCV NS5A) was determined using a direct sequencing method as reported previously<sup>[18]</sup>. The core amino acid substitutions at positions 70 and 91 of the HCV genome were determined by direct sequencing as reported previously<sup>[19]</sup>.

### Treatment efficacy

SVR that is defined as undetectable serum HCV RNA at 24 wk after the end of treatment was successful treatment. Early virological responses during the first 12 wk of treatment were defined as rapid virological response (RVR), which was undetectable HCV RNA at week 4, and complete early virological response (cEVR), which was undetectable at week 12. End of treatment response (ETR) was defined as undetectable HCV RNA at the end of treatment. Relapse was defined as an ETR response but non-SVR.

### Interleukin 28B single-nucleotide polymorphism

Human genomic DNA was extracted from the peripheral blood. Single-nucleotide polymorphism (SNP) genotyping of the interleukin 28B (IL28B) (rs8099917) gene was performed using the TaqMan allelic discrimination demonstration kit (Applied Biosystems, Foster City, CA). The rs8099917 genotype was classified into the following 2 categories: TT (major genotype) and non-TT (minor genotype, TG or GG).

### Statistical analysis

Continuous data from patients are expressed as the median with the interquartile range. The significance of the differences was analyzed statistically by the  $\chi^2$ , Fisher's exact test, or Mann-Whitney *U* test, as appropriate, using SPSS software (Ver.18, SPSS Inc., Chicago, IL). To evaluate independent factors for predicting an SVR, variables that reached the  $P < 0.1$  level in the univariate tests were used as candidate factors in a multivariate logistic regression analysis. In all of the cases, the level of

significance was set as  $P$  value  $< 0.05$ .

## RESULTS

### Patient characteristics

The patient characteristics in the TVR group ( $n = 112$ ) and SMV group ( $n = 76$ ) are summarized by age in Tables 1 and 2. The analysis of the pretreatment factors revealed that serum albumin,  $\gamma$ -glutamyl-transpeptidase, and the estimated glomerular filtration rate in the older patients were significantly lower than those of the younger patients in the TVR group (Table 1). Pretreatment serum chemokine C-X-C motif ligand 10 (CXCL10) levels were not significantly different between the younger (543 pg/mL, range: 118–1218 pg/mL) and older (510 pg/mL, range: 95–1794 pg/mL) groups. In the SMV group, BW, white blood cell count, hemoglobin, serum albumin, and serum alanine aminotransferase (ALT) in the older patients were significantly lower than those of the younger patients (Table 2). No significant differences in the prior treatment response, HCV core 70/91 mutations, or IL28B SNPs were found between the younger and older group in both TVR and SMV groups.

### Virological response and outcome

Figure 1 shows the virological responses by age. RVR, cEVR, ETR and SVR did not significantly differ between the younger and older patients in the TVR group (60.2% vs 58.8%, 92.3% vs 94.1%, 87.2% vs 88.2%, and 80.8% vs 88.2%, respectively). Similar to the TVR group, RVR, cEVR, ETR and SVR did not significantly differ between the younger and older patients in the SMV group (81.1% vs 92.3%, 94.6% vs 94.9%, 94.6% vs 100% and 81.1% vs 82.1%, respectively). In the older patients, SVR did not significantly differ between the TVR and SMV groups, although RVR was significantly higher in the SMV group than in the TVR group (92.3% vs 58.5%,  $P < 0.01$ ).

Figure 2 shows the virological responses according to prior treatment responses. In both the TVR and SMV groups, SVR did not significantly differ between the younger and older patients with the same treatment responses. In the older patients in the SMV group, SVR

**Figure 2** Rates of sustained virological response to telaprevir and simeprevir by prior treatment responses. Percentages indicate the proportion of patients with undetectable serum hepatitis C virus (HCV) RNA levels at 24 wk after the end of treatment. Patient numbers are shown in parenthesis. <sup>a</sup> $P = 0.033$  (compared to relapsers in the older patients). NR: Non-responders; TVR: Telaprevir; SMV: Simeprevir; SVR24: Sustained virological response defined as undetectable serum HCV RNA at 24 wk after the end of treatment.

**Figure 3** Rates of sustained virological response to telaprevir and simeprevir by interleukin 28B single-nucleotide polymorphism. Percentages indicate the proportion of patients with undetectable serum hepatitis C virus RNA levels at 24 wk after the end of treatment. Patient numbers are shown in parenthesis. TT, interleukin 28B (IL28B) (rs8099917) TT-genotype; non-TT, IL28B TG/GG-genotypes <sup>a</sup> $P = 0.038$  (compared to older patients with the IL28B TT-genotype). <sup>b</sup> $P = 0.005$  (compared to older patients with the IL28B TT-genotype). TVR: Telaprevir; SMV: Simeprevir; SVR24: Sustained virological response defined as undetectable serum HCV RNA at 24 wk after the end of treatment.

was significantly lower in the prior non-responders than the prior relapsers (60% vs 93.8%,  $P = 0.033$ ). Figure 3 shows the virological responses according to IL28B (rs8099917) SNP status. In the TVR group, the SVR rate for the older patients with the IL28B TT-genotype was significantly higher than for the older patients with the IL28B TG/GG-genotypes (92.9% and 60%,  $P = 0.038$ ). In the SMV group, the SVR rate for the older patients with the IL28B TT-genotype was also significantly higher than for the older patients with the IL28B TG/GG-genotypes (100% and 64.7%,  $P < 0.01$ ).

### Safety and tolerability

Treatment tolerability was summarized in Tables 3 and 4. In the TVR group, adverse events resulted in treatment discontinuation in 16.7% (13/78 cases) and 11.8% (4/34 cases) of patients in the younger and older groups, respectively. Although a greater number of older patients in the TVR group was treated with the lower initial dose of TVR (1500 mg/d) than the younger patients ( $P < 0.01$ )<sup>[20]</sup>, 9 patients (26.4%) discontinued TVR because of adverse events (four patients experienced skin rash, four patients experienced anemia, and one patient experienced renal dysfunction). However, the rate of dis-

continuation of TVR did not significantly differ between the younger and older patients (Table 3). The cumulative exposure to RBV for the whole 24-wk treatment period (as a percentage of the target dose) was significantly higher in the younger patients than in the older patients ( $79.3\% \pm 26.2\%$  vs  $62.7\% \pm 25.3\%$ ,  $P < 0.01$ ), but the cumulative exposure to TVR was not significantly different between the younger and older patients ( $88.8\% \pm 22.8\%$  vs  $83.5\% \pm 25.5\%$ ,  $P = 0.103$ ). Conversely, SMV was not discontinued in either the younger or older patients, although the rate of discontinuation of RBV was significantly higher in the older patients than the younger patients in the SMV group (58.9% vs 29.7%,  $P = 0.012$ ) because of anemia. Adverse events resulted in treatment discontinuation in 8.1% (3/37 cases) and 7.6% (3/39 cases) of patients in the younger and older groups, respectively.

### Predictive factors correlated with SVR24

To identify pretreatment and treatment factors that contribute to SVR, univariate and multivariate analyses were performed in the TVR and SMV groups including the following variables: Gender, age, body mass index, baseline HCV viral load, serum ALT, hemoglobin, platelet

counts, IL28B SNP, initial dose of TVR, TVR/BW (mg/kg per day), SMV/BW (mg/kg per day), dose reduction of treatments, and RVR (Tables 5 and 6). In the TVR group, the IL28B SNP significantly correlated with SVR according to the univariate analysis. A multivariate logistic regression analysis identified the IL28B TT-genotype (OR = 8.160; 95%CI: 1.593-41.804,  $P = 0.012$ ) and the adherence of RBV (> 60%) (OR = 11.052; 95%CI: 1.160-105.273,  $P = 0.037$ ) as independent factors associated with the SVR (Table 5). In the SMV group, the IL28B SNP and the absence of a dose reduction in PegIFN significantly correlated with SVR according to the univariate analysis. In the multivariate logistic regression analysis, the independent factors associated with the SVR were IL28B TT-genotype (OR = 9.677; 95%CI: 1.114-84.087,  $P = 0.040$ ) and the absence of a dose reduction in PegIFN (OR = 6.557; 95%CI: 1.328-32.377,

$P = 0.021$ ) (Table 6).

## DISCUSSION

In this study, we evaluated and compared the efficacy and safety of TVR- and SMV-based triple therapies in combination with PegIFN and RBV in elderly Japanese patients with chronic hepatitis C (CHC), specifically patients aged 66 years or older. The rate of SVR did not differ significantly between younger and older patients in either the TVR or the SMV groups. Among the older patients who were more difficult to treat, more patients carrying the IL28B TG/GG genotypes and prior non-responders were enrolled in the SMV group than the TVR group. However, the rate of SVR did not differ significantly between the TVR and SMV group, although the rates of RVR and relapse were significantly higher in

HCV: Hepatitis C virus; ALT: Alanine aminotransferase; NR: Non-responder; IL28B SNP: Interleukin-28B single nucleotide polymorphism; SMV: Simeprevir; BW: Bodyweight; PEG-IFN: Pegylated interferon; RBV: Ribavirin; RVR: Rapid virological response.

the SMV group than the TVR group. When we performed univariate analyses of factors associated with SVR in all the enrolled patients, we did not find any significance in the type of treatment (TVR vs SMV) (OR = 1.115, 95%CI: 0.415-3.192,  $P = 0.787$ ). Ogawa *et al*<sup>[21]</sup> reported that the rates of SVR were similar for patients with HCV genotype 1b who were treated with TVR- and SMV-based triple therapies, although patients treated with TVR-based triple therapy had more frequent severe adverse events than those treated with SMV-based triple therapy. In this study, the rate of adverse events that resulted in treatment discontinuation did not differ between the younger and older patients in either the TVR or the SMV group, although a higher frequency and severity of adverse events have been reported in patients treated with TVR-based triple therapy compared to patients treated with PegIFN and RBV dual therapy<sup>[10,11]</sup>.

We found that both TVR- and SMV-based triple therapy were effective and tolerable among older patients aged 66 years or older.

In Japan, an estimated 1.5-2 million people are infected with HCV, and these patients are older than those infected in Europe and the United States<sup>[3,22]</sup>. However, previous studies describing the safety and efficacy of TVR- and SMV-based triple therapies, especially in elderly patients with CHC, are limited. One of the reasons may be that the inclusion criteria for clinical trials were usually set to a maximum age of 65 years<sup>[11,23]</sup>. Furusyo *et al*<sup>[4]</sup> reported that there were no differences in the efficacy, frequency and severity of adverse events between patients aged > 60 years and those aged  $\leq 60$  years who were treated with TVR-based triple therapy. Consistent with our study, they reported that a multivariate analysis revealed that the IL28B TT-genotype and the achievement of

RVR were independent factors associated with SVR. Although the decrease in hemoglobin was significantly higher in patients aged > 60 years compared to younger patients aged ≤ 60 years, the rate of adverse events that resulted in treatment discontinuation was similar between the two groups<sup>[4]</sup>. Abe *et al.*<sup>[23]</sup> also reported that in patients treated with TVR-based triple therapy, the SVR rate in patients aged > 65 years was similar to that of patients aged ≤ 65 years and that there was no notable increase of the rate of treatment discontinuation. In our study, the rate of adverse events that resulted in treatment discontinuation in the older patients was lower in the SMV group than in the TVR group, but the difference was not statistically significant. However, considering the risk of higher frequency and severity of adverse events associated with TVR-based triple therapy, we recommend the use of SMV rather than TVR.

The IL28B SNP genotype had a limited impact on the SVR rate with triple therapy in treatment-experienced patients<sup>[24]</sup>, and the strength of the association between the IL28B genotype and the treatment outcome was attenuated in the triple therapy compared to the dual therapy<sup>[23,25]</sup>. In the present study, the IL28B SNP genotype displayed a striking influence on the outcome of both TVR- and SMV-based triple therapy, especially in older patients. In the older patients carrying the IL28B TT-genotype, the rates of SVR were 92.9% and 100% in the TVR and SMV groups, respectively. In contrast, in the older patients carrying the IL28B TG or GG-genotype, the rates of SVR were significantly decreased to 60% and 64.7% in the TVR and SMV groups ( $P = 0.038$  and  $P < 0.01$ ), respectively. Although the substitutions in the core aa70 of the HCV genotype 1b were reported to be important predictors of the efficacy of dual therapy and triple therapy<sup>[26,27]</sup>, our study revealed that the substitutions in the HCV core aa70 were not associated with the achievement of SVR (data not shown). This discrepancy may be explained by the differences in the study population, as our study consisted of a relatively higher number of aged patients. We also measured serum CXCL10 in patients treated with TVR-based triple therapy because previous studies have reported that pretreatment serum CXCL10 concentrations were associated with early virological response and treatment efficacy in patients treated with this therapy<sup>[28,29]</sup>. However, we did not confirm the utility of pretreatment CXCL10 concentrations as a predictor of virological response in patients treated with TVR-based triple therapy.

The present study has a number of limitations. First, the sample size might have provided inadequate statistical power to detect definitive differences between the SVR and no-SVR data in both the older and younger patients. However, the best of our knowledge, this is the first study to compare the efficacy and safety of TVR- and SMV-based triple therapies for elderly patients aged 66 years or older. Second, we only investigated Japanese patients with the HCV genotype 1b. Among the Japanese population, the favorable IL28B SNP is

found in the majority of the population (approximately 75%)<sup>[4]</sup>. Therefore, our results may not be generalizable to other racial cohorts. Third, the older patients who enrolled in the study did not have any severe baseline complications, such as renal and hematological diseases. Therefore, the conclusions drawn regarding the safety of triple therapies may be limited. However, we believe that our selection of older patients for the triple therapies was appropriate and acceptable. Therefore, our findings regarding the absence of severe adverse events, even in the older patients, are important.

Treatment for CHC has been changing worldwide<sup>[30,31]</sup>, and IFN-free DAA combination therapies are now available in Japan. Although the majority of CHC patients are usually treated with IFN-free DAA combination therapies, PegIFN and RBV-based therapy may still have utility in a small number of patients who do not show a favorable effect after the treatment with IFN-free DAA therapies. Moreover, considering the effect of preventing HCC by an eradication of HCV, long-term prevention of HCC has been shown only through the use of IFN-based therapies thus far<sup>[32,33]</sup>. Therefore, we believe that the present study will provide useful information regarding antiviral treatment for older patients with CHC.

In conclusion, we found that both TVR- and SMV-based triple therapies can be successfully used to treat patients aged 66 years or older with genotype 1b CHC. The IL28B genotype indicates a potential to achieve SVR in these difficult-to-treat older patients.

## COMMENTS

### Background

In Japan, an estimated 1.5-2 million people are infected with hepatitis C virus (HCV), and these patients are older than those infected in Europe and the United States. However, previous studies describing the safety and efficacy of telaprevir (TVR)- and simeprevir (SMV)-based triple therapies, especially in elderly patients with chronic HCV infections, are limited.

### Research frontiers

The patients were categorized into two groups according to age as follows: a younger group of patients aged ≤ 65 years old and an older group of patients aged > 65 years old. The rate of sustained virological response (SVR) did not significantly differ between the younger and older patients in both the TVR and SMV groups. The rate of SVR did not significantly differ between the TVR and SMV group, although the rate of rapid virological response was significantly higher in the SMV group than the TVR group. The rate of adverse events resulted in treatment discontinuation did not differ between the younger and older patients in both TVR and SMV group, although a higher frequency and severity of adverse events has been reported in patients treated with TVR-based triple therapy compared to patients treated with pegylated interferon (PegIFN) and ribavirin (RBV) dual therapy.

### Innovations and breakthroughs

In this study, the authors found that both TVR- and SMV-based triple therapies can be successfully used to treat patients aged 66 years or older with genotype 1b chronic hepatitis C (CHC). The interleukin 28B genotype indicates a potential to achieve SVR in these difficult-to-treat elderly patients.

### Applications

Treatment for CHC has been changing worldwide, and interferon (IFN)-free direct-acting antiviral agents (DAA) combination therapies are now available

in. Although the majority of CHC patients are usually treated with IFN-free DAA combination therapies, PegIFN $\alpha$  and RBV-based therapy may still have utility in a small number of patients who do not show a favorable effect after the treatment with IFN-free DAA therapies. Importantly, HCV mutants that are resistant to multiple IFN-free DAA therapies have been shown to be sensitive to IFN-based therapies. Moreover, considering the effect of preventing HCC by an eradication of HCV, long-term prevention of HCC has been shown only through the use of IFN-based therapies thus far. Therefore, they believe that the present study will still provide useful information regarding antiviral treatment for older patients with CHC.

## Terminology

TVR: An HCV non-structural 3/4A (NS3/4A) protease inhibitor; SMV: A second-generation oral HCV NS3/4A protease inhibitor with antiviral activity against HCV genotype 1, 2, 4, 5, and 6 infections.

## Peer-review

The manuscript is well written and it is clear.

## Abstract

### AIM

To verify how malnutrition is related to health-related quality of life (HRQL) impairment in patients with cirrhosis.

### METHODS

Data was retrospectively abstracted from medical records and obtained by direct interview. We included patients with cirrhosis from any etiology, evaluated at the Liver Clinic from Gastroenterology Department in a tertiary healthcare center, from June 2014 to June 2016. Child-Pugh score, data about complications, and demographic, clinical and anthropometric characteristics of patients were obtained. Nutritional status was evaluated by the Subjective Global Assessment (SGA). HRQL was evaluated through the Chronic Liver Disease Questionnaire. Patients were requested to assess their global HRQL with the following code: 0 = impairment

of HRQL, when it was compared with other healthy subjects; 1 = good HRQL, if it was similar to the quality of life of other healthy subjects. To compare the primary outcome between malnourished and well-nourished groups, the  $\chi^2$  test, Fisher's exact test or Student's *t*-test were used, based on the variable type. Associations between predictor variables and deterioration of HRQL were determined by calculating the hazard ratio and 95% confidence interval using Cox proportional hazards regression.

## RESULTS

A total of 127 patients with cirrhosis were included, and the mean age was  $54.1 \pm 12.3$  years-old. According to Child-Pugh scoring, 25 (19.7%) were classified as A (compensated), 76 (59.8%) as B, and 26 (20.5%) as C (B/C = decompensated). According to SGA, 58 (45.7%) patients were classified as well-nourished. Sixty-nine patients identified HRQL as good, and 76 patients (59.8%) perceived impairment of their HRQL. Multivariate analysis to determine associations between predictor variables and self-perception of an impairment of HRQL found strong association with malnutrition ( $P < 0.0001$ ). The most important impaired characteristics in malnourished patients were: Presence of body pain, dyspnea on exertion with daily activities, decreased appetite, generalized weakness, trouble lifting or carrying heavy objects, and decreased level of energy ( $P < 0.0001$ ).

## CONCLUSION

Malnutrition is a key factor related to impairment of HRQL in patients with cirrhosis.

**Key words:** Malnutrition; Subjective global assessment; Health-related quality of life; Cirrhosis; Chronic liver disease questionnaire

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Several factors, particularly the severity of disease, development of ascites, need for paracentesis and history of hospitalization for any cause, are factors that worsen the health-related quality of life (HRQL) of patients with cirrhosis. Noteworthy malnutrition is a very important factor which impacts negatively on HRQL of patients suffering cirrhosis; clinicians must recognize it promptly and search for strategies to avoid this preventable comorbidity.

Malnutrition negatively impacts the quality of life of patients with cirrhosis: An observational study. *World J Hepatol* 2017; 9(5): 263-269 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i5/263.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i5.263>

## INTRODUCTION

Cirrhosis and its complications are important factors which contribute to mortality worldwide<sup>[1]</sup>. Compared with healthy people, the patients with compensated cirrhosis have five times more risk of non-survival, and those with decompensated cirrhosis have ten times more risk of non-survival during follow-up<sup>[2]</sup>.

Malnutrition is highly prevalent in cirrhotic patients. It is related to development of complications, or even death<sup>[3-5]</sup>.

Despite new treatment options for viral hepatitis, the high frequency of undiagnosed patients with chronic viral hepatitis and the increased incidence of metabolic syndrome with non-alcoholic steatohepatitis had led to the number of individuals progressing to cirrhosis being expected to increase until about 2030<sup>[6]</sup>. Moreover, despite increased knowledge of the pathogenesis of cirrhosis and major advances in the treatment, there remains a paucity of information related to health-related quality of life (HRQL) in these patients. Furthermore, the emotional impact of cirrhosis on individual's lives is rarely considered in clinical practice<sup>[7]</sup>.

HRQL is defined as the impact on three health domains regarding the patient's perception of their wellbeing: Physical, psychological, and social health. Measurement of HRQL requires administration of self-reported questionnaires<sup>[8,9]</sup>.

The Chronic Liver Disease Questionnaire (CLDQ) assesses HRQL in patients with chronic liver disease across diagnoses, at all stages of disease and treatment. The CLDQ is a 29-item self-reported questionnaire, with patient response options extending from 1 to 7 (all to none of the time). The CLDQ addresses the following domains that when combined give a composite score that indicates overall HRQL: Fatigue, activity, emotional function, abdominal pain, systemic symptoms, and anxiety. Mean domain scores and an overall quality of life score can be calculated, with higher scores representing better outcome<sup>[9,10]</sup>. Previous studies have confirmed how HRQL deteriorates from compensated to decompensated cirrhosis<sup>[11]</sup>.

Our aim in this study was to verify how malnutrition is related to HRQL impairment in patients with cirrhosis.

## MATERIALS AND METHODS

### Study design

We designed an observational analytic study. Data were retrospectively abstracted from medical records and obtained by direct interview. All study participants provided verbal informed consent prior to study enrollment.

### Patients

We included patients with cirrhosis from any etiology, who were evaluated at the Liver Clinic from Gastroenterology Department in a tertiary healthcare center,

**Figure 1** Kaplan-Meier curves showing the impairment of quality of life through the course of chronic liver disease, in patients with cirrhosis and malnutrition according to subjective global assessment. Malnourished patients had a worse quality of life during the follow-up in each visit to the physician, compared with those well-nourished patients.  $P < 0.0001$ . SGA: Subjective global assessment.

from June 2014 to June 2016. The Child-Pugh score was used to define compensated cirrhosis (Child-Pugh A) and decompensated cirrhosis (Child-Pugh B/C). We also collected data about complications of cirrhosis, including: Ascites, need of paracentesis, variceal bleeding, hepatic encephalopathy, and bacterial infection needing hospitalization. Patients with other chronic comorbidities, such as diabetes, chronic renal failure, heart or lung disease, neoplasms and acquired immunodeficiency syndrome, were excluded. We collected demographic, clinical and anthropometric characteristics of patients.

#### Anthropometric parameters

Weight, height, mid-arm circumference and triceps skinfold thickness were measured<sup>[12]</sup>. Body mass index (BMI) and ideal mid-arm muscle circumference were also calculated<sup>[13,14]</sup>.

#### Nutritional status

Nutritional status was evaluated by the Subjective Global Assessment (SGA)<sup>[4,5,15]</sup>. Patients were catalogued as well nourished, or moderately or severely malnourished. We chose the SGA for this study because of its being a simple bedside method recommended by the experts when other more accurate methods, such as phase angle or body cell mass measured by bioelectric impedance analysis, are not available to assess nutritional status.

#### HRQL

HRQL was evaluated through the CLDQ<sup>[10]</sup>. In addition, patients were requested to assess their global HRQL with the following coding system: 0 = impairment of HRQL, when it was compared with other healthy subjects; 1 = good HRQL, if it was similar to the quality of life of other healthy subjects.

#### Statistical analysis

Numeric variables were stated as mean and standard deviation (SD); categorical variables were stated as

proportions and percentages. To compare the primary outcome between malnourished and well-nourished groups, the  $\chi^2$  test, Fisher's exact test or Student's *t*-test were used, as appropriate. Associations between predictor variables and deterioration of quality of life were determined by calculating the hazard ratio (HR) and 95% confidence interval (CI) using Cox proportional hazards regression. The significant variables ( $P < 0.05$ ) in the univariate model were included in the multivariate model. Kaplan-Meier curves were constructed to compare quality of life between well-nourished and malnourished patients, and for this purpose, we identified the time when patients were diagnosed with cirrhosis and the estimated time when patients noticed impairment of their quality of life. Statistical significance was considered as a  $P$ -value  $< 0.05$ .

## RESULTS

A total of 127 patients with cirrhosis were included, 70 of which were female (55.1%) and 57 were male (44.9%); the mean age was  $54.1 \pm 12.3$  years-old. Regarding the etiology of the cirrhosis, 68 patients (53.3%) had alcoholic cirrhosis, 23 (18.1%) had chronic hepatitis C, 21 (16.5%) had cryptogenic etiology, 11 (8.7%) had autoimmune hepatitis, 3 (2.4%) had non-alcoholic steatohepatitis, and 1 (0.8%) had chronic hepatitis B. According to Child-Pugh scoring, 25 patients (19.7%) were classified as A (compensated), 76 (59.8%) as B, and 26 (20.5%) as C (B/C = decompensated). As determined by the SGA, 58 patients (45.7%) were well-nourished and 69 (54.3%) had some degree of malnutrition, including 66 (52%) with mild to moderate malnutrition and 3 (2.3%) with severe malnutrition. A total of 51 patients (40.2%) assessed their HRQL as good quality of life or similar to other healthy subjects; on the other hand, 76 patients (59.8%) perceived impairment of their HRQL in comparison with other healthy subjects. Characteristics of patients according to their self-perception of HRQL are shown and compared in Table 1. In the univariate analysis, decompensated cirrhosis, presence of ascites, need for paracentesis, hospitalization for any cause, and malnutrition were factors significantly associated with poor HRQL.

Multivariate analysis to determine associations between predictor variables and self-perception of an impairment of HRQL is shown in Table 2. The most important factor related to poor HRQL was malnutrition ( $P < 0.0001$ ). Also, patients with malnutrition had poorer HRQL through the time course of their chronic liver disease, when compared with the well-nourished patients ( $P < 0.0001$ ) (Figure 1).

Finally, the comparison of characteristics evaluated through CLDQ between malnourished and well-nourished patients is shown in Table 3. The most important impaired characteristics in malnourished patients were: Presence of body pain, dyspnea on exertion with daily activities, decreased appetite, generalized weakness, trouble lifting or carrying heavy objects, and decreased

**Table 1** Comparison between the patient characteristics according to the self-perception of quality of life

Characteristic	Good quality of life ( <i>n</i> = 51)	Impairment of quality of life ( <i>n</i> = 76)	<i>P</i>
Male	24 (47.1)	33 (43.4)	0.69
Age (yr)	54.8 ± 10.3	53.7 ± 13.5	0.61
Decompensated or Child B/C	30 (58.8)	63 (82.9)	0.003
Etiology			
Alcohol	28 (55.0)	40 (52.7)	0.83
Viral	9 (17.6)	15 (19.7)	
NASH	2 (3.9)	1 (1.3)	
Cryptogenic	8 (15.7)	13 (17.1)	
Autoimmune	4 (7.8)	7 (9.2)	
Weight in kg	65.2 ± 14.9	63.7 ± 13.4	0.55
Body mass index (kg/m <sup>2</sup> )	26.6 ± 5.2	26.8 ± 4.0	0.32
Triceps skinfold thickness (cm)	1.4 ± 0.7	1.4 ± 0.8	0.79
Mid-arm circumference (cm)	26.4 ± 4.7	23.9 ± 3.7	0.001
Ideal mid-arm muscle circumference (cm)	22.1 ± 4.1	19.6 ± 2.8	< 0.0001
Malnourished according to SGA	14 (27.5)	55 (72.4)	< 0.0001
Presence of ascites	19 (37.3)	48 (63.2)	0.004
Need for paracentesis	7 (13.7)	25 (32.9)	0.02
Development of variceal bleeding	12 (23.5)	18 (23.7)	0.98
Development of hepatic encephalopathy	19 (37.3)	30 (39.5)	0.80
Bacterial infection requiring hospitalization	6 (11.8)	14 (18.4)	0.45
Any complication requiring hospitalization	32 (62.7)	62 (81.6)	0.02

Categorical variables are expressed as *n* (%), and compared by  $\chi^2$  or Fisher's exact test. Numeric variables are expressed as median and SD, and compared by Student's *t*-test. Statistical significance was considered as a *P*-value of < 0.05. NASH: Non-alcoholic steatohepatitis; SGA: Subjective global assessment.

**Table 2** Multivariate analysis to identify factors associated with self-perception of impairment of quality of life

Characteristic	HR (95%CI)	<i>P</i>
Malnourished according to SGA	2.8 (1.6-5.0)	< 0.0001
Need for paracentesis	1.8 (1.0-3.2)	0.05
Presence of ascites	1.4 (0.7-2.7)	0.38
Any complication requiring hospitalization	1.1 (0.5-2.6)	0.82
Decompensated or Child B/C	1.8 (0.0-4.0)	0.14

Cox regression, statistical significance was considered as a *P*-value of < 0.05. HR: Hazard ratio; SGA: Subjective global assessment.

level of energy (*P* < 0.0001).

## DISCUSSION

Cirrhosis represents the final stage of all chronic liver diseases. In its decompensated form, cirrhosis can result in portal hypertension and hepatic dysfunction. Cirrhosis is a leading cause of morbidity and mortality worldwide, and not only is related to decreased survival but also to poor HRQL<sup>[16]</sup>.

Quality of life is a concept that reflects the positive and negative aspects of an individual's life. The term "HRQL" specifically addresses the impact of health on patients' wellbeing<sup>[9]</sup>. There are many factors that influence outcome and HRQL in patients with cirrhosis, however liver function clearly plays a major role affecting the HRQL of patients with cirrhosis. Patients with decompensated cirrhosis have an important impairment on HRQL<sup>[17]</sup>. Also, many symptoms can negatively impact HRQL in patients with cirrhosis; these symptoms can include abdominal bloating, nausea, somnolence, weight

loss, weakness, fatigue and itching. All of these may interfere with patient's work, schooling, social activities, and sense of wellbeing<sup>[18]</sup>.

In our study, we found that decompensated cirrhosis (Child B/C) is a factor related to impairment of HRQL; this finding is similar to other studies. Marchesini *et al.*<sup>[19]</sup> also reported that the severity of liver disease or the development of complications were conditions clearly related to deterioration of perception of health. Similarly, we found that the presence of ascites and need for paracentesis were associated factors related to poor quality of life. Furthermore, hospitalization for any cause was a condition related to poor HRQL in patients with cirrhosis.

In our study, interestingly we found that patients with cirrhosis and malnutrition had a poorer HRQL when compared with well-nourished patients with cirrhosis. Furthermore, malnutrition was the main factor contributing to impairment of HRQL in these patients. Cirrhosis is also associated with malnutrition, which is a complication that negatively affects cirrhotic patients, particularly those decompensated<sup>[20-23]</sup>. In patients with cirrhosis, the prevalence of malnutrition has been reported between 20% to 60%<sup>[24-27]</sup>. In a previous study conducted by Pérez-Reyes *et al.*<sup>[4]</sup> in a Hispanic population, the prevalence of malnutrition was as high as 56.3%. In the present study, we also found a high frequency of malnutrition in patients with cirrhosis (54.3%). Malnutrition in cirrhosis is related to development of ascites, encephalopathy, spontaneous bacterial peritonitis, other bacterial infections and hepatorenal syndrome<sup>[4,28-32]</sup>. But also, malnutrition deteriorates the HRQL in patients with cirrhosis<sup>[33-35]</sup> and several other gastrointestinal and non-gastrointestinal diseases<sup>[36,37]</sup>. Our study confirms that malnutrition is

**Table 3** Chronic Liver Diseases Questionnaire items comparison according to nutritional status

CLDQ item	Well-nourished (n = 58)	Malnourished (n = 69)	P
1 How much of the time during the last 2 wk have you been troubled by a feeling of abdominal bloating?	5.72 ± 1.531	4.67 ± 2.056	0.001
2 How much of the time have you been tired or fatigued during the last 2 wk?	3.69 ± 1.366	2.94 ± 1.259	0.002
3 How much of the time during the last 2 wk have you experienced body pain?	4.14 ± 0.868	3.57 ± 0.848	0.0001
4 How often during the last 2 wk have you felt sleepy during the day?	5.05 ± 1.343	4.55 ± 1.105	0.02
5 How much of the time during the last 2 wk have you experienced abdominal pain?	5.45 ± 1.273	4.96 ± 1.529	0.05
6 How much of the time during the last 2 wk have you experienced dyspnea on exertion, being a problem for you in your daily activities?	6.16 ± 0.951	5.33 ± 1.431	0.0001
7 How much of the time during the last 2 wk have you not been able to eat as much as you would like?	6.12 ± 1.010	3.55 ± 1.549	0.0001
8 How much of the time in the last 2 wk have you been bothered by having decreased strength?	4.91 ± 1.218	2.90 ± 1.447	0.0001
9 How often during the last 2 wk have you had trouble lifting or carrying heavy objects?	5.62 ± 0.834	4.09 ± 1.391	0.0001
10 How often during the last 2 wk have you felt anxious?	5.52 ± 1.112	5.33 ± 1.379	0.41
11 How often during the last 2 wk have you felt a decreased level of energy?	5.19 ± 1.100	3.20 ± 1.491	0.0001
12 How much of the time during the last 2 wk have you felt unhappy?	5.12 ± 1.077	4.41 ± 1.527	0.003
13 How often during the last 2 wk have you felt drowsy?	4.97 ± 1.324	4.55 ± 1.051	0.05
14 How much of the time during the last 2 wk have you been bothered by a limitation of your diet?	4.14 ± 1.206	3.91 ± 1.160	0.29
15 How often during the last 2 wk have you been irritable?	5.52 ± 1.128	5.36 ± 1.175	0.45
16 How much of the time during the last 2 wk have you had difficulty sleeping at night?	5.02 ± 1.493	4.87 ± 1.444	0.57
17 How much of the time during the last 2 wk have you been troubled by a feeling of abdominal discomfort?	5.62 ± 1.437	4.77 ± 1.816	0.004
18 How much of the time during the last 2 wk have you been worried about the impact your liver disease has on your family?	5.84 ± 1.056	5.94 ± 1.371	0.66
19 How much of the time during the last 2 wk have you had mood swings?	5.50 ± 1.417	5.83 ± 1.283	0.18
20 How much of the time during the last 2 wk have you been unable to fall asleep at night?	5.10 ± 1.360	4.67 ± 1.569	0.99
21 How often during the last 2 wk have you had muscle cramps?	5.52 ± 1.047	5.39 ± 1.074	0.51
22 How much of the time during the last 2 wk have you been worried that your symptoms will develop into major problems?	4.19 ± 1.515	4.45 ± 1.586	0.35
23 How much of the time during the last 2 wk have you had a dry mouth?	5.40 ± 1.184	5.30 ± 1.192	0.66
24 How much of the time during the last 2 wk have you felt depressed?	5.33 ± 1.082	4.68 ± 1.745	0.01
25 How much of the time during the last 2 wk have you been worried about your condition getting worse?	4.05 ± 1.191	4.28 ± 1.454	0.34
26 How much of the time during the last 2 wk have you had problems concentrating?	5.34 ± 1.132	4.74 ± 1.569	0.01
27 How much of the time have you been troubled by itching during the last 2 wk?	5.71 ± 1.451	6.20 ± 1.065	0.03
28 How much of the time during the last 2 wk have you been worried about never feeling any better?	4.07 ± 1.153	4.36 ± 1.382	0.20
29 How much of the time during the last 2 wk have you been concerned about the availability of a liver if you need a liver transplant?	4.22 ± 1.312	4.23 ± 1.467	0.97

Data are expressed as median and SD, and compared with Student's *t*-test. Statistical significance was considered as a *P*-value of < 0.05. CLDQ: Chronic Liver Diseases Questionnaire.

a key factor related to impairment of HRQL in patients with cirrhosis, even when we adjusted for advanced liver disease or decompensation status, and for other major complications such as ascites, need for paracentesis and need for hospitalization for any cause.

In conclusion, cirrhosis is the end-stage of all chronic liver diseases; it contributes importantly to morbidity and mortality worldwide but also has a negative impact on HRQL that must be considered. Several factors contribute to a poor HRQL in patients with cirrhosis, however malnutrition, which is a highly prevalent comorbidity in patients with cirrhosis, represents a key factor related to poor HRQL in these patients. There is a need for developing strategies to evaluate more accurately patients with cirrhosis and to identify promptly those patients at risk of malnutrition.

## COMMENTS

### Background

Cirrhosis is a significant contributor to global mortality. Prevalence of malnutrition is high in patients with cirrhosis and is related to increased complications or even death. Despite increased knowledge of the pathogenesis of cirrhosis, there

remains a paucity of information related to health-related quality of life (HRQL) in these patients.

### Research frontiers

The emotional impact of cirrhosis on individual's lives is rarely considered in clinical practice. The Chronic Liver Disease Questionnaire assesses HRQL in patients with chronic liver disease across diagnoses, at all stages of disease and treatment.

### Innovations and breakthroughs

Cirrhosis is a leading cause of morbidity and mortality worldwide, and not only is related to decreased survival but also to poor quality of life. The term "HRQL" addresses the impact of health on a patient's wellbeing. Many factors influence HRQL in patients with cirrhosis, however the impact of comorbidities, such as malnutrition, are not well understood. The authors found that patients with cirrhosis and malnutrition had worse quality of life when compared with well-nourished patients with cirrhosis. In this study, malnutrition was the main factor contributing to impairment of quality of life in these patients.

### Applications

In this study, the authors found that several factors contribute to a poor health-related quality of life in patients with cirrhosis, however malnutrition, which is a highly prevalent comorbidity in these patients, represents a key factor related to poor quality of life in these patients. There is a need for developing strategies to evaluate more accurately patients with cirrhosis and to identify promptly those patients at risk of malnutrition.

# Terminology

Nutritional status was defined through the Subjective Global Assessment and patients were divided as follows: Well-nourished, or moderately or severely malnourished. The HRQL is defined as the impact on three health domains-physical, psychological, and social health-on patient perception of their wellbeing.

# Peer-review

Very nice and well written paper.

## Abstract

### AIM

To determine whether addition of simvastatin could be an important pharmacological rescue therapy for carvedilol non-responders.

### METHODS

One hundred and two consecutive patients of cirrhosis of liver with significant portal hypertension were included. Hepatic venous pressure gradient (HVPG) was measured at the base line and after proper optimization of dose; chronic response was assessed at 3 mo. Carvedilol non-responders were given simvastatin 20 mg per day (increased to 40 mg per day at day 15). Carvedilol plus simvastatin was continued for 1 mo and hemodynamic response was again measured at 1 mo.

## RESULTS

A total of 102 patients with mean age of  $58.3 \pm 6.6$  years were included. Mean baseline HVPg was  $16.75 \pm 2.12$  mmHg and after optimization of dose and reassessment of HVPg at 3 mo, mean reduction of HVPg from baseline was  $5.5 \pm 1.7$  mmHg and  $2.8 \pm 1.6$  mmHg among responders and non-responders respectively ( $P < 0.001$ ). Addition of simvastatin to carvedilol non-responders resulted in significant response in 16 patients (42.1%) and thus overall response with carvedilol and carvedilol plus simvastatin was seen in 78 patients (80%). Two patients were removed in chronic protocol study with carvedilol and three patients were removed in carvedilol plus simvastatin study due to side effects.

## CONCLUSION

Addition of simvastatin to carvedilol non-responders may prove to be an excellent rescue therapy in patients with portal hypertension.

**Key words:** Simvastatin; Cirrhosis; Carvedilol; Liver cirrhosis; Portal hypertension; Hepatocellular carcinoma

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** There is no pharmacological option available for treatment of carvedilol nonresponders in patients with portal hypertension. Addition of simvastatin could be an important pharmacological rescue therapy for carvedilol nonresponders. This study showed that addition of simvastatin to carvedilol non responders can increase overall response to around 80%, which is one of the best possible pharmacologically produced chronic response and it opens a new strategy for portal hypertension treatment.

Wani ZA, Mohapatra S, Khan AA, Mohapatra A, Yattoo GN. Addition of simvastatin to carvedilol non responders: A new pharmacological therapy for treatment of portal hypertension. *World J Hepatol* 2017; 9(5): 270-277 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i5/270.htm> DOI: <http://dx.doi.org/10.4254/wjgh.v9.i5.270>

## INTRODUCTION

The prevalence of esophageal varices in an asymptomatic compensated patient is around 40%<sup>[1]</sup>. While the incidence of variceal development is roughly 6% per year, it doubles if hepatic venous pressure gradient (HVPg) rises above 10 mmHg. Thus, cirrhotics with HVPg of > 10 mmHg represent higher risk group. HVPg > 10 mmHg also correlates with higher risk of decompensation and hepatocellular carcinoma (HCC)<sup>[2,3]</sup>. The result of a number of meta-analysis has shown that, prognosis of cirrhotic patients improve with significant decrease in portal pressure, *i.e.*, when target decrease in HVPg (> 20% from baseline or to < 12 mmHg) is achieved<sup>[4,5]</sup>.

In practice, cirrhotic patients complicated with varices should be treated except for Child-Pugh (C-P) class A patients with small varices without red color signs<sup>[6]</sup>.

The role of non-selective beta blockers (NSBBs) and endoscopic variceal ligation (EVL) in the prevention of first variceal bleeding is conflicting. Analysis of a recent meta-analysis did not show any differences on mortality or bleeding rates between the two groups in trials with adequate bias control<sup>[7]</sup>. In contrast, another meta-analysis showed that compared with BBs, EVL reduced the risk of a first variceal bleed, although, there was no significant difference in survival<sup>[8]</sup>. Hence, the author concluded that EVL should be offered to patients with moderate to large oesophageal varices who are unlikely to comply or intolerant or who bleed while taking BB.

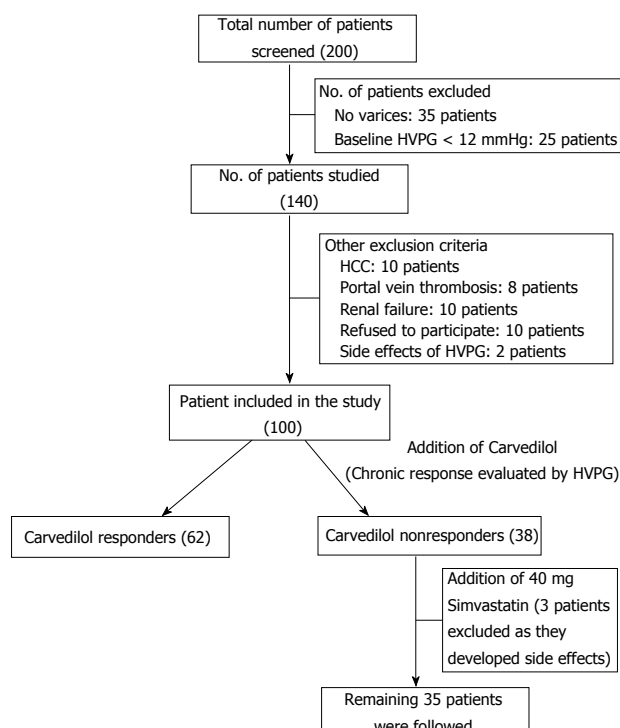

Still, the mainstream in pharmacological treatment of portal HTN (PHT) is NSBB like propranolol and nadolol which help in preventing first and recurrent variceal bleeding, gastropathy and spontaneous bacterial peritonitis (SBP)<sup>[9]</sup>. Drugs like isosorbide-5 mononitrate, prazosin or statins when added to NSBBs help in reducing the hepatic vascular tone and thus may turn many non-responders to responders<sup>[10,11]</sup>. Also, HVPg can be further decreased with these drugs. Recently our group has published a combined study on carvedilol in which 50% of the patients showed acute response and more than 60% of patients showed chronic response (please refer to definitions for details)<sup>[12]</sup>. We also showed in a separate study that, optimization of dose of carvedilol on chronic basis is an excellent policy for portal hypertension across different C-P class of liver disease<sup>[13]</sup>.

Simvastatin improves liver generation of nitric oxide (NO) and hepatic endothelial dysfunction in patients with cirrhosis. Hence, it could be an effective therapy for portal hypertension. Recently, ideal drug for portal hypertension was pictured as one that should reduce portal pressure by decreasing intrahepatic vascular resistance while maintaining or enhancing hepatic blood flow<sup>[14,15]</sup>. Other desirable action would be an antifibrotic effect and a capacity to improve liver function. The drug that would be able to increase NO bioavailability in liver would fulfill many of the requirements<sup>[15-18]</sup>. However in patients with advanced cirrhosis, non-selective NO donors such as organic nitrates which enhance peripheral vasodilatation further decrease arterial pressure and activate endogenous vasoactive system. Thus, selectivity for hepatic circulation is a further requirement for vasodilators used to treat portal hypertension<sup>[19]</sup>.

Recent experimental and human data<sup>[20,21]</sup> suggests that statins (3-hydroxy-3-methyl-COA reductase inhibitor) could decrease intra hepatic vascular resistance and improve flow mediated vasodilatation of liver vasculature in the cirrhotic liver. These effects are mediated by an up regulation of NO at the liver vasculature through an enhancement in endothelial NO synthetase activity<sup>[20]</sup>. Moreover, NO production in liver by statins is selective and could behave as true liver selective vasodilator.

Thus, the concept of our study was to assess the response of 3<sup>rd</sup> generation beta blocker carvedilol on

**Figure 1 Study design.** HVPG: Hepatic venous pressure gradient; HCC: Hepatocellular carcinoma.

chronic basis (after proper optimization of dose) and then to add simvastatin along with carvedilol, optimise dose in carvedilol non responders to have a new pharmacological approach and better rescue therapy.

## MATERIALS AND METHODS

### Patients and methods

We prospectively evaluated one hundred and two cirrhotic patients who were referred to our institution for hemodynamic evaluation from January, 2010 to December, 2014. The study was approved by the institutional review board (IRB) and all included patients gave informed consent for participation.

Diagnostic criteria for cirrhosis was based on clinical, biochemical, radiological and if needed on liver biopsy. The criteria for esophageal varices was based on quantitative grading used by Bavino consensus, *i.e.*, esophageal varices less than 5 mm are small varices and esophageal varices equal to or greater than 5 mm are considered large varices. Criteria used to diagnose ascites was according to international ascites club 2003, *i.e.*, grade I - mild (ultrasound based), Grade II - moderate, *i.e.*, (symmetrical abdominal distension) and Grade III - gross with marked abdominal distension.

The inclusion criteria of the study include evidence of esophageal varices on upper gastrointestinal (GI) endoscopy, without a previous history of hemorrhage and a baseline HVPG of greater than 12 mmHg. Exclusion criteria were age < 18 years; severe liver failure INR > 2.5, or PT < 40% of control, bilirubin > 5 mg/dL; active alcohol consumption; IV drug abuse; renal failure, *i.e.*,

creatinine > 1.5 mg/dL; HCC; contraindication to NSBB; pre or post hepatic cause of PHT; pregnancy; previous surgical shunt or TIPPS; treatment with calcium channel blockers; treatment with (3-hydroxy-3-methyl-COA reductase inhibitor) in past three months; a known hypersensitivity to simvastatin and refusal to participate in study.

### Dosing Of NSBB

Baseline HVPG was measured for all included patients after 8 h of fasting. They were started on carvedilol 6.25 mg/d from the next day and dose was titrated by steps of 6.25 mg/wk. Dose of carvedilol was increased weekly until arterial systolic blood pressure (BP) was not less than < 90 mmHg and heart rate (HR) not less than < 55 bpm. Compliance with therapy was monitored by recording HR and BP during clinical visit.

### Dosing of simvastatin

Carvedilol non-responders were added simvastatin 20 mg/d for 15 d (then increased to 40 mg). Complete clinical examination and blood tests were performed at day 15, patients were interrogated specifically for muscle weakness, if no safe end point was met, dose was increased to 40 mg/d and continuing with continuation of carvedilol. Treatment was maintained for 1 mo and then repeat hemodynamic response was measured.

### Definitions

**Acute response to carvedilol:** Acute response to carvedilol is defined as "a drop in HVPG greater than 20% and or less than 12 mmHg from baseline at 90 min after administration of a single dose (12.5 mg) of carvedilol".

**Chronic response to carvedilol:** Chronic response to carvedilol is defined as "a drop in HVPG greater than 20% and or less than 12 mmHg from baseline at 3 mo after proper optimization of dose of carvedilol".

### Response with addition of simvastatin

After 30 d of 40 mg simvastatin addition to carvedilol in carvedilol non responders, HVPG drop of greater than 20% from baseline and or less than 12 mmHg HVPG. The study design is illustrated in Figure 1. Dose optimization was done in all patients who were started with carvedilol. Once doses were optimized, weekly follow-up of each patient was done and HVPG was again measured at 3 mo of treatment. Patients were assessed for side effects; their BP and HR were measured on each follow-up visit. Carvedilol non responders were added with simvastatin 20 mg/d and after 15 d, all blood tests were taken for side effects of simvastatin and clinical history specifically muscle weakness was taken. With no clinical and biochemical evidence of adverse effects, patients were given 40 mg of simvastatin per day and continuing carvedilol for 1 mo, repeat hemodynamic assessment was done to see response in carvedilol non responders and thus overall response in the study group

**Table 1** Baseline characteristics of 102 patients

Parameters	Description
Age (mean $\pm$ SD)	58.35 $\pm$ 6.62

Prothrombin time	14.13 $\pm$ 1.91
International normalized ratio	1.29 $\pm$ 0.16

NASH: Non-alcoholic steatohepatitis; AIH: Autoimmune hepatitis.

was seen.

### Haemodynamic measurements

Under fluoroscopic guidance, hepatic vein catheterization was performed according to the standards described by Bosch *et al.*<sup>[22]</sup>. A 7F balloon tipped catheter was advanced to main right hepatic vein to measure wedged hepatic venous pressure gradient (WHPG). HVPG was measured as the difference between WHPG and free hepatic pressure gradient (FHPG). Swangaz catheter was advanced to pulmonary artery for measurement of cardio pulmonary pressures like pulmonary artery pressure (PAP), wedged pulmonary pressures (WPP), right arterial pressure (RAP), etc. All measurements were repeated three times and tracing were noted. Mean arterial pressure was measured non-invasively by automatic sphygmomanometer. HR was derived by continuous ECG monitoring and systemic vascular resistance (SVR) as (MAP - RAP/CO  $\times$  80).

### Statistical analysis

The statistical methods of this study were reviewed by Dr. Khan from Noora Multispeciality Hospital, Srinagar, India. Statistical analysis was performed by using statistical package for social sciences (SPSS) version 22.0. Descriptive statistics was presented as proportion, Mean  $\pm$  standard deviation (SD) and median with inter-quartile range. Comparative analysis was done by utilizing student's *t*-test and  $\chi^2$  test. The univariate and multivariate logistic regression was used for finding the predictors. A *P*-value less 0.05 was considered significant.

## RESULTS

A total of 68 patients (66.7%) had large varices and 34 patients (33.3%) had small varices on upper GI endoscopy and 63 (61.8%) patients had no ascites while others had ascites. The baseline parameters are shown in Table 1.

After optimization of dose and reassessment of HVPG after 3 mo, total number of chronic responders was 62. However two patients discontinued treatment because of side effects. Mean duration of dose optimization was

15  $\pm$  3 d. Mean reduction of HVPG from baseline and after 3 mo was 5.5  $\pm$  1.7 mmHg and 2.8  $\pm$  1.6 mmHg among responders and non-responders on chronic basis, respectively (*P* < 0.001). Mean dose of carvedilol was higher among non-responders (19.2  $\pm$  5.7 mg) as compared to responders (18.7  $\pm$  5.1 mg).

### Effect of simvastatin addition to carvedilol non responders with continuation of carvedilol on reduction of portal hypertension and hemodynamic parameters

After assessing the chronic response at 3 mo with carvedilol, there were 38 patients who did not respond significantly to carvedilol and were thus called as carvedilol non-responder. In these 38 patients, simvastatin 20 mg/d was added initially for 15 d and at 15 d, side effects like muscle weakness along with biochemical parameters like CPK and ALT was seen. If CPK > 5 times and ALT > 3 times was found in any patient, they were withdrawn from the study. One patient developed CPK > 5 times with normal ALT was withdrawn from study on 15<sup>th</sup> day. Second patient developed hepatic encephalopathy and 3<sup>rd</sup> patient developed severe dizziness and both of these were withdrawn from study. Four patients developed minor side effects with normal CPK and ALT and were continued with treatment.

Among 38 carvedilol non responders, therefore, 35 patients continued carvedilol and simvastatin for 1 mo and then a repeat hemodynamic assessment was done. There were 16 responders and 19 non-responders at one month after adding simvastatin. Thus, overall carvedilol response in the study was 79.56% (78 patients). The pre baseline mean HVPG of carvedilol non responders was 16.429 mmHg which dropped to 13.029 mmHg, i.e., 3.4 mmHg drop (> 20%) after adding simvastatin. The post carvedilol HVPG (post chronic) in carvedilol non responders was 14.457 mmHg which dropped to 13.029 mmHg, i.e., 1.428 mmHg drop (9.87%) by adding simvastatin. It means that, simvastatin is responsible for HVPG drop of 9.87% in isolation.

Baseline and hemodynamic parameters of patients in whom simvastatin was added are shown in the Tables 2 and 3.

Gender, etiology, C-P class, ascites and variceal size were not seen to be statistically significant between responders and non-responders in simvastatin protocol. Among baseline hemodynamic parameters, only pre WHPG was significantly higher in responders as compared to non-responders (*P* = 0.01). HVPG was higher, though not statistically significant predictor of response. All hemodynamic parameters significantly decreased from baseline after treatment with simvastatin except FHVP which was significantly raised. All hemodynamic parameter were significantly decreased after treatment with simvastatin except FHVP which was significantly raised with respect to their values after chronic treatment with carvedilol (chronic protocol). Pre (baseline), post chronic (chronic carvedilol at 3 mo) and post simvastatin haemodynamic parameters in carvedilol non responders

**Table 2** Baseline characteristics of 38 carvedilol non responders patients in whom Simvastatin was added

are shown as general linear model in Figure 2.

## DISCUSSION

The mechanism of portal hypertension primarily involves an increase in resistance to portal outflow circulation. It leads to the formation of portosystemic collateral veins, of which esophageal varices have the highest clinical impact and the most severe complications. Other manifestations of portal hypertension include portal hypertensive gastropathy and large spontaneous shunts which refer to presence of patent paraumbilical vein, spleno-renal shunt, ano-rectosigmoid varices<sup>[23]</sup>. Recently, it has been showed that identifying cirrhotic patients with high blood ammonia concentrations could be clinically useful, as high levels would lead to suspicion of being in presence of collaterals<sup>[24]</sup>. The first line pharmacological therapy in portal hypertension is NSBB therapy. It decreases portal pressure through a reduction in portal venous inflow as a result of a decrease in cardiac output ( $\beta_1$ -adrenergic blockade) and splanchnic blood flow ( $\beta_2$ -adrenergic blockade). However, a major drawback of NSBBs is that not all patients respond to beta-blockers with a reduction of the HVPg.

Clinicians and researchers have always been looking for a more powerful portal hypotensive agent than propranolol and nadolol either administered alone or combination with nitrovasodilators. Advantages of medical therapy include safety and correction of detrimental systemic effects of portal hypertension. Our study tries to use best portal hypotensive agent, *i.e.*, 3<sup>rd</sup> generation beta blocker (non-selective) with mild vasodilating properties, *i.e.*, carvedilol which has been proven to show excellent hemodynamic response on chronic basis to the tune of 50%-72% of patients<sup>[25]</sup>.

There are six studies which investigated chronic effects of carvedilol<sup>[26-28]</sup> with longest period of follow-up of 11 wk in one study. In another study by Stanley *et al.*<sup>[27]</sup>, seven of patients inclusively studied in acute protocol were unable to complete chronic administration of carvedilol as a result of side effects. This study suggests that, atleast for study group the administration of 25 mg without attempts to titrate according to response may

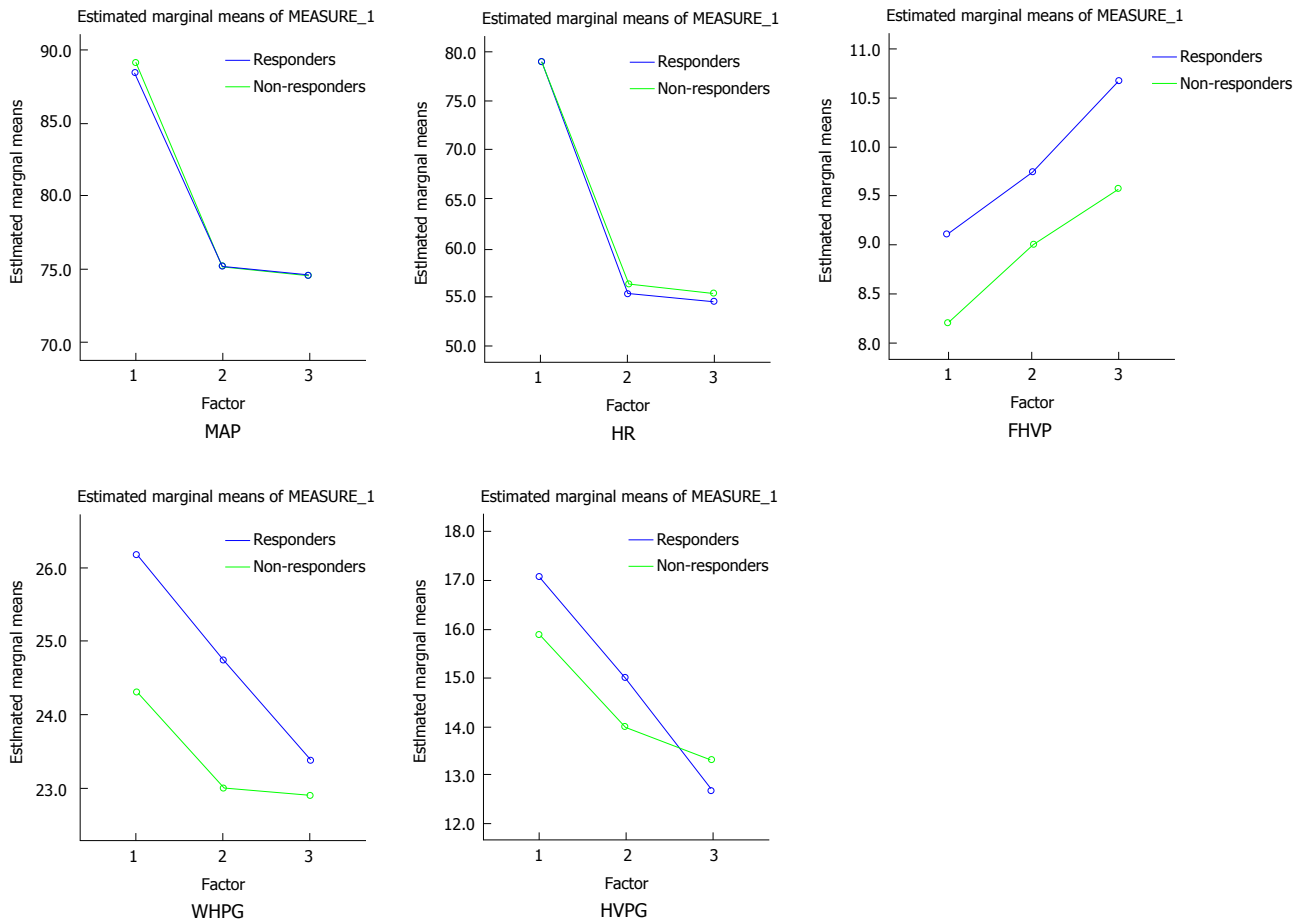

**Table 3** Hemodynamic parameters (mean) of studied population

Hemodynamic parameters	Baseline	Post chronic carvedilol (3 mo)	Post simvastatin
CO (L/min)	7.525 $\pm$ 0.19	6.38 $\pm$ 0.13	6.195 $\pm$ 0.17
HR (beats/min)	79.45 $\pm$ 2.50	57.45 $\pm$ 2.44	55.053 $\pm$ 1.67
MAP (mmHg)	89.53 $\pm$ 2.42	75.54 $\pm$ 1.97	74.500 $\pm$ 1.48
FHVP (mmHg)	8.28 $\pm$ 1.85	9.45 $\pm$ 1.90	10.086 $\pm$ 1.68
WHPG (mmHg)	25.08 $\pm$ 2.55	22.04 $\pm$ 2.56	23.114 $\pm$ 2.32
HVPG (mmHg)	16.75 $\pm$ 2.12	12.60 $\pm$ 2.24	13.029 $\pm$ 1.56

CO: Cardiac output; HR: Heart rate; MAP: Mean arterial pressure; FHVP: Free hepatic venous pressure; WHPG: Wedged hepatic venous pressure gradient; HVPG: Hepatic venous pressure gradient.

not be ideal. Keeping in view the results of the above study, we used a titration or dose optimization based strategy for assessing chronic carvedilol response. It also studies difference of response between early liver disease and advanced liver disease, *i.e.*, between C-P class A and B/C on chronic basis. Further this study looks into maximum dose tolerated by different C-P class of liver disease on chronic basis apart from looking into predictor of chronic response. Idea of our study was to further move to add an agent to carvedilol non responders which has no effects on MAP or peripheral vascular resistance and which behaves like a true liver selective vasodilator, *i.e.*, simvastatin. Thus, it is the first study which has used a new pharmacological agent simvastatin in carvedilol non responders. Additive effects of simvastatin may markedly increase the number of patients who are protected effectively from portal hypertensive related complication. Such an effect is in agreement with liver perfusion studies in experimental model of cirrhosis which showed statins exert their hepatic vasodilating effect by upregulating endothelial NO production<sup>[29,30]</sup>. Our study shows that, chronic carvedilol non-responders were 62 (60%) which increased to overall response of nearly 80% once simvastatin was added to it. Thus around 42% of carvedilol non responders became responders by adding simvastatin.

In titration protocol on chronic basis, mean dose of carvedilol was 18.7  $\pm$  5.1 mg and 19.7  $\pm$  5.4 mg in responders and non-responders respectively. It was difficult to further increase the carvedilol dose in non-responders because of apprehension of hypotension and bradycardia. On multivariate analysis, absence of adverse events (OR = 11.3, 95%CI: 1.9-67.8) were the only independent predictors of chronic response ( $P < 0.05$ ). Explanation for such results is that patients with less adverse events tolerated good dose to get good response. Major adverse events which resulted in drug discontinuation were hypotension in 2 patients and these patients could not be assessed further as shown in study design. Minor adverse events like fatigue, dyspnea, headache, temporary impotency, and dizziness were resolved without drug discontinuation. In addition, 2 patients had increase in ascites which resolved with escalation of diuretics. Further in our study, patients with

**Figure 2** General linear model comparing Pre (baseline), chronic (carvedilol at 3 mo) and post simvastatin haemodynamic parameters with respect to time in carvedilol responders and non-responders. HR: Heart rate; MAP: Mean arterial pressure; FHVP: Free hepatic venous pressure; WHPG: Wedged hepatic venous pressure gradient; HVPG: Hepatic venous pressure gradient.

C-P class A cirrhosis has shown better chronic response as compared to C-P class B and C but it was not statically significant.

Our studies showed that addition of simvastatin to carvedilol non responders can increase overall response to around 80%, which is one of the best possible pharmacologically produced chronic response and it opens a new strategy for portal hypertension treatment.

Etiology, C-P class, gender, ascites, adverse events, variceal size was not seen statically significant predictors of response for simvastatin protocol. Pre WHPG (baseline WHPG) was seen significantly higher among responders than non-responders and all hemodynamic parameters significantly decreased from baseline after treatment with simvastatin except FHVP which significantly raised. Similar results were observed after chronic treatment with carvedilol. In our study, HVPG after adding simvastatin decreased mainly because of increase in FHVP. Previous studies have shown that patients with cirrhosis have blood pooling in splanchnic region that correlates with degree of portal hypertension<sup>[20]</sup>. This might suggest that decreases in hepatic resistance by simvastatin could reduce splanchnic congestion and improving central blood volume<sup>[21]</sup> and alternatively simvastatin may have normalized venous compliance and by this mechanism

can inverse venacaval and right arterial pressure and thus increase FHVP.

It is well known that simvastatin improves hepatic clearance, intrinsic clearance, and hepatic extraction of indocyanine green, parameters that reflect effective liver perfusion. Thus, an increase in intrahepatic bioavailability of NO might result in improvement in amount of blood that has functional contact with hepatocytes that explains the improvement in quantitative tests of liver function after simvastatin. We have not done these tests of liver function in our study as it is already a proven fact<sup>[11,12]</sup>.

An important concern with the use of statins in patients with cirrhosis is potential for inducing liver toxicity. A number of studies have shown the safety of statins in patients with liver disease<sup>[31-33]</sup>. Our study particularly evaluated these issues in cirrhotic patients and our safety evaluation included Bil, ALP, GGT, ALT, AST, CPK and questionnaire for muscle weakness at 15<sup>th</sup> and 30<sup>th</sup> day of treatment. There was no major safety concern seen in our study. Some minor adverse events which were observed after addition of simvastatin are: (1) muscle weakness with CPK > 5 times in one patient and was withdrawn; (2) pruritis in one patient which settled and treatment continued; (3) diarrhea in one patient, self-settled and treatment continued; (4) severe dizziness and treatment

withdrawn; and (5) hepatic encephalopathy in one patient and withdrawn from the study, not related to simvastatin likely part of disease.

However, whether safety profile is maintained after long term administration needs further long term studies especially with larger doses in advanced liver disease. Newer drugs like rovastatin have been shown to be safe in chronic liver disease also.

Overall, 7 patients had adverse events, 4 (57.1%) among responders, and 3 (42.9%) among non-responders with no statistical significance. Three patients were withdrawn due to side effects, first one because of increase in CPK > 5 times with muscle weakness, second one developed dizziness and 3<sup>rd</sup> patients developed hepatic encephalopathy not related to simvastatin. Liver function test after 30 d and CPK did not change and remained static and no further side effects were observed after 30 d.

Thus in conclusion, our study is first study which clearly shows that a sequential treatment strategy is an excellent policy in the pharmacological management of portal hypertension by which around 80% of response can be achieved. Further long term safety profile of statins with large doses particularly in advanced disease needs further studies and safe drugs like pravastatin needs to be evaluated in future that can be used for adjuvant treatment along with carvedilol.

## COMMENTS

### Background

Carvedilol, a potent 3<sup>rd</sup> generation non-selective beta blocker (NSBB) has shown to be a promising therapy for reduction of portal hypertension. Although up to 60% of patients respond to carvedilol, options for carvedilol non responders in patients with portal hypertension is limited. Simvastatin improves liver generation of NO and hepatic endothelial dysfunction in patients with cirrhosis without affecting the hemodynamics such as heart rate and blood pressure. Hence, it could be used as an effective adjuvant therapy with carvedilol without causing any major side effects in patients with portal hypertension.

### Research frontiers

Current guidelines recommend using NSBB, such as propranolol or nadolol, with or without isosorbide-5-mononitrate to prevent variceal bleeding. Carvedilol, which blocks both  $\alpha$  and  $\beta$  receptors, was shown to have better results than NSBBs by further reducing intrahepatic resistance and thus, could be used for propranolol non-responders. However, treatment option for carvedilol non-responders has not been studied yet.

### Innovations and breakthroughs

Addition of simvastatin could be an important pharmacological rescue therapy for carvedilol nonresponders. This study showed that addition of simvastatin to carvedilol non responders can increase overall response to around 80%, which is one of the best possible pharmacologically produced chronic response and may open a new strategy for the treatment of portal hypertension.

### Applications

Addition of simvastatin to carvedilol non-responders may prove to be an excellent therapy in patients with portal hypertension.

### Terminology

NSBB are very useful drugs in preventing first variceal bleeding and re-bleeding in patients with cirrhosis.

## Peer-review

The observational study of Wani *et al* seems to be the first which demonstrate that a sequential treatment (carvedilol + simvastatin) strategy is an excellent policy in the pharmacological management of portal hypertension. The study is well designed and well presented.

## Abstract

### AIM

To investigate the relationship between vitamin D and liver fibrosis in hepatitis C-monoinfected or hepatitis C virus (HCV)-human immunodeficiency virus (HIV) co-infected patients.

### METHODS

Pertinent studies were located by a library literature search in PubMed/Embase/Cochrane/Scopus/LILACS by two individual reviewers. Inclusion criteria: (1) studies with patients with HCV or co-infected HCV/HIV; (2) studies with patients  $\geq 18$  years old; (3) studies that evaluated liver fibrosis stage, only based on liver biopsy; and (4) studies that reported serum or plasma 25(OH)D levels. Studies that included pediatric patients, other etiologies of liver disease, or did not use liver biopsy for fibrosis evaluation, or studies with inadequate data were excluded. Estimated measures of association reported in the literature, as well as corresponding measures of uncertainty, were recorded and corresponding odds ratios with 95%CI were included in a meta-analysis.

### RESULTS

The pooled data of this systematic review showed that 9 of the 12 studies correlated advanced liver disease defined as a Metavir value of F3/4 with 25(OH) D level insufficiency. The meta-analysis indicated a significant association across studies.

## CONCLUSION

Low vitamin D status is common in chronic Hepatitis C patients and is associated with advanced liver fibrosis.

**Key words:** Vitamin D; Liver fibrosis; Hepatitis C virus; Chronic hepatitis C

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Vitamin D levels are associated with more advanced fibrosis in chronic hepatitis C.

Influence of vitamin D on liver fibrosis in chronic hepatitis C: A systematic review and meta-analysis of the pooled clinical trials data. *World J Hepatol* 2017; 9(5): 278-287 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i5/278.htm> DOI: <http://dx.doi.org/10.4254/wjgh.v9.i5.278>

## INTRODUCTION

Hepatitis C virus (HCV) infection remains one of the most common etiologies of liver disease worldwide. A number of epidemiological papers have addressed the global prevalence of Hepatitis C. Lanini *et al.*<sup>[1]</sup> reported that 100 million people globally have serological evidence of current or past HCV infection causing 700000 deaths annually while others suggest that the actual occurrence is double<sup>[2]</sup>. HCV remains the most common indication for liver transplantation in the United States<sup>[3]</sup>. Chronic infection with HCV can lead to liver inflammation, liver fibrosis, cirrhosis, and hepatocellular carcinoma. Liver fibrosis is a result of excessive accumulation of extracellular matrix proteins, as part of the wound healing response to chronic injury and chronic inflammation<sup>[4]</sup>. Various factors have been associated with progression of fibrosis including duration of infection, age, male sex, diabetes, alcohol consumption and human immunodeficiency virus (HIV) co-infection<sup>[5]</sup>.

Vitamin D is a hormone that has numerous biological properties that influence host physiology by regulating epigenetic regulation of more than 2000 genes throughout the body. Vitamin D is best known for its role in maintaining bone mineralization but has diverse and profound influences which can determine disease development and outcome. Although referred to as a vitamin, this steroid hormone is synthesized in the body by a series of hydroxylation reactions that occur in skin (7-hydroxylation), the liver (25-hydroxylation) and the kidney (1-hydroxylation)<sup>[6]</sup> (Figure 1). Reduction of the enzymatic conversion of 7-dehydrocholesterol to 1,25 hydroxy vitamin D at any of the three conversion steps can result in suboptimal vitamin D status<sup>[7]</sup>. Vitamin D has a number of influences on innate and adaptive immunity which are pertinent to study in conditions that are driven by

**Figure 1 Vitamin D metabolism.** Vitamin D has diverse influences throughout the body as vitamin D receptors present on virtually every cell. The actions of vitamin D can be subdivided into two larger categories: Calcemic and non-calcemic actions. The non-calcemic actions of vitamin D are legion and have been reviewed elsewhere<sup>[6,54-56]</sup>. Reproduced with permission<sup>[6]</sup>.

chronic inflammation and maladaptive tissue injury<sup>[8,9]</sup>. Given the ubiquitous distribution of vitamin D receptors in virtually every cell in the body-suboptimal vitamin D status has been studied for its relationship to numerous diseases<sup>[10]</sup>. For example, there is substantial evidence that vitamin D benefits rheumatoid arthritis, due to its immunomodulatory effect<sup>[11]</sup>. The role of vitamin D in various cancers has been established linked to its anti-proliferative action mediated through vitamin D nuclear receptor<sup>[12]</sup>. There have been numerous reports on lower serum vitamin D levels in patients with chronic liver disease from various etiologies<sup>[13]</sup>. In chronic HCV, Low vitamin D levels have been reported in 46% to 92% of patients<sup>[10]</sup> raising suspicion of its potential contribution to disease pathogenesis. There is growing evidence from various groups, that vitamin D levels are inversely correlated with liver inflammation and stage of liver fibrosis in patients with HCV; however, the studies are heterogeneous with occasionally the results are conflicting. Additionally, the methods of reporting liver fibrosis were variable.

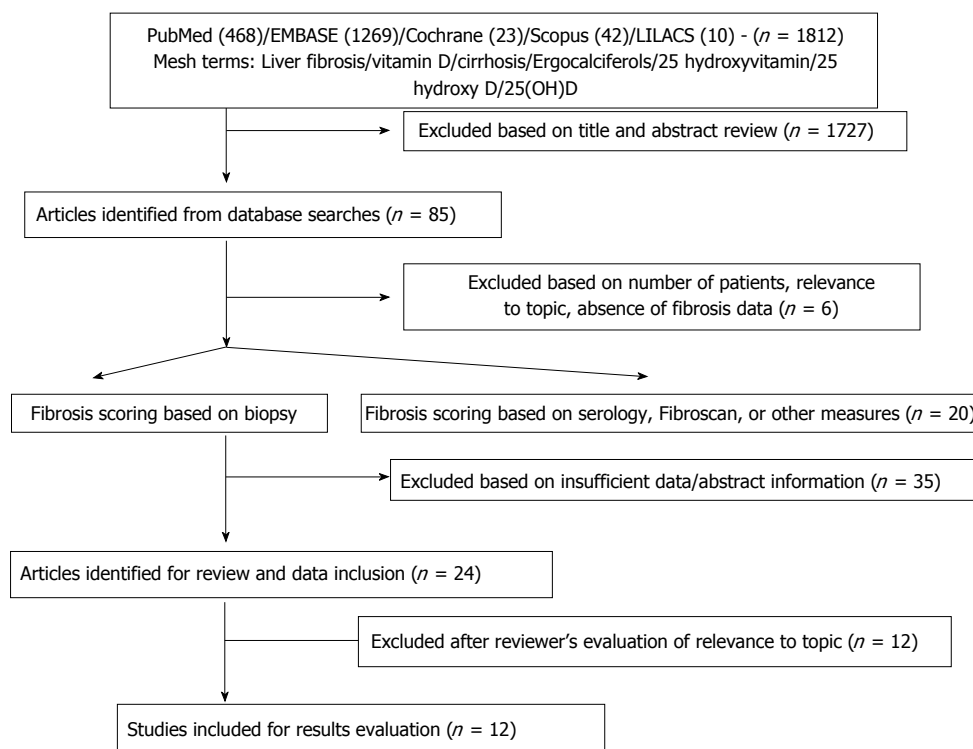

The aim of this study was to evaluate the relationship between vitamin D status and hepatic fibrosis based on histopathological staging in patients with chronic HCV mono-infection or co-infected HIV-HCV infection, by performing a systematic review of the scientific literature followed by a meta-analysis.

## MATERIALS AND METHODS

### Search method

Applicable studies were identified by a library literature search in Pubmed/Embase/Cochrane/Scopus/LILACS utilizing the PRISMA checklist<sup>[14]</sup> "Present full electronic search strategy for at least one database, including any limits used, such that it could be repeated" and the Cochrane review reporting guidelines (6.6.2.2)<sup>[15]</sup>.

**Figure 2 Flowchart of study selection process.** Eighteen hundred and twelve articles were identified using PubMed ( $n = 468$ )/EMBASE ( $n = 1269$ )/Cochrane ( $n = 23$ )/Scopus ( $n = 42$ )/LILACS ( $n = 10$ ) search engines. Detailed evaluation of the articles by at least two independent reviewers (total of three) narrowed the studies to twelve ( $n = 2521$ ) based upon inclusion and exclusion criteria as listed in Table 1.

The search terms were as follows: ["Liver cirrhosis" or "liver" and ("cirrhosis" or "fibrosis")] and ["vitamin D" or "Ergocalciferols" or "25 hydroxyvitamin D" or "25 hydroxy vitamin D" or "25 hydroxy D" or "25(OH)D"]. Also, the studies cited by the selected articles were searched for further pertinent studies. The search was performed before July 6, 2016.

### Selection criteria

The title and abstract of the studies were carefully reviewed by two individual reviewers, based on the inclusion and exclusion criteria. If there was an agreement between two reviewers, then the study was selected for further analysis. When there was a disagreement, a third reviewer determined if the study qualified for inclusion. Once the articles met the criteria, then the text was reviewed, and data extraction was completed.

Inclusion criteria: (1) studies with patients with HCV or co-infected HCV/HIV; (2) studies with patients  $\geq 18$  years old; (3) studies that evaluated liver fibrosis stage, only based on liver biopsy; and (4) studies that reported serum or plasma 25(OH)D levels. Exclusion criteria: (1) liver diseases other than hepatitis C; (2) studies with inadequate data; (3) studies that used non-invasive methods in evaluating liver fibrosis; and (4) age  $< 18$  years.

### Data extraction

A total of 12 studies were included for extraction which was performed by two independent reviewers based on

data quality, sufficiency, and relevance. Disagreements were resolved by a third reviewer to reach a consensus. The following data were extracted: Last name of the first author, demographic information of patients, publication year, sample size, HCV genotype, presence or absence of HIV co-infection, pathological fibrosis stage using Metavir score, vitamin D levels, and association of serum vitamin D level and fibrosis stage (Figure 2). The quality of evidence was ascertained by two independent reviewers using The Grading of Recommendations Assessment, Development and Evaluation (GRADE) analysis whereby very low = 1, low = 2, moderate = 3, high = 4<sup>[16]</sup>. The strength of recommendations were 1 (strong) or 2 (weak)<sup>[17]</sup>. When there was a disagreement, a third reviewer determined GRADE assessment and strength of recommendations.

### Statistical analysis

All statistical computations were conducted in R (Version 3.3.1, R Foundation for Statistical Computing, Vienna, Austria, 2016)<sup>[18]</sup>. Estimated odds ratios (OR) reported in the literature, as well as 95%CI, were inverted when necessary and included in a meta-analysis. In several studies, the odds ratio for severe fibrosis corresponding to vitamin D deficiency was not reported, but the distribution (mean and standard deviation or inter-quartile range) of vitamin D levels were reported for subjects with and without severe fibrosis separately. To estimate the odds ratio from these studies, a Monte Carlo simulation approach was adopted: For each such study, 1000

**Figure 3** Meta-analysis of the pooled data from the 12 included studies. The odds ratio for severe fibrosis comparing low vitamin D levels was estimated by meta-analyzing studies including a total of 2521 patients. Details concerning the analytic strategy are provided in the Materials and Methods section.

simulated studies were created assuming that vitamin D levels were normally distributed with the reported parameters and the observed number of subjects in each group. The odds ratio for severe fibrosis comparing vitamin D levels with a cutoff of 15 ng/mL was estimated for each simulated dataset. A sensitivity analysis was also conducted by using thresholds of 20 ng/mL and 30 ng/mL. The average odds ratio across simulated datasets were then estimated, and quantile-based confidence intervals were also recorded and included into the meta-analysis. A random-effects meta-analysis fit using restricted maximum likelihood was then fit using the Metafor package in R<sup>[19]</sup>.  $P < 0.05$  was considered statistically significant.

## RESULTS

The initial protocol established a series of mesh terms used to identify articles that would evaluate the severity of liver fibrosis in chronic hepatitis C patients with vitamin D levels. Eighteen hundred and twelve articles were found using PubMed ( $n = 468$ )/EMBASE ( $n = 1269$ )/Cochrane ( $n = 23$ )/Scopus ( $n = 42$ )/LILACS ( $n = 10$ ) search engines. Mesh terms used were liver fibrosis/

vitamin d/cirrhosis/Ergocalciferols/25 hydroxyvitamin/25 hydroxy d/25(OH) D. Detailed evaluation of the articles by at least two independent reviewers (total of three) assessed the sufficiency of data, method of fibrosis qualification, relevance to the topic to narrow the studies to twelve. The data extraction algorithm is summarized in Figure 3. Table 1 reflects the characteristics of the studies relating fibrosis to chronic hepatitis C and vitamin D level. When patients were stratified according to vitamin D status, we found substantial differences between the levels of severity of liver fibrosis. The sensitivity analysis with different cutoffs for the Monte Carlo simulations showed robustness of the result to the choice of cutoff, with significant effects for all thresholds employed.

### Definition of vitamin D levels

Vitamin D insufficiency was defined in most studies as below  $< 30$  ng/mL, and deficiency ranged from  $< 20$  ng/mL to 10 ng/mL. While there was some variability in these definitions, there was consistency in the lower limit of normal being  $< 30$  ng/mL. Two of the studies used nmol/L to express 25(OH)D, but were consistent with vitamin D insufficiency below the lower limit of normal  $< 80$  nmol/L.

**Table 1** Pooled data of vitamin D levels and liver fibrosis from the 12 included studies

Year	Author	Country	Design	n	HCV GT	HIV	Definition of vitamin D insufficiency (I)/deficiency (D)	Outcome (serum vitamin D and liver fibrosis)	P value/OR 95%CI	GRADE quality of evidence very low = 1, low = 2, moderate = 3, high = 4 and strength of recommendation: 2 = strong 1 = weak
2010	Petta	Italy	Prospective	197	1	No	< 30 ng/mL for low vitamin D level	Low 25(OH)D associated with severe fibrosis (F3/F4)	0.942 [0.893, 0.994] P = 0.009	GRADE 3 Strong

2015	Esmat	Egypt	Prospective	101	4	No	< 20 ng/mL (D), 20-30 (I)	No correlation found between vitamin D levels and stage of liver fibrosis	P = 0.26	Weak GRADE 3

HCV: Hepatitis C virus; HIV: Human immunodeficiency virus; GRADE: Grading of Recommendations Assessment, Development and Evaluation.

**Table 2 Selection criteria for inclusion and exclusion**

Inclusion criteria
Age $\geq$ 18 yr
Studies including mono-infected HCV or co-infected HCV/HIV
Studies that evaluated liver fibrosis stage, only based on liver histology
Studies that reported serum or plasma 25(OH)D levels
Exclusion criteria
Age < 18 yr
Other etiologies of liver disease, other than hepatitis C
Studies that used non-invasive methods in evaluating liver fibrosis
Inadequate data

HCV: Hepatitis C virus; HIV: Human immunodeficiency virus.

### Association between vitamin D deficiency and severity of liver disease

Among the articles used for data extraction, there were seven prospective studies, three retrospective studies, one cross-sectional analysis, and one cohort study (Table 1). In a review of the results, nine studies demonstrated a significant association between plasma levels of vitamin D and degree of HCV-related hepatic fibrosis. Three studies showed no correlation was found between vitamin D levels and stage of liver fibrosis. Patient characteristics between these studies were all similar and could not account for the variability of the findings between the three negative studies and the nine positive studies. Only one of the three negative studies was conducted in the northern hemisphere. Overall, hepatitis C genotypes were not different among the negative studies, although El-Maouche *et al*<sup>[20]</sup> did not identify which genotype(s) were included. The forest plot of the data used in this systematic review showed that advanced liver disease defined as a Metavir value of F3/4 was associated with severe 25(OH)D insufficiency as follows; OR (95%CI): 1.88 (1.27, 2.77), and  $I^2$  (total heterogeneity/total variability): 66.94% indicated substantial heterogeneity between studies.

### Plasma vitamin D levels and seasonal variation

Notably there were several latitudes identified in the studies which can affect Vitamin D levels, however, the scope of this difference in this analysis's outcome was not assessed. In the article by Guzmán-Fulgencio *et al*<sup>[21]</sup> significant seasonal variation of plasma 25(OH)D levels was observed with the subjects in the first semester (winter/spring) having lower plasma 25(OH)D levels than patients evaluated in the second semester (summer/autumn) ( $P < 0.001$ ). A higher percentage of patients with vitamin D deficiency (25(OH)D < 25 nmol/L) was found in the first semester (winter/spring) ( $P < 0.001$ ). Since not all the studies identified the time frame of vitamin D levels and biopsy procurement, we were unable to qualify the significance of this on the study results.

## DISCUSSION

The results of our systematic analysis of the literature

demonstrated an association between advanced liver fibrosis (defined as Metavir F3/F4) in chronic hepatitis C (CHC) with vitamin D status as reflected by 25-hydroxyvitamin D [25(OH)D] serum levels. In nine<sup>[21-29]</sup> of twelve studies (75%) that qualified for data extraction (Tables 1 and 2) the final analysis demonstrated an overall association between low vitamin D status as defined as serum 25(OH)D < 15 ng/mL with advanced liver fibrosis (F3/F4 stage disease) in CHC as proven by biopsy analysis for fibrosis stage. These data are highly consistent with prior reports, and the expected pathophysiological interference of 25-hydroxylation of vitamin D as liver fibrosis increases and functional hepatic capacity decreases over the course of hepatitis C disease progression<sup>[6]</sup>.

A recent systematic review of the literature by Abbasi *et al*<sup>[30]</sup> studied the relationship between low vitamin D status [ $< 20$  ng/mL 25 OH(D)] and the severity of the CLD. A comparatively abridged search strategy yielded 641 articles for consideration and ultimately 19 articles and 4895 study patients with CLD for data extraction showing that almost 80% of patients with chronic liver disease had severe vitamin D deficiency. García-Álvarez *et al*<sup>[31]</sup> conducted a systematic review evaluating the relationship of vitamin D status to advanced liver fibrosis in CHC-naïve patients and sustained virological response (SVR) to therapy using pegylated interferon/ribavirin (Peg-IFN/RBV). Seven of fourteen papers utilized for their extraction evaluated advanced liver fibrosis (1083 patients) and eleven for SVR (2672 patients). Approximately 70% of CHC patients had low 25(OH)D whereby the definition of insufficiency varied (20 or 30 ng/mL), and 50% of the HCV-infected patients had 25(OH)D levels < 10 or 20 ng/mL. Overall, low vitamin D status was related to a diagnosis of advanced stage of liver disease. Luo *et al* utilized a search methodology restricted to PubMed and Embase databases before October 2013 included studies that analyzed the association between serum vitamin D status and the severity of liver fibrosis in 8231 CHC patients without other restrictions yielding six global studies for data extraction<sup>[13]</sup>. One study recruited 6567 participants as part of the Swiss Hepatitis C Cohort Study<sup>[23]</sup> raising concerns for skewing of the extracted data. The mean data from extracted studies suggested that lower serum vitamin D is a risk factor for progressive liver fibrosis in CHC patients. However, there was a high heterogeneity and inconsistencies depending upon data set utilized (OR data studies vs mean data extracted). Our search methodology instead included 2521 patients which incorporated the 2012 study by Lange *et al*<sup>[32]</sup> which evaluated 468 HCV patients treated with alpha interferon-based regimens for vitamin D status and advanced disease demonstrating that fibrosis stages F2-F4 vs F0-F1 associated with low 25(OH)D.

The nine studies showing a positive association between low vitamin D with an advanced stage of fibrosis had variations in their definition of vitamin D status which challenged our ability to Meta-analyze the data. Low vitamin D was stratified according to by either

insufficient (I) or deficient (D) (Table 1) in eight<sup>[21-27,29]</sup> of the nine studies. Gerova *et al.*<sup>[28]</sup> used three categories; mild insufficiency, profound insufficiency, and deficiency. Overall, of the twelve papers in our final analysis, two<sup>[28,33]</sup> utilized nmol/L to measure serum 25(OH) vitamin D status. Insufficiency was defined as < 30 ng/mL in seven with another two using equivalent levels in nmol/L<sup>[28,34]</sup>, < 20 ng/mL in two<sup>[23,25]</sup> while El-Maouche studied only deficient patients (< 15 ng/mL)<sup>[20]</sup>. The definition of "deficiency" was utilized by all but two<sup>[20,34]</sup> of the studies as < 10 ng/mL 25(OH) vitamin D. The prevalence of vitamin D deficiency in a population depends on upon the definition used [ $< 20$  or  $< 30$  ng/mL (50 or 75 nmol/L)]. In the National Health and Nutrition Examination Survey (NHANES), 41.6 percent of United States adults had (25[OH]D) levels < 20 ng/mL (50 nmol/L)<sup>[35]</sup>. The Institute of Medicine recommends the attainment of the serum 25(OH)D levels of  $> 20 < 40$  ng/mL (50 to 100 nmol/L), however, many define sufficient vitamin D status as 25(OH)D  $> 30$  and  $< 50$  ng/mL (75 to 125 nmol/L)<sup>[36,37]</sup>.

Hepatitis C genotype (1-6) did not change the outcome of analyses between advanced fibrosis in CHC with vitamin D status<sup>[20,33,34]</sup>. The geographical latitudes of study site and variable seasonal fluctuations have provided challenges to vitamin D status, but did not appear to influence the outcome of the negative outcome studies<sup>[20,33,34]</sup>. Esmat *et al.*<sup>[34]</sup> conducted a open-labelled RCT of 101 HVC4 Egyptian patients undergoing standard of care (SOC) Peg-IFN/RBV plus/minus 15000 IU vitamin D<sub>3</sub> (cholecalciferol). The fibrosis stage (F1-F3) at baseline was not different according to 25(OH) vitamin D levels. El-Maouche *et al.*<sup>[20]</sup> evaluated HIV-HCV co-infected patients for histological fibrosis using the Metavir system [0 (no fibrosis) to 4 (cirrhosis)] and used banked serum as a source for vitamin D determination. Similar to Esmat *et al.*<sup>[34]</sup>, the prevalence of significant fibrosis (F2  $\geq$  2) was similar among those with and without low vitamin D while low 25(OH)D status was not associated with significant fibrosis after adjusting for other confounders. Finally, Kitson *et al.*<sup>[38]</sup> from Australia evaluated pre-treatment 25-hydroxyvitamin D [25(OH)D] level in a cohort of 274 treatment-naïve patients with HCV-1 to evaluate the association between vitamin D status, virological response, and liver histology after 48 wk of pegylated interferon alfa-2a plus ribavirin therapy. Baseline 25(OH)D level did not vary with fibrosis stage (F3/4 vs F0-2).

The manner by which vitamin D may influence the course of CHC may be due to effects on viral clearance, immune modulation, cell differentiation and proliferation and inflammation regulation. Vitamin D is not only involved in calcium homeostasis but has also has been associated with the mechanism of cellular proliferation, and immunomodulation<sup>[39]</sup>. Several studies have shown that vitamin D levels are inversely correlated with stage of liver fibrosis in patients with CHC. Nine<sup>[21-29]</sup> of the twelve studies that we included for data extraction reported the inverse correlation of vitamin D levels with the stage of liver fibrosis in patients with CHC. Vitamin D has anti-

inflammatory, anti-proliferative and anti-fibrotic effects that dampen inflammatory cell recruitment to the liver and mitigate hepatic fibrosis progression<sup>[40]</sup>. HCV may also have its own direct actions that impair vitamin D activity and status. It has been hypothesized that HCV affects 25-hydroxylation of vitamin D through cytokine induction or oxidative stress or through disruption in lipid metabolism where HCV suppress 25(OH)D levels due to a decrease in the production of vitamin D precursor, 7-dehydrocholesterol<sup>[10]</sup>.

The profound relationship of vitamin D to immunity and inflammation, and our findings raise questions about how vitamin D status may impact the outcome of the many non-HCV chronic liver diseases. Individuals with chronic liver disease have significant global prevalence, morbidity, poor quality of life and mortality. Prior works have demonstrated adverse survival outcomes in patients with lowered vitamin D status<sup>[41,42]</sup>. In our analyses, we excluded papers reporting the analysis of vitamin D in chronic liver diseases other than HCV including chronic hepatitis B (CHB) which has a higher global prevalence of approximately 300 million infected individuals. Yu *et al.*<sup>[43]</sup> evaluated the potential association between serum vitamin D level and liver histology or virological parameters in treatment-naïve patients with chronic hepatitis B infection in Southern China. They reported that patients infected with genotype B had a higher prevalence of vitamin D insufficiency than individuals with CHC. Furthermore, in chronic hepatitis B patients, serum 25(OH) D was not correlated with viral load or fibrosis. Mi *et al.*<sup>[44]</sup> reported that vitamin D status was not different among Asians with non-cirrhotic CHB and CHC.

Low vitamin D status is associated with the risk of progression and the severity of hepatic inflammation in patients with non-alcoholic fatty liver disease<sup>[45,46]</sup>. Primary biliary cirrhosis has been extensively analyzed for correlations of vitamin D status predicting the outcome to ursodeoxycholic acid (UCDA) therapy and the influence of vitamin D supplementation to UCDA intervention<sup>[47-49]</sup>. Autoimmune hepatitis (AIH) has also been studied for the potential influence of vitamin D given the epidemiological association of this hormone with a number of diseases with autoimmunity<sup>[50,51]</sup>. However, there are not sufficient studies to draw meaningful conclusions of serum 25(OH)D and AIH at this time.

Altered vitamin D physiology *via* resistance from genetic polymorphisms of the vitamin D receptor (VDR) could also influence the outcome of CHC. Baur *et al.*<sup>[25]</sup> demonstrated that low 25(OH)D plasma levels and VDR bAt[CCA]haplotype were associated with rapid fibrosis progression in CHC, separately and synergistic when co-present. Petta *et al.*<sup>[52]</sup> reported that low hepatic VDR expression was inversely related to the severity of advanced liver fibrosis in patients with genotype 1 cCHC patients. Grunhage reported that a single nucleotide polymorphism (SNP) linked to the *DHCR7* gene coding vitamin D precursor dehydrocholesterol was related to altered serum 25(OH)D in chronic liver disease patients

with no or mild fibrosis<sup>[53]</sup>.

CHC with severely low vitamin D status is accompanied by advanced liver fibrosis. Interventional trials aimed to normalize vitamin D status in early stages of CHC may shed light on whether correction of vitamin D status in this patient population should become the standard of care.

## COMMENTS

### Background

Hepatitis C remains a global health burden affecting over 100 million people worldwide. There is growing evidence that vitamin D is inversely associated with liver inflammation and fibrosis in patients with chronic hepatitis C.

### Research frontiers

Currently hepatitis C is being dramatically eradicated with DAA therapy. Possible augmentation of DAA therapy by vitamin D in those patients who already have fibrosis may decrease long term damage in the liver parenchyma.

### Innovations and breakthroughs

The pooled data of this systematic review showed that 9 of the 12 studies correlated advanced liver disease defined as a Metavir value of F3/4 with 25(OH) D level insufficiency. The meta-analysis indicated a significant association across studies. Low vitamin D status is common in chronic Hepatitis C patients and is associated with advanced liver fibrosis.

### Applications

Augmentation of standard hepatitis C therapy of direct acting antiviral meds with vitamin D may assist with long term decrease in liver fibrosis.

### Peer-review

This is a very interesting and informative paper, and it deserves publication.

### Abstract

#### AIM

To reduce hepatic and extrahepatic complications of chronic hepatitis C in kidney transplant recipients.

#### METHODS

We conducted a systematic review of kidney only transplant in patients with hepatitis C and advanced fibrosis.

#### RESULTS

The 5 year patient survival of kidney transplant recipients with and without hepatitis C cirrhosis ranged from 31% to 90% and 85% to 92%, respectively. Hepatitis C kidney transplant recipients had lower 10-year survival when compared to hepatitis B patients, 40% and 90% respectively. There were no studies that included patients with virologic cure prior to kidney transplant that reported post-kidney transplant outcomes. There were no studies of direct acting antiviral therapy and effect on patient or graft survival after kidney transplantation.

#### CONCLUSION

Data on kidney transplant only in hepatitis C patients that reported inferior outcomes were prior to the development of potent direct acting antiviral. With the development of potent direct acting antiviral therapy for hepatitis C with high cure rates studies are needed to determine if patients with hepatitis C, including those with advanced fibrosis, can undergo kidney transplant alone with acceptable long term outcomes.

**Core tip:** Individuals with chronic hepatitis C with advanced fibrosis and kidney failure who undergo kidney transplant alone are believed to have lower long-term survival. Surprisingly, we have only a few studies with inconsistent results. The concern about isolated-kidney-transplant alone is that the liver disease would progress to decompensated cirrhosis and liver failure in the setting of immunosuppression after kidney transplant. Earlier, interferon was associated with low virologic cure and high adverse events including graft rejection. However, with development of newer directly acting anti-virals we wish to invite our readers to reconsider the need for a combined liver-kidney transplant in hepatitis C patients with advanced fibrosis or compensated cirrhosis.

Shah NJ, Russo MW. Is it time to rethink combined liver-kidney transplant in hepatitis C patients with advanced fibrosis? *World J Hepatol* 2017; 9(5): 288-292 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i5/288.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i5.288>

## INTRODUCTION

Patients with hepatitis C virus (HCV) cirrhosis undergoing kidney transplantation only have lower post-transplant survival rates compared to recipients without hepatitis C or cirrhosis<sup>[1]</sup>. After the implementation of the model for end-stage liver disease (MELD) scoring system for allocating liver transplants, the number of simultaneous liver-kidney transplantation has increased by 300%<sup>[2]</sup>. Some of these patients may have relatively well compensated cirrhosis and patients with well compensated cirrhosis but kidney failure may receive a MELD score of 20 based upon a creatinine of 4 mg/dL. These patients may have compensated cirrhosis without complications of portal hypertension. Thus, kidney failure, not liver failure may be the driving factor for priority for liver transplant in this subgroup. This is particularly relevant in areas of the country where patients may receive liver transplants at relatively low MELD scores compared to areas with higher demand.

The reason for dual listing patients with hepatitis C cirrhosis and kidney failure who may be well compensated is the concern of decompensation after liver-kidney transplant. Immunosuppressive therapy to prevent rejection increases the titers of HCV RNA and immunosuppression has been associated with accelerated hepatitis injury such as fibrosing cholestatic hepatitis C<sup>[3]</sup>. However, the impact on treating and curing candidates before or after kidney transplant has not been well studied. The high virologic cure rates may have important implications for patients in kidney failure with hepatitis C and advanced liver fibrosis.

The guidelines for liver kidney transplant are conflicting or without detailed recommendations. The AASLD

and KDIGO guidelines do not directly address the issue of isolated kidney transplant in the setting of cirrhosis or advanced liver fibrosis. The EASL guidelines state that patients with established cirrhosis and portal hypertension who fail (or are unsuitable for) HCV antiviral treatment, isolated renal transplantation may be contra-indicated and consideration should be given to combined liver and kidney transplantation<sup>[4]</sup>. Patients with symptomatic or presence of portal hypertension are considered candidates for kidney-liver transplantation<sup>[2]</sup>. There is no consensus for patients with hepatitis C and periportal fibrosis or bridging fibrosis who are kidney transplant candidates.

The aim of this systematic review was to assess the outcome of hepatitis C cirrhotics undergoing kidney only transplant and suggest areas for further study in patients with hepatitis C and advanced fibrosis who are kidney transplant candidates.

## MATERIALS AND METHODS

### Literature search

We conducted online electronic searches (published human clinic trials in English) of the National Library of Medicine's (Bethesda, MD, United States) MEDLINE database, Cochrane Library and manual searches of selected specialty journals to identify any pertinent literature. Three MEDLINE database engines (Ovid, PubMed and EMBASE) were searched using the key words "cirrhosis", "cirrhotics", "chronic hepatitis C", "renal transplantation", "kidney transplantation", "mortality", "graft outcomes". The references of articles were reviewed for additional articles.

### Inclusion criteria

Clinical studies (prospective and retrospective) from the last 20 years on kidney transplant recipients with HCV cirrhosis (both compensated and decompensated) were included. The studies required a minimum of a 1 year post transplant follow-up with information regarding graft and patient survival outcomes.

### Exclusion criteria

Studies not published in English or published only in the abstract form were excluded.

### Primary end point

To compare post kidney transplant survival in hepatitis C cirrhotics undergoing kidney transplant alone to recipients without hepatitis C and without cirrhosis.

### Source of support

This systematic review was not supported by any pharmaceutical company, governmental agency or other grants.

## RESULTS

Figure 1 shows studies<sup>[5-9]</sup> in patients with hepatitis C

Figure 1 Studies in patients with hepatitis C who underwent kidney transplant only. HCV: Hepatitis C virus.

Figure 2 Graft survival in kidney only transplant patients. HCV: Hepatitis C virus.

who underwent kidney transplant only. Five studies were identified that included 2511 patients. Of these 2511 patients, 458 had hepatitis C while 69 were confirmed to have cirrhosis based on a liver biopsy. The mean age ranged from 35 to 57 years with a male to female ratio of 1.73:1. The study by Mathurin *et al*<sup>[6]</sup> consisted of 66% Europeans and 31% Africans, while in most of the other studies 66%-79% of the study population was African-American. The most common etiology of kidney disease was diabetes mellitus. Only one study provided the mean MELD score (20.6)<sup>[9]</sup>. Data on hepatitis C genotyping was not reported in any study. In all the studies the donors were deceased donors. One patient in the Mouquet *et al*<sup>[5]</sup> study was coinfectd with hepatitis B. Two studies reported the specific immunosuppressive regimen with either cyclosporine or tacrolimus.

### Outcomes of studies

The studies reported either 1, 3, 5 or 10 year survival of HCV cirrhotics vs non-cirrhotics. One year and three year survival were available for 3 studies. The 1-year and 3-year patient survival was 88.9% to 95% and 37% to 90% in cirrhotics vs 95% to 96.3% and 76% to 90% in non-cirrhotics. The 5-year and 10-year graft survival was 31%-90% and 33%  $\pm$  11% in cirrhotics when compared to 85%-92% and 69%  $\pm$  7% in non-cirrhotics.

Mathurin *et al*<sup>[6]</sup> reported that the presence of cirrhosis ( $P = 0.02$ ) and HbsAg positive status ( $P < 0.0001$ ) were associated with poor 5 and 10-year survival, 84%

$\pm$  7% and 33%  $\pm$  11%, respectively. Maluf *et al*<sup>[7]</sup> demonstrated the Knodell histology score was associated with mortality in hepatitis C kidney transplant patients ( $P = 0.012$ ).

The study by Campbell *et al*<sup>[8]</sup> reported that survival after kidney transplant only in recipients with hepatitis C was similar between patients with minimal liver fibrosis compared to patients with advanced fibrosis. Paramesh *et al*<sup>[9]</sup> reported kidney transplant alone to be safe in compensated hepatitis C cirrhosis; HR = 1.4,  $P = 0.7817$  compared to graft survival in non-cirrhotics: HR = 0.81,  $P = 0.758$ ) (Figure 2).

## DISCUSSION

Individuals with chronic hepatitis C with advanced fibrosis and kidney failure who undergo kidney transplant alone are believed to have lower long term survival although there are surprisingly few studies on this patient population. Furthermore, there has not been consistent results among studies reporting outcomes of isolated kidney transplant in hepatitis C infected recipients. The concern about isolated kidney transplant alone in a patients with hepatitis C and advanced liver fibrosis is that the liver disease will progress to decompensated cirrhosis and liver failure in the setting of immunosuppression after kidney transplant. The progression of liver disease from hepatitis C after kidney transplant was of particular concern during the interferon era because of limited

therapy for hepatitis C. Interferon is associated with low virologic cure and high adverse events including graft rejection. However, with the development of interferon free regimens and direct acting antiviral agents the need of combined liver-kidney transplant in hepatitis C patients who have hepatitis C and advanced fibrosis or compensated cirrhosis needs to be readdressed.

Patients with cirrhosis after kidney transplant may be at a greater risk of immune dysfunction and developing lethal infections because patients with cirrhosis have multiple immunological defects. Cirrhotic patients have reduced cell-mediated immunity<sup>[10,11]</sup> reduced neutrophil phagocytic ability<sup>[12]</sup> and impaired macrophage Fc receptor function<sup>[13]</sup>. In the setting of immunosuppression the risk of infection in patients with cirrhosis is likely higher than without immunosuppression. However, if liver fibrosis regresses then the risk of infection may be reduced. In a 10-year study following 51 kidney transplant recipients with hepatitis C who underwent serial liver biopsies, Kamar *et al*<sup>[14]</sup> showed that HCV infection was not associated with worsening liver histology in 50% of patients. Furthermore, there may be regression of liver fibrosis in some patients after kidney transplantation<sup>[15]</sup>. In fact, Paramesh *et al*<sup>[9]</sup> concluded that the presence of cirrhosis in HCV-positive patients is not a significant variable affecting either graft or patient survival.

One strategy is to treat all chronic hepatitis C patients with direct acting antiviral therapy while waiting for kidney transplant. The regimens that are currently available include sofosbuvir/ledipasvir, sofosbuvir/daclatasvir, and paritaprevir/ritonavir/ombitasvir/dasabuvir. Each of these regimens may require the addition of ribavirin depending on patient characteristics such as genotype or presence of cirrhosis. Sofosbuvir is renally cleared and not indicated in patients with glomerular filtration rates less than 30 mL/min. Ribavirin is renally cleared and although there is renal dosing for ribavirin it may be associated with a 2-4 g/dL drop in hemoglobin which may not be tolerated in some patients with kidney failure. Thus, given these limitations many patients with kidney failure may not be candidates for therapy with the currently available direct acting antiviral agents. Paritaprevir/ritonavir/ombitasvir/dasabuvir has been studied in patients with hepatitis C and kidney failure with virologic cure rates exceeding 85%<sup>[16]</sup>. There are other direct acting antiviral agents in development for hepatitis C patients with kidney failure that will provide additional treatment options for this patient population.

During the era of interferon based regimens for hepatitis C high rates of rejection in kidney transplant recipients was reported. Rejection rates of 40%-60% were reported with interferon based regimens with rare cases of graft loss<sup>[17-22]</sup>. The mechanism of rejection is believed to be the immune mediated injury from interferon. The direct-acting antiviral agents regimens are interferon free and due not stimulate the T cell response and should not be associated with rejection. The direct acting agents have been studied in liver transplant recipients with virologic cure exceeding 90% and

acceptable safety profile with little or no rejection<sup>[23-27]</sup>. Although there is no theoretical reason to believe the direct acting antiviral agents would be associated with increased risk of kidney rejection this would be studied in clinical trials. Additional important findings from this review include the lack of reporting of relevant data related to hepatitis C including genotype, liver fibrosis, viral load and prior treatment history. Studies of hepatitis C in patients with kidney disease should systematically report these data in a standardized fashion. Furthermore, the number of subjects with hepatitis C and advanced fibrosis was small and it is likely a multicenter study will best demonstrate if there is any difference in outcomes between kidney transplant recipients without hepatitis, with hepatitis C and mild liver fibrosis, and hepatitis C and advanced fibrosis.

We suggest we should treat all chronic hepatitis C patients irrespective of the fibrotic staging; especially those that we anticipate may be on the waiting list for a longer time.

In conclusion, data are lacking or outdated on post renal transplant outcomes in recipients with chronic hepatitis C. There is no substantiated evidence on which to base a decision to perform kidney transplant alone or a kidney-liver transplantation in a patient with chronic hepatitis C and advanced fibrosis or well compensated cirrhosis. Given limited resources of organs data are sorely needed so evidence based decisions can be made on how best to allocate kidneys in patients with liver disease. The time has come to conduct a large multicenter trial in kidney transplant candidates and recipients with hepatitis C to determine how organs should best be allocated.

## COMMENTS

### Background

Individuals with chronic hepatitis C with advanced fibrosis and kidney failure who undergo kidney transplant alone are believed to have lower long-term survival. Surprisingly, the authors have only a few studies with inconsistent results. The concern about isolated-kidney-transplant alone is that the liver disease would progress to decompensated cirrhosis and liver failure in the setting of immunosuppression after kidney transplant.

### Research frontiers

With further research on the use of direct-acting antiviral agents's (DAA's) in this subgroup of patients with hepatitis C virus (HCV) listed for renal transplant; the authors could come to a consensus to draft acceptable guidelines for better management of this subgroup of patients.

### Innovations and breakthroughs

Earlier, interferon was associated with low virologic cure and high adverse events including graft rejection. This has been replaced by newer DAA's that are safe and potent with fewer side events.

### Applications

The main objective is to invite hepatologist, transplant hepatologist and transplant nephrologist to consider DAA's in all HCV patients on the renal transplant list.

### Terminology

DAA's: Directly acting anti-virals.

# Peer-review

This is a correct, well-written review on the different autoimmune forms of liver disease, clinical manifestations and evolution, and treatment.

- 310 Fibrosis assessment using FibroMeter combined to first generation tests in hepatitis C  
*Chindamo MC, Boursier J, Luiz RR, Fouchard-Hubert I, Pannain VLN, de Araújo Neto JM, Coelho HSM, de Mello Perez R, Calès P, Villela-Nogueira CA*

#### Observational Study

- 318 Thrombocytopenia in cirrhosis: Impact of fibrinogen on bleeding risk  
*Thakrar SV, Mallett SV*

### SYSTEMATIC REVIEWS

- 326 Sarcopenia and non-alcoholic fatty liver disease: Is there a relationship? A systematic review  
*Tovo CV, Fernandes SA, Buss C, de Mattos AA*

### META-ANALYSIS

- 333 Vitamin E for the treatment of children with hepatitis B e antigen-positive chronic hepatitis: A systematic review and meta-analysis  
*Fiorino S, Bacchi-Reggiani ML, Leandri P, Loggi E, Andreone P*

### CASE REPORT

- 343 Hyperammonemia crisis following parturition in a female patient with ornithine transcarbamylase deficiency  
*Kido J, Kawasaki T, Mitsubuchi H, Kamohara H, Ohba T, Matsumoto S, Endo F, Nakamura K*

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Savio John, MD, Assistant Professor, Division of Gastroenterology, Department of Medicine, State University of New York Upstate Medical University, Syracuse, NY 13210, United States

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Hepatorenal syndrome (HRS) is a manifestation of extreme circulatory dysfunction and entails high morbidity and mortality. A new definition has been recently

recommended by the International Club of Ascites, according to which HRS diagnosis relies in serum creatinine changes instead that on a fixed high value. Moreover, new data on urinary biomarkers has been recently published. In this sense, the use of urinary neutrophil gelatinase-associated lipocalin seems useful to identify patients with acute tubular necrosis and should be employed in the diagnostic algorithm. Treatment with terlipressin and albumin is the current standard of care. Recent data show that terlipressin in intravenous continuous infusion is better tolerated than intravenous boluses and has the same efficacy. Terlipressin is effective in reversing HRS in only 40%-50% of patients. Serum bilirubin and creatinine levels along with the increase in blood pressure and the presence of systemic inflammatory response syndrome have been identified as predictors of response. Clearly, there is a need for further research in novel treatments. Other treatments have been assessed such as noradrenaline, dopamine, transjugular intrahepatic portosystemic shunt, renal and liver replacement therapy, *etc.* Among all of them, liver transplant is the only curative option and should be considered in all patients. HRS can be prevented with volume expansion with albumin during spontaneous bacterial peritonitis and after post large volume paracentesis, and with antibiotic prophylaxis in patients with advanced cirrhosis and low proteins in the ascitic fluid. This manuscript reviews the recent advances in the diagnosis and management of this life-threatening condition.

**Key words:** Hepatorenal syndrome; Acute-on-chronic liver failure; Liver cirrhosis; Terlipressin; Acute kidney injury

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Hepatorenal syndrome (HRS) is a life-threatening complication present in very advanced liver cirrhosis. This manuscript addresses many recent advances in this field, including the recent change in the definition of HRS according to acute kidney injury

criteria, the potential consequences of the adoption of this new definition, and the use of biomarkers to help in the diagnostic algorithm. Moreover, it reviews the recent advances in treatment of HRS such as the use of continuous infusion of terlipressin instead of bolus and the low efficacy of midodrine plus octreotide. Potential areas of research are identified as well.

Acevedo JG, Cramp ME. Hepatorenal syndrome: Update on diagnosis and therapy. *World J Hepatol* 2017; 9(6): 293-299 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i6/293.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i6.293>

## INTRODUCTION

Hepatorenal syndrome (HRS) is a manifestation of extreme circulatory dysfunction. It develops in the setting of advance stage in cirrhosis and carries an ominous prognosis.

HRS is diagnosed clinically. Its definition has been updated recently in accordance with the acute kidney injury (AKI) criteria.

Current standard of care involves the use of vasoconstrictor therapy (*i.e.*, terlipressin) and volume expansion with albumin. Treatment is effective in only 40%-50% of cases and it recurs in up to 50% of those cases responding to treatment. Liver transplant (LT) should be considered in all patients without contraindications for it.

Areas of research would be aimed at improving the accuracy of diagnosis of HRS, identifying predictors of non-response, and testing novel treatments.

## PATHOPHYSIOLOGY

HRS is caused by extreme circulatory dysfunction. Hepatocytes and stellate cells in a cirrhotic liver produce numerous local acting vasodilators such as nitric oxide, cannabinoids, *etc.* These vasodilators act locally on the splanchnic circulation producing splanchnic arterial vasodilation. Splanchnic circulation represents an important part of the circulation of the body. Thus, splanchnic vasodilation produces a decrease in mean arterial pressure (MAP), which in turn triggers the activation of the sympathetic nervous system, leading to high levels of circulating noradrenaline, which along with an increase in cardiac output are the early mechanisms compensating circulatory dysfunction during this early stage and keep MAP stable<sup>[1]</sup>.

As the disease progresses and splanchnic vasodilation gets worse other vasoconstrictor systems get activated such as the renin-angiotensin-aldosterone system and vasopressin release<sup>[1]</sup>.

Aldosterone enhances retention of sodium and water by the kidneys leading to development of ascites. Vasopressin enhances retention of free water conducting to hyponatremia. The splanchnic vascular bed is refractory to the action of all these vasoconstrictor systems which

on the contrary act effectively on other vascular beds such as the femoral and brachial vessels (producing cramps), in vessels in the brain (potentially playing a role in encephalopathy) and in the renal arteries (leading to HRS)<sup>[1,2]</sup>. In this sense, mean renal artery resistive index increases gradually from patients with cirrhosis but no ascites, in those with ascites, refractory ascites and HRS<sup>[3,4]</sup>.

Therefore, HRS is a functional disease characterised by marked vasoconstriction of the renal arteries secondary to the effect of hyper-activation of different vasoconstrictor systems aimed at compensating the systemic vasodilation caused by the initial splanchnic vasodilation. HRS always develops in the setting of advance circulatory dysfunction and it is always accompanied by ascites and usually by hyponatremia<sup>[1]</sup>.

HRS can develop in the setting of infection, mainly after spontaneous bacterial peritonitis (SBP), as a consequence of a worsening degree of circulatory dysfunction caused by sepsis. Volume expansion with albumin prevents effectively development of HRS in patients with SBP<sup>[5]</sup>.

HRS can also develop in the setting of circulatory dysfunction after large volume paracentesis (LVP). This complication is prevented by replacing albumin after LVP<sup>[6]</sup>.

## DIAGNOSIS OF HRS ACCORDING TO THE NEW DEFINITION OF AKI

Classically, acute renal failure in cirrhosis was defined as an increase in serum creatinine (sCr) levels of  $\geq 50\%$  from baseline to a final level above 1.5 mg/dL (133  $\mu\text{mol/L}$ ), and classical definition of HRS type-1 was doubling sCr levels over 2.5 mg/dL or 220  $\mu\text{mol/L}$  within 2 wk. Serum creatinine overestimates renal function in cirrhotic patients due to a number of factors: Creatinine production in patients with cirrhosis is reduced due to muscle wasting, there is an increased secretion of creatinine in the renal tubules, sCr may be diluted due to an increased volume of distribution, and finally, high bilirubin levels may interfere with the assays to measure accurately its level. Recently, the International Club of Ascites (ICA) has adopted the concept of AKI which was developed originally to be used in general critically-ill patients. AKI is defined as the increase of at least 0.3 mg/dL (26  $\mu\text{mol/L}$ ) and/or  $\geq 50\%$  from baseline, within 48 h<sup>[7]</sup>.

Diagnostic criteria of HRS according to ICA-AKI criteria are the following<sup>[7]</sup>: (1) diagnosis of cirrhosis and ascites; (2) diagnosis of AKI according to ICA-AKI criteria; (3) no response after 2 consecutive days of diuretic withdrawal and plasma volume expansion with albumin (1 g/kg of body weight); (4) absence of shock; (5) no current or recent use of nephrotoxic drugs (non-steroidal anti-inflammatory drugs, aminoglycosides, iodinated contrast media, *etc.*); and (6) no macroscopic signs of structural kidney injury, defined as absence of proteinuria ( $> 500$  mg/d), absence of microhematuria ( $> 50$  red blood

cells per high power field) and normal findings on renal ultrasound.

The main change produced by adopting the new definition of HRS is the removal of a rigid very high cut-off value of sCr (2.5 mg/dL or 220  $\mu$ mol/L) to start pharmacologic treatment. In this way, treatment can be administered early and potentially better efficacy could be achieved.

However, these clinical criteria do not allow differentiation between HRS and parenchymal renal disease, which is extremely important because vasoconstrictors will not be effective and could even worsen the renal dysfunction. Thus, there is a wide interest in developing urinary biomarkers to help in the differential diagnosis of HRS.

## URINARY BIOMARKERS IN AKI

Currently, numerous biomarkers have been assessed in the setting of AKI and liver cirrhosis including neutrophil gelatinase-associated lipocalin (NGAL), interleukin-18, liver-type fatty acid binding protein (L-FABP), kidney injury molecule-1, toll-like receptor 4,  $\pi$ -glutathione S-transferase and  $\alpha$ -glutathione S-transferase<sup>[8]</sup>. Among all of them, current data show that NGAL is the most useful marker. NGAL detects patients with acute tubular necrosis (ATN). On the contrary, NGAL is not helpful to differentiate between pre-renal azotemia and HRS. NGAL urinary levels are much higher in patients with ATN compared to patients with other causes of AKI. Urinary levels of NGAL in ATN were 417  $\mu$ g/L, compared with levels at 30  $\mu$ g/L in pre-renal azotemia, 82  $\mu$ g/L in chronic kidney disease and 76  $\mu$ g/L in HRS,  $P < 0.001$ <sup>[9,10]</sup>. Thus, incorporating NGAL into the clinical decision algorithm would be of benefit to rule out structural kidney injury and detecting a group of patients in whom treatment with vasoconstrictors wouldn't be effective and only would produce potentially serious side effects<sup>[11]</sup>.

## CURRENT TREATMENT (STANDARD OF CARE)

Once patients with AKI have received volume expansion with albumin (1 g per kilogram) with no response achieved in the following 48 h, and criteria of HRS are fulfilled, then treatment with terlipressin is recommended. Expansion with albumin should be continued at the dose of 20–40 g daily.

Response to treatment should be assessed regularly and terlipressin should be titrated gradually up to a maximum dose of 12 mg per day. Terlipressin should be used for a maximum of 14 d and stopped in case of lack of response<sup>[7]</sup>.

Response is defined as a reduction of at least 25% from baseline sCr level, that is from sCr level before treatment with terlipressin was started<sup>[7]</sup>.

Response is achieved in around 40%–50% of patients. The rate of recurrence of HRS is 30%. A definitive treatment of the circulatory dysfunction and the underlying liver

cirrhosis with liver transplantation should be considered in all cases with no contraindications. Otherwise, the persistent advanced circulatory dysfunction makes HRS recur frequently and predispose the patient to other major decompensations<sup>[12]</sup>. This is the rationale supporting prioritization of patients with HRS on the waiting list for LT in some centres. Terlipressin and albumin is not a definitive treatment but should be considered as a bridge to a definitive treatment, *i.e.*, LT.

Two randomized studies showed that HRS reversal rate when terlipressin plus albumin was employed was higher compared to the reversal achieved employing albumin alone. Martín-Llahí *et al.*<sup>[13]</sup> reported a much higher rate of improvement in renal function in patients treated with terlipressin and albumin compared to those patients treated only with albumin (43.5% vs 8.7%,  $P = 0.017$ ). This result may be influenced by the fact that patients who did not tolerate terlipressin were excluded from the analysis. Sanyal *et al.*<sup>[14]</sup> also showed that HRS reversal was achieved more frequently in those patients treated with terlipressin and albumin compared with those treated only with albumin (33.9% vs 12.5%,  $P = 0.008$ ). Any of these studies showed difference in survival at 3-mo and 6-mo. A large randomized trial has been published recently and it showed a higher rate of HRS reversal in those patients receiving terlipressin (23.7% vs 15.2%,  $P = 0.13$ ). This difference did not reach statistical significance, probably due to the fact that one third of patients received fewer than three days of treatment, which could affect the effectiveness of the treatment. When the analyses were done stratifying patients by the degree of reduction in serum creatinine level, data showed that a decrease in sCr level, even if not reaching a complete reversal, has a positive impact on survival<sup>[15]</sup>.

Traditionally, terlipressin has been used in bolus 0.5–1.0 mg every 4–6 h. Recent data show that continuous infusion of terlipressin has the same efficacy compared with bolus administration and it is better tolerated presenting fewer side effects (35.29% vs 62.16%,  $P < 0.025$ ). Probably, side effects were lower because the total effective daily dose required was lower in the infusion groups compared to the bolus group ( $2.23 \pm 0.65$  mg/d vs  $3.51 \pm 1.77$  mg/d,  $P < 0.05$ )<sup>[16]</sup>.

Therefore, we recommend employing terlipressin at 2 mg per day in continuous infusion (diluted in 250 mL of Dextrose 5%) along with albumin (20–40 g per day). Response should be assessed every 48 h. If response is not achieved in 48 h, then terlipressin dose should be increased in a stepwise manner (increase in 2 mg per day).

These patients need careful observation, including review of ischaemic side effects on acral parts, ischaemic heart events, bowel ischaemia (diarrhoea). They can also develop hyponatremia and arrhythmias.

## PREDICTORS OF RESPONSE TO TERLIPRESSIN AND ALBUMIN

There are only few published studies assessing pre-

dictors of response to treatment in HRS. These studies show there is a close relationship between effectiveness of treatment and capacity to improve systemic hemodynamics. Patients in whom terlipressin did not increase the MAP in at least 5 mmHg at day 3 of treatment had a lower rate of response. Effectiveness of treatment is also related with degree of liver dysfunction. Those patients who did not increase MAP at day 3 and who also had high baseline bilirubin levels  $\geq 171 \mu\text{mol/L}$  (10 mg/dL) had a poor response rate, of only 9%<sup>[17]</sup>. Another study showed that baseline creatinine levels predicted HRS reversal, suggesting that early intervention would be more effective<sup>[18]</sup>. A recent retrospective study showed that those patients with systemic inflammatory response syndrome (SIRS) had a much higher response rate to terlipressin (42.9% vs 6.7%,  $P = 0.018$ ), while terlipressin did not show more efficacy than placebo when employed in patients without SIRS (15.9% vs 18.8%,  $P = \text{NS}$ )<sup>[19]</sup>.

A recent abstract showed that no response to treatment was associated with higher urinary NGAL levels (728.8  $\mu\text{g/L}$  vs 182.9  $\mu\text{g/L}$ ,  $P = 0.02$ ), probably related to the presence of acute tubular necrosis in those patients<sup>[20]</sup>.

In summary, the following markers to predict response to treatment (terlipressin) have been identified: Low baseline creatinine and bilirubin levels, increase in blood pressure, presence of SIRS and low urinary NGAL.

## OTHER TREATMENTS

### LT

Patients with HRS type-1 with no contraindications for a LT should be invariably worked up and place in the LT waiting list because LT is the only definitive treatment for HRS. LT reverses liver dysfunction and portal hypertension. Patients with HRS have worse survival expectancy than other patients with cirrhosis for any given value of MELD score, which suggests HRS is a factor of poor prognosis independently from MELD score<sup>[21,22]</sup>. Furthermore, there is evidence that structural injury to the renal tubules occur early in the course of HRS-1 and the longer the patient is awaiting the transplant and suffering from HRS the higher the risk of not recovering their renal function or even requiring a renal transplant after LT<sup>[23]</sup>. In this sense, experts recommend to prioritize these patients by using pre-treatment levels of creatinine or considering the pharmacological treatment of HRS as haemodialysis when calculating MELD score<sup>[24]</sup>. Currently, there is no general consensus about prioritization of patients with HRS awaiting a LT. Some centres prioritize these patients and some others don't. The major challenge LT programmes face is the shortage of donors and consequently optimization in the allocation of the few organs available becomes extremely necessary. Thus, we suggest that those patients with recurrent episodes of HRS-1, hence at high risk of developing refractory HRS, are at high risk of dropping out of the LT waiting list or at risk of not recovering their renal function after LT, and therefore will

get most benefit from early transplantation.

### Midodrine and octreotide

Combination of midodrine and octreotide (MID/OCT) plus albumin is widely used in countries where terlipressin is not available. A recent randomized trial showed a much lower response rate in patients treated with MID/OCT compared to patients treated with terlipressin (4.8% vs 55.6%,  $P < 0.01$ ). Three-month survival rate, after exclusion of patients who received rescue treatment, was also lower in the MID/OCT group (29% vs 56%,  $P = 0.06$ )<sup>[25]</sup>. These data show midodrine in combination with octreotide is not an effective treatment for HRS.

### Noradrenaline

A recent randomized study comparing noradrenaline with terlipressin showed HRS reversal is achieved in 43.4%, similar to the reversal rate achieved with terlipressin (39.1%). Survival at 15 d of therapy was similar in the noradrenaline and terlipressin group (39.1% vs 47.8%,  $P = 0.461$ )<sup>[26]</sup>. A recent meta-analysis analysed 4 studies including 152 patients and suggested that treatment with noradrenaline is as effective as terlipressin in reversing HRS when used along with albumin<sup>[27]</sup>. Therefore, noradrenaline is an effective therapy for HRS. Noradrenaline main drawback is that its use generally requires an intensive care unit setting.

### Dopamine

Low-dose dopamine increases renal blood flow but shows no effect on glomerular filtration rate or on the outcome in HRS. In a recent study, dopamine didn't show reduction of creatinine levels after 5 d of treatment<sup>[28,29]</sup>. It is not considered an appropriate treatment for HRS.

### Transjugular intrahepatic portosystemic shunt

HRS type-1 usually occurs in the setting of advanced liver dysfunction and transjugular intrahepatic portosystemic shunt (TIPS) is usually contraindicated on this basis. There are few small trials showing improvement on renal function and deactivation of vasoconstrictor system, *i.e.*, reduction in levels of renin, aldosterone and noradrenaline after TIPS insertion<sup>[30,31]</sup>. However, data is very limited to recommend its use in clinical practice.

### Renal and liver replacement therapy

Haemodialysis is employed in those patients awaiting LT whose renal function failed to respond to medical treatment and at the same time bring the extra points required for prioritization.

Liver support with molecular adsorbent recirculating system (MARS) has been tested in small cohorts of patients who did not respond to vasoconstrictors and had advanced liver dysfunction, which usually precludes TIPS insertion. One trial showed the reduction in creatinine and bilirubin levels was higher in the MARS group compared with the continuous haemodialysis group<sup>[32]</sup>. Another study showed no significant changes in systemic

haemodynamics and glomerular filtration rates following MARS treatment<sup>[33]</sup>. Treatments employed at this stage should be restricted to patients awaiting a definitive treatment (*i.e.*, LT). It would be controversial to employ such invasive treatments in patients with contraindication for LT, and thus with no option for a definitive treatment.

### Serelaxin

Serelaxin is a recombinant form of the human peptide hormone relaxin-2, increases renal perfusion in healthy human volunteers. Its properties have been explored in a pilot study on compensated cirrhotic patients and it showed increase renal blood flow by 65.4% from baseline with no effect on systemic blood pressure<sup>[34]</sup>. Data on this hormone is still scarce.

## PREVENTION

HRS can be prevented in different clinical scenarios. The first one is in the setting of SBP. The deleterious effect on circulatory dysfunction produced by SBP can be prevented by volume expansion with albumin. The pioneer study of the Barcelona group showed that those patients receiving albumin prevented development of renal failure (10% vs 33%,  $P = 0.002$ ) and reduced short-term mortality (mortality at 3-mo, 22% vs 41%,  $P = 0.03$ )<sup>[9]</sup>. There are still no convincing data to recommend plasmatic expansion with albumin in patients with other types of infections different from SBP. One trial showed a tendency to develop renal failure less frequently in those patients without renal failure at baseline and receiving expansion with albumin (3% vs 10%,  $P = \text{NS}$ )<sup>[35]</sup>.

HRS can be prevented after LVP, albumin at a dose of 6-8 g per litre of ascites removed is the dose most commonly used to prevent worsening of circulatory dysfunction, and thus minimize the impact on electrolytes, creatinine and renin levels. Volume expansion with albumin also improves survival after LVP and it is recommended by international societies<sup>[36,37]</sup>.

HRS can also be prevented with primary antibiotic prophylaxis of SBP. Fernández *et al.*<sup>[38]</sup> showed in a cohort of patients with advanced cirrhosis that SBP primary prophylaxis reduced development of HRS (28% vs 41%,  $P = 0.02$ ) and mortality at 3 mo (94% vs 62%,  $P = 0.003$ ), this effect is probably related to the effect of Norfloxacin in reducing the levels of bacterial products within the gut and hence reducing bacterial translocation.

## AREAS FOR FUTURE RESEARCH

Definition of HRS is continuously changing and it is based on clinical grounds, relying on serum creatinine levels, which has many limitations as marker of renal function. Research focused on new biomarkers, such as urinary NGAL, to make the diagnostic algorithm of HRS more accurate is clearly needed and fortunately, interest in this field is increasing.

Moreover, identifying patients with low probability of

responding to treatment is of major importance in order to start early alternative treatments and potentially prioritize these patients on the LT waiting list.

Finally, research looking for novel treatments besides intravenous terlipressin and expansion with albumin is also needed.

## CONCLUSION

HRS is a major decompensation in advanced liver cirrhosis. It entails a high short-term mortality rate. Current definition is based on clinical grounds and has been recently modified adopting AKI definition. Recent data on urinary NGAL show it is useful to differentiate acute tubular necrosis and should be incorporated in the diagnostic algorithm of HRS. Terlipressin and noradrenaline are the only effective treatment currently available and reversal rate is only 40%-50% of cases. Data on predictors of response to treatment suggest that treatment should be started as early as possible. In this sense, ICA new definition of HRS allows an early diagnosis. New treatments should be tested for this life-threatening condition. Finally, LT is the only curative treatment and should be always considered.

### Abstract

Combined hepatocellular-cholangiocarcinoma (CHC) is a rare tumor with poor prognosis, with incidence ranging from 1.0%-4.7% of all primary hepatic tumors. This entity will be soon renamed as hepato-cholangiocarcinoma. The known risk factors for hepatocellular carcinoma (HCC) have been implicated for CHC including viral hepatitis and cirrhosis. It is difficult to diagnose this tumor pre-operatively. The predominant histologic component within the tumor largely determines the predominant radiographic features making it a difficult distinction. Heterogeneous and overlapping imaging features of HCC and cholangiocarcinoma should raise the suspicion for CHC and multiple core biopsies (from different areas of tumor) are recommended before administering treatment. Serum tumor markers CA19-9 and alpha-fetoprotein can aid in the diagnosis, but it remains a challenging diagnosis prior to resection. There is sufficient data to support bipotent hepatic progenitor cells as the cell of origin for CHC. The current World Health Organization classification categorizes two main types of CHC based on histo-morphological features: Classical type and CHC with stem cell features. Liver transplant is one of the available treatment modalities with other management options including transarterial chemoembolization, radiofrequency ablation, and percutaneous ethanol injection. We present a review paper on CHC highlighting the risk factors, origin, histological classification and therapeutic modalities.

**Key words:** Combined hepatocellular-cholangiocellular carcinoma; Hepatocellular carcinoma; Cholangiocellular carcinoma; Hepatic progenitor cell(s); Histogenesis; Classification

## INTRODUCTION

Combined hepatocellular-cholangiocarcinoma (CHC) is a rare tumor, with variation reported from 1.0%-4.7% of all primary hepatic tumors in series of patients undergoing hepatic resection<sup>[1-6]</sup>, although accurate incidence is not known. CHC has been known with several nomenclatures in the literature including mixed hepatocellular carcinoma-cholangiocarcinoma (HCC-CC), hybrid HCC-CC or combined liver and bile duct carcinoma<sup>[7]</sup>. Some of the more common risk factors for CHC mentioned in the literature are hepatitis B virus (HBV) infection, male predominance, cirrhosis and hepatitis C virus (HCV) infection<sup>[8-12]</sup>. Molecular evidence supports that the hepatic progenitor cell (HPC) is the cell of origin for CHC. On histology, it is divided into two main subtypes-classical type and subtypes with stem cell features (further discussed in histology section)<sup>[13]</sup>. Separate HCC and CC in the same liver does not classify as CHC. We present a review of current understanding of clinical features, histogenesis and histology of the combined hepatocellular-cholangiocarcinoma that will be soon renamed as hepato-cholangiocarcinoma.

## CLINICAL FEATURES AND RISK FACTORS

Owing to the rarity of CHC, the majority of the series describing clinical features and prognostic factors consist of retrospective studies from single institutions encompassing small patient populations with little statistical power. This is further compounded by inconsistent histologic inclusion criteria and definition of CHC across the studies, with many series including collision tumors and separate nodules of HCC and CC as CHC. Thus, it is not surprising that identification of clinical features and prognostic factors are not consistent or reproducible among the different studies. A clear profile of the patient demographic afflicted by this rare primary hepatic malignancy has remained vague and is highly dependent on geographic region.

Etiology and risk factors for these tumors may be common or differ in different regions in eastern and western series. This reflects variability in the prevalence of infectious agents such as hepatitis viruses and liver flukes, as well as the lifestyle and nutritional differences.

Multiple studies have highlighted risk factors such as male gender, cirrhosis, hepatitis infection, family history of liver cancer, heavy alcohol consumption and diabetes mellitus<sup>[4,8-11,14-16]</sup>. The high male: Female ratio and prevalence of HBV in CHC patients in Asian countries are generally more similar to HCC compared to CC<sup>[15,16]</sup>. On the other hand, western studies have shown a less pronounced male predominance of CHC, paralleling with relatively low prevalence of HBV (15%-16.6%) and high prevalence of HCV<sup>[1,4,12,17]</sup>. Taken together, these findings suggest that geographical characteristics heavily influence clinical profiles of patients with CHC. This demonstrates that CHC is associated with overlapping clinical features of both HCC and CC. Some studies have reported that CHC has poor prognosis and more aggressive behavior in comparison to HCC and CC<sup>[18-20]</sup>, which some authors attribute to increased lymph node involvement<sup>[8]</sup>.

## IMAGING CHARACTERISTICS AND PRE-OPERATIVE DIAGNOSIS

Historically, CHC has been an elusive and difficult pre-operative diagnosis. This is due to its heterogeneous imaging characteristics with overlapping features of both HCC and CC. The predominant histologic component within the tumor largely determines the predominant radiographic features. This is also true in tissue specimens, as sampling error (e.g., sampling only the area of HCC or CC within a CHC) may also lead to an erroneous pre-operative diagnosis. Thus, the majority of CHC cases in the literature were initially misdiagnosed as either HCC or CC and the proper diagnosis was only reached in the surgical resection specimens. Correct pre-operative diagnosis is important, especially distinction from HCC, as it may determine different management strategy. In the United States the vast majority of HCCs are diagnosed based on characteristic radiological features alone without pathologic confirmation. HCC in selected patients is an indication for liver transplant, with excellent outcomes equivalent to non-neoplastic entities and 5-year survival > 70%<sup>[21]</sup>. Taking into account the scarcity of grafts available for transplantation and the poor prognosis associated with CHC, differentiation from HCC becomes paramount.

The characteristic features of HCC on contrast enhanced CT and MRI are arterial phase diffuse enhancement, portal venous washout, and an enhanced pseudocapsule on delayed imaging. The hallmark radiological findings of CC are arterial peripheral rim enhancement with progressive fibrous stroma central enhancement, dilation of the biliary system, and retraction of the capsule<sup>[22]</sup>. CHC may show all of these radiographic characteristics to varying degrees, making distinction from HCC and particularly from CC very challenging. Some authors have suggested that the presence of heterogeneous or overlapping imaging features should prompt an extended tissue biopsy from different appearing tumor areas to aid in this diagnostic

conundrum and mitigate sampling bias<sup>[22]</sup>. Another clue that should raise suspicion for CHC pre-operatively is discordant tumor markers. Generally, elevated alpha-fetoprotein (AFP) levels are associated with HCC, while elevated CA 19-9 levels are associated with CC. If a tumor shows characteristic imaging features of HCC, but is associated with elevated CA 19-9 levels, or if a tumor has characteristic CC imaging features and is associated with elevated AFP levels, or if both serum markers are elevated, biopsy for pathologic confirmation should be strongly considered.

## HISTOGENESIS

The concept of cancer stem cells may explain the origin and progression of different kinds of cancers, and CHC is no exception. Although histogenesis of the CHC has been a topic of debate, three types of tumor origins have been hypothesized: (1) collision tumors; (2) de-differentiation or re-differentiation of a primary HCC into a biliary phenotype or vice versa; (3) derivation from bipotent HPC<sup>[5,23]</sup>. The first theory, collision tumor consisting of separate populations of HCC and CC occurring in the same liver without intimate relationship, does not qualify as CHC. De-differentiation or redifferentiation of HCC or CC into the other component is controversial, as some studies have shown differences in the clinical features, histology and molecular genetics of CHC and HCC/CC while others have supported this theory owing to existing similarities between CHC and HCC as well as CHC and CC.

The bipotent HPC is a stem cell that differentiates into both hepatocytes and bile duct epithelial cells, and is suspected to be the cancer stem cell responsible for CHC growth<sup>[5,23-26]</sup>. Theise *et al.*<sup>[23]</sup> described four primary liver cancers with three different components including hepatocellular, cholangiocellular and a third component of small or undifferentiated cells (oval-like cells) with high N/C ratio, scant basophilic cytoplasm and nuclear pleomorphism. Oval cells (described in animal models) or intermediate cells (in humans) or stem cells can be found in regenerative nodules. These cells are located in canals of Hering<sup>[23,27]</sup> and can differentiate bidirectionally into hepatocytes and cholangiocytes, also called as bipotent progenitor cells<sup>[5,23,24]</sup>. There is morphological and immunohistochemical similarity between these oval-cell like progenitors and hepatoblasts (both positive for CK19 and Hep-Par1).

HPC and stem cell markers which have been studied in relation to CHC include CD133, CD90, CD44, epithelial cell adhesion molecule (EpCAM), nuclear cell adhesion molecule (NCAM/CD56), OV6, CD13, c-kit, YAP1, SALL4 and Delta-like 1 homolog (DLK-1)<sup>[5,28-33]</sup>. Kim *et al.*<sup>[24]</sup> demonstrated that c-kit-positive HPCs have a potential to differentiate into both hepatocytes and cholangiocytes and are neoplastic counterparts of HPCs.

Evidence including identification of HPC-like cells merging with HCC and CC components, as well as shared expression of HPC markers in the different components,

supports these cells as the origin for CHC<sup>[23,25]</sup>. Furthermore, inoculation of cells from a CHC cell line positive for the HPC marker EpCAM has been associated with development of CHC in mice<sup>[26]</sup>. HPC activation in non-tumor liver in CHC cases has been linked with recurrence and poor prognosis in CHC<sup>[34]</sup>. Microdissection has shown that both components share a single clonal background, which is consistent with the shared origin of both components deriving from HPCs<sup>[35]</sup>.

The role of the HPC is reflected in the current World Health Organization (WHO) classification, which is subdivided into CHC, classical type and three subtypes of CHC with stem cell features<sup>[13]</sup>. In making this classification, the authors noted that it was uncertain whether biological differences existed between these subtypes, and determination of subtype relied mainly on histological and immunohistochemical features. HPC marker expression has been shown to varying degree in all stem cell subtypes and to a lesser degree in the classical subtype, while prominent in transitional areas of CHC<sup>[24,29-31]</sup>. Ikeda *et al.*<sup>[30]</sup> showed that the stem cell markers DLK-1 and NCAM/CD56 were expressed most frequently in CHC with stem cell features, and were most frequently expressed in typical and cholangiocellular subtypes. Akiba *et al.*<sup>[29]</sup> showed that stem cell markers CD133 and EpCAM were more often expressed in CHC with stem cell features compared to those with classical features. They further showed that among CHC subtypes with stem cell features, cholangiocellular subtype more often expressed CD133 and EpCAM in comparison to intermediate subtype (their study did not include sufficient cases of typical subtype for statistical analysis)<sup>[29]</sup>. Komuta *et al.*<sup>[36]</sup> supported origin of cholangiocellular carcinoma from HPCs that was initially a subtype of cholangiocarcinoma.

Molecular studies have shown that CHC shares some traits with HCC and others with CC, confirming its status as a distinct entity. Gene profiling of CC, HCC and CHC by microarray shows increased differential expression in CC vs HCC as compared to CC vs CHC, reflecting this concept<sup>[37]</sup>. Analysis of copy number changes in CC and HCC components of CHC showed concordance in the overall trend of gain or loss for several target genes although magnitude of copy number change differed. The copy number gains in the CC component were likely to be paired with a similar but not identical copy number gain in the HCC component of the tumor, with the same holding true for copy number losses. The specific genes most often amplified in this study were MYC, ADAMTSL4, TM4SF1 and CUL4A, which are each associated with HCC although CUL4A has also been associated with CC<sup>[38]</sup>. Similarly, comparative genomic hybridization showed specific chromosomal gains and losses similar to those of HCC<sup>[39]</sup>. This study also showed high prevalence of chromosomal imbalances similar to those seen in CC. Similarly, a high level of chromosomal instability, in addition to recurrent loss of heterozygosity at 3p and 14q is also noted<sup>[40]</sup>.

Genome-wide transcriptional analysis of 20 CHC cases

**Figure 1** Representative picture classic type combined hepatocellular-cholangiocarcinoma, hematoxylin and eosin, 10 × - intermediate areas with both hepatocytic and cholangiocytic components.

showed that CHC clustered with CC and separately from HCC, with upregulated signaling pathways of TGF $\beta$  and Wnt similar to those seen in CC. The TGF $\beta$  pathway upregulated in CHC recalled the key role of fibrosis and extracellular matrix remodeling in CC, and the Wnt pathway signature was similar to that seen in biliary ductal morphogenesis. However, CHC also clustered with a subset of poorly differentiated HCC with progenitor cell features, as would be expected given the postulated HPC origin of CHC, while CHC showed repression of the transcription factor HNF4A associated with mature hepatocyte differentiation<sup>[41]</sup>. Likewise it is also shown that CHCs were clustered with CC by gene expression profiling<sup>[42]</sup>. A recent whole genome sequencing analysis showed that genome-wide substitution patterns in liver cancers of biliary phenotype (both CC and CHC) overlapped with those of HCC in cases associated with chronic viral hepatitis, while biliary cancers (mostly CC in this study) unrelated to chronic hepatitis differed from HCC<sup>[43]</sup>. TERT promoter mutations, for example, were common in CHC and in other hepatitis-related cancers. Carcinogenesis arising from HBV acts largely through the HBV X protein that promotes HPC tumorigenesis so it is possible that these tumors may share a similar pathogenesis<sup>[44]</sup>.

## HISTOLOGY

### Classification

There are multiple classifications for CHC in the literature. Allen and Lisa<sup>[7]</sup> made the first histological classification for CHC in 1949. They described three subtypes. Type 1 consisted of discrete foci of HCC and CC. Type 2 had contiguous masses with features of both HCC and CC. Type 3 was described as a solitary mass comprising of both components. Goodman *et al.*<sup>[45]</sup> in 1985 proposed another classification, also encompassing three subtypes: Type 1 or collision tumor with separate and colliding areas of HCC and CC in the same liver; type 2 or transitional tumor with transitional areas with intimate intermingling of two components with actual transition of HCC elements to CC elements in the same tumor; and type 3

or mucin producing fibrolamellar tumor. Allen and Lisa<sup>[7]</sup>'s type 3 and Goodman *et al.*<sup>[45]</sup>'s type 2 has similar features to the current WHO criteria for CHC. The current edition of the WHO classification describes two main types of CHC: Classical type and CHC with stem cell features. The stem-cell features type is further divided into 3 subtypes: Typical subtype, intermediate cell subtype and cholangiolocellular subtype<sup>[13]</sup>. Representative images of each subtype highlighting histological features and immunohistochemical profile are shown in Figures 1-4.

### Histopathology

WHO 2010 classification defines these tumors as histological demonstration of unequivocally differentiated hepatocellular and biliary components in the tumor with intermingling of the two components<sup>[13]</sup>. Collision tumor, which is a separate entity, consists of HCC and CC occurring in the same liver without intimate relationship and is not categorized as CHC. The definite diagnosis of CHC can be made by histology only along with use of IHC and special stains<sup>[5]</sup>. The diagnosis of CHC is a challenging diagnosis on core biopsy as it depends on the area sampled<sup>[46]</sup>. Hepatocytic differentiation is defined by bile production, Mallory-Denk bodies, alpha-1 antitrypsin globules and trabecular arrangement of tumor cells. The cholangiocarcinoma component is appreciated by mucin production, prominent desmoplastic stroma and glandular structures. Combined fibrolamellar HCC in combination with cholangiocellular component has also been described in the literature<sup>[45,47]</sup>.

In the CHC classic type (Figure 1), both the hepatocytic and cholangiocarcinoma components are present and can vary from well to poorly differentiated<sup>[13]</sup> with intermediate areas demonstrating features of both the components. Hepatocytic component is usually represented by thickened trabeculae composed of polygonal cells with abundant granular eosinophilic cytoplasm and scant stroma while cholangiocarcinoma component has gland formation with low cuboidal/columnar cells and dense fibrotic stroma. HCC with pseudoglandular pattern and expression of CK7/CK19 is not classified as CHC<sup>[5]</sup>.

The first subtype of CHC with stem cell features, the typical subtype (Figure 2A and B), is characterized by peripheral small cells with hyperchromatic nuclei and a high nuclear to cytoplasmic ratio with nests of mature appearing hepatocytes in the center. The intermediate cell subtype (Figure 3A and B) consists of tumor cells with intermediate features between hepatocytes and cholangiocytes. Kim *et al.*<sup>[24]</sup> described these tumor cells as small and oval shaped with hyperchromatic nuclei and scant cytoplasm arranged in either trabeculae, solid nests or strands, present within a desmoplastic stroma. Well-formed glands are not seen but ill-formed gland like structures may be present. These tumors were initially termed as intermediate carcinomas (hepatocyte-cholangiocyte) as these had features that were intermediate between HCC and CC<sup>[13,24]</sup>. The cholangiolocellular subtype (Figure 4A and B) is characterized

**Figure 2 Combined hepatocellular-cholangiocarcinoma with stem cell features, typical subtype.** A: H and E, 4 × - tumor nests present on the right side with non-neoplastic liver on the left side; B: H and E, 10 × - peripheral small cells with hyperchromatic nuclei with mature appearing hepatocytes in the center; C: CK7, 4 × - scattered expression of CK7 by tumor cells; D: CK19, 4 × - patchy staining of the tumor and highlighting small tumor cells located at the periphery. Tumor was also positive for Hep-Par1 (not shown). H and E: Hematoxylin and eosin.

**Figure 3 Combined hepatocellular-cholangiocarcinoma with stem cell features, intermediate subtype.** A: H and E, 4 × - tumor is present in trabecular/nested pattern on the right side with ill-formed gland like structures seen on the left side; B: H and E, 10 × - tumor cells with intermediate features between hepatocytes and cholangiocytes; C: CD10, 10 × - tumor showing canalicular staining pattern for CD10 (hepatocytic marker); D: CK19, 4 × - tumor cells strongly and diffusely expressing CK19 (cholangiocytic marker). Focal tumor cells were positive for Hep-Par1 and CD56 (not shown). H and E: Hematoxylin and eosin.

**Figure 4 Combined hepatocellular-cholangiocarcinoma with stem cell features, cholangiocellular subtype.** A: H and E, 4 × - tumor cells present in tubular, anastomosing (antler-like) pattern; B: H and E, 10 × - small hyperchromatic tumor cells with high nuclear to cytoplasmic ratio present within dense fibrous stroma; C: CK7, 10 × - tumor is diffusely positive for CK7; D: CD56, 10 × - CD56 staining the cholangiolocellular component as well as the tumor cells at the periphery of the trabeculae. The tumor was diffusely positive for CK19 while negative for HepPar-1 and AFP (not shown). H and E: Hematoxylin and eosin.

by small cells with a high nuclear to cytoplasmic ratio and hyperchromatic oval shaped nuclei arranged in a tubular, cord like, anastomosing pattern (also referred to as an “antler-like” pattern) within a dense fibrous stroma. No significant cellular atypia or evidence of mucin production is seen in both intermediate and cholangiolocellular subtypes<sup>[13]</sup>. Although there are distinct histological features described by the WHO to classify all these types/subtypes, there is no mention of percentage of stem cell area required to categorize CHC with stem cell features. If the stem cells predominate, the tumor is classified as one of the subtype of CHC with stem cell features depending on the histologic appearance. It appears that CHCs with less than 5% stem cell area have better prognosis than those with stem cell areas greater than 5%<sup>[30]</sup>. Sasaki *et al.*<sup>[48]</sup> proposed certain clinico-pathological findings for CHC with stem cell features. The intermediate subtype was more commonly associated with female patients, larger tumor size, higher histological grade of HCC component, and less fibrosis while cholangiocellular subtype had smaller tumor size and lower histological grade of HCC. The typical subtype has less inflammation in comparison with the cholangiocellular subtype<sup>[48]</sup>.

On cytology specimens, diagnosis of CHCs can be challenging<sup>[49,50]</sup>. Cell blocks and immunohistochemical stains can prove helpful in reaching a correct diagnosis of CHC. With CHC being an uncommon tumor, arriving at a diagnosis and classification of CHC can be difficult with histology alone.

### Special and immunohistochemical stains

Immunohistochemical stains are required for demonstrating hepatic and biliary phenotypes. The hepatocellular component is positive for HepPar1, pCEA, CD10 and glypican<sup>[5]</sup>. The CC component shows expression of CK7, CK19 and mucin/mucicarmine although HCC components can also express CK7 and CK19<sup>[5]</sup>. Mucin is essential to demonstrate the biliary component<sup>[51]</sup>. CAM 5.2 and AE1 can also be useful to differentiate between HCC and CC component; HCC will be positive for CAM5.2 while AE1 will be positive in CC component<sup>[49]</sup>. CHC with stem cell features expresses stem cell markers including c-kit, NCAM, and EpCAM. Kim *et al.*<sup>[32]</sup> demonstrated similar expression of these stem cell markers in CHC and HCC. Oval cell-like progenitors or small cells (or HPCs) described originally by Theise *et al.*<sup>[23]</sup> are focally positive for AFP and alpha-antitrypsin while negative for Hep-Par1, c-Kit, vimentin and CHR-A. CD44, which is one of the cancer stem cell markers, is associated with poor prognosis and early recurrence in patients with CHC<sup>[32]</sup>. DLK1 is another marker of HPCs in adult liver<sup>[30]</sup>. Survival of patients with high expression of DLK1 is worse<sup>[30]</sup> suggesting that patients with CHC with stem cell features do worse in comparison to classical type CHC.

CHC with stem cell features, typical subtype stains positively with CK7, CK19 (Figure 2C and D), NCAM1/CD56, cKIT and/or EpCAM.

The intermediate subtype that is characterized by

intermediate cells (between hepatocytes and cholangiocytes), shows simultaneous expression of hepatocyte and biliary markers (Figure 3C and D). Akiba *et al.*<sup>[52]</sup> demonstrated that intermediate cells stain better with Arginase-1 and CK8. Biliary phenotypes (CK7 and CK19) are more commonly positive in intermediate subtype than Hep-Par1<sup>[29]</sup>.

The cholangiolocellular subtype is positive for CK19, and stem cell markers- cKIT, NCAM1/CD56 and EpCAM (Figure 4C and D).

## TREATMENT OPTIONS

Currently, minor or major hepatic resection, with or without lymph node dissection, is the consensus recommended treatment for CHC. However, the absence of randomized prospective studies precludes the determination of optimal management strategies in these patients.

The role of liver transplant in the treatment of CHC remains to be defined. Most of the data on transplanted CHC patients comes from patients that were initially misdiagnosed with HCC or from incidentally discovered tumors in the explanted livers. The outcome data of this cohort is mixed, although outcomes are consistently worse when compared with HCC due to associated higher recurrence rates after transplant in CHC<sup>[53,54]</sup>. A recent study found no survival benefit of transplant over resection in CHC, with 3-year overall survival of 48% and 46% ( $P = 0.56$ ), respectively<sup>[55]</sup>. Interestingly, a few studies have reported favorable outcomes in CHC patients undergoing transplantation. Chan *et al.*<sup>[56]</sup> reported three cases, with two of them alive without recurrence 25 and 35 mo post-transplant. The other patient died of metastatic disease 16.5 mo after transplant. Another more recent publication found that transplanted CHC patients have better 5-year overall survival than those treated with major resection (41.1% vs 28.1%,  $P = 0.039$ )<sup>[57]</sup>. However, the 5-year overall survival rate of transplanted CHC patients was still much worse than transplanted HCC patients in both studies (41.1% vs 67%,  $P < 0.001$  and 48% vs 78%,  $P = 0.01$ )<sup>[55,57]</sup>. These findings were further supported by Vilchez *et al.*<sup>[12]</sup> in their UNOS database analysis. They found an overall 5-year survival of 40% in transplanted CHC patients, which was similar to CC (47%) but much worse than HCC (62%,  $P = 0.002$ ). The authors concluded that currently, liver transplant is not a viable option for these patients. It should be emphasized that these results may be influenced by the fact that majority of CHC patients are misdiagnosed pre-operatively and managed as HCC. Improved initial diagnostic accuracy may allow for optimization and more aggressive neo-adjuvant therapies for CHC patients. This may in turn improve outcomes in this group and make transplant a viable option in the future.

Other treatment modalities that have been reported in CHC include transarterial chemoembolization, radio-frequency ablation, and percutaneous ethanol injection, but the data regarding the benefits of these interventions

are inconclusive. The role of chemotherapy and radiotherapy remains to be defined.

## PROGNOSIS

Despite the ambiguity and discordance of CHC clinical features reported in the literature, the studies consistently supported that CHC is associated with a more aggressive course and a worse prognosis than HCC. With regards to CC, the studies are varied with some showing CHC to have a worse<sup>[9]</sup> or similar prognosis while others show an improved outcome. Overall most studies showed that the prognosis of CHC is grim. Reported 3-year and 5-year overall survivals range from (37.3%, 47%, 46%, 12.4%, 10.5%, 34.6%) and (9.2%, 40%, 32%, 23.1%, 33%), respectively<sup>[8-12,55,57,58]</sup>.

Adverse clinicopathologic prognostic factors associated with increased tumor recurrence and worse survival in various studies include large tumor size ( $> 5$  cm), presence of satellite nodules, lymph node involvement, multifocality, vascular invasion, portal vein invasion, high tumor stage, high levels of CA 19-9, decreased capsule formation, free surgical resection margins  $< 2$  cm, and GGT levels  $> 60$  U/L<sup>[11,58,59]</sup>. However, many of these factors did not reach statistical significance on multivariate analysis. This may be due to the retrospective nature and low number of patients within each study due to the low incidence of CHC.

A recent population level study analyzed the SEER database for patients diagnosed with CHC between 1988-2009 in the United States. Of the 465 cases studied, they founded that a majority of CHC patients were male (66%) and Caucasian (74.9%), and a plurality were 66 years or older (44.3%)<sup>[57]</sup>. Clinical features of CHC patients fell in between those for HCC and CC, suggestive of the mixed characteristics associated with this tumor and in concordance with its bi-phenotypic differentiation. The authors found that CHC had a worse overall survival when compared to HCC, but better when compared with CC. The reported 5-year overall survival and disease specific survival for HCC, CHC, and CC were 11.7%, 10.5%, 5.7% and 21%, 17.8% and 11.9%, respectively ( $P < 0.001$ ). The authors of the study concluded that CHC patients have intermediate clinical characteristics, demographics, and prognosis when compared with HCC and CC patients. Another study compared the post-resection outcomes of CHC, HCC and CC and found no significant differences in tumor recurrence rates, but did find worse survival rates when compared to HCC. However, results of this study are not representative of true CHCs as the authors used the Allen and Lisa<sup>[7]</sup> classification. The majority of patients in this study were classified as "combined type" or type 2 of the Allen and Lisa classification, which is not currently considered a true CHC according to the WHO classification<sup>[6]</sup>.

The intermediate biological behavior of CHC has been further supported by other studies. Multiple series have found clinico-pathologic features in CHC that are commonly associated with either HCC or CC. These

include a high rate of lymph node metastasis, commonly associated with CC, and vascular invasion and portal vein invasion, commonly associated with HCC. Reported rates of lymph node metastasis in CHC cases are as high as 42%<sup>[8]</sup>. This may be explained by the biphenotypic nature of these malignancies<sup>[9]</sup>.

In summary, CHC is a rare tumor with bad prognosis and overlapping clinical and radiological features with HCC and CC. More studies are required to adequately define its histogenesis including molecular genetics of this tumor.

## ACKNOWLEDGMENTS

The authors wish to thank Hongfa Zhu, MD, PhD, at Mount Sinai Hospital, New York, United States, for providing the microphotographs of classic type combined hepatocellular-cholangiocarcinoma.

## Abstract

### AIM

To evaluate the performance of FibroMeter<sup>Virus3G</sup> combined to the first generation tests aspartate amino-transferase-to-platelet ratio index (APRI) or Forns index

to assess significant fibrosis in chronic hepatitis C (CHC).

## METHODS

First generation tests APRI or Forns were initially applied in a derivation population from Rio de Janeiro in Brazil considering cut-offs previously reported in the literature to evaluate significant fibrosis. FibroMeter<sup>Virus3G</sup> was sequentially applied to unclassified cases from APRI or Forns. Accuracy of non-invasive combination of tests, APRI plus FibroMeter<sup>Virus3G</sup> and Forns plus FibroMeter<sup>Virus3G</sup> was evaluated in the Brazilian derivation population. APRI plus FibroMeter<sup>Virus3G</sup> combination was validated in a population of CHC patients from Angers in France. All patients were submitted to liver biopsy staged according to METAVIR score by experienced hepatopathologists. Significant fibrosis was considered as METAVIR  $F \geq 2$ . The fibrosis stage classification was used as the reference for accuracy evaluation of non-invasive combination of tests. Blood samples for the calculation of serum tests were collected on the same day of biopsy procedure or within a maximum 3 mo interval and stored at  $-70^{\circ}\text{C}$ .

## RESULTS

Seven hundred and sixty CHC patients were included (222 in the derivation population and 538 in the validation group). In the derivation population, the FibroMeter<sup>Virus3G</sup> AUROC was similar to APRI AUROC (0.855 *vs* 0.815,  $P = 0.06$ ) but higher than Forns AUROC (0.769,  $P < 0.001$ ). The best FibroMeter<sup>Virus3G</sup> cut-off to discriminate significant fibrosis was 0.61 (80% diagnostic accuracy; 75% in the validation population,  $P = 0.134$ ). The sequential combination of APRI or Forns with FibroMeter<sup>Virus3G</sup> in derivation population presented similar performance compared to FibroMeter<sup>Virus3G</sup> used alone (79% *vs* 78% *vs* 80%, respectively,  $P = 0.791$ ). Unclassified cases of significant fibrosis after applying APRI and Forns corresponded to 49% and 54%, respectively, of the total sample. However, the combination of APRI or Forns with FibroMeter<sup>Virus3G</sup> allowed 73% and 77%, respectively, of these unclassified cases to be correctly evaluated. Moreover, this combination resulted in a reduction of FibroMeter<sup>Virus3G</sup> requirement in approximately 50% of the entire sample. The stepwise combination of APRI and FibroMeter<sup>Virus3G</sup> applied to the validation population correctly identified 74% of patients with severe fibrosis ( $F \geq 3$ ).

## CONCLUSION

The stepwise combination of APRI or Forns with FibroMeter<sup>Virus3G</sup> may represent an accurate lower cost alternative when evaluating significant fibrosis, with no need for liver biopsy.

**Core tip:** Liver fibrosis assessment still poses a challenge

when prioritizing hepatitis C treatment due to logistical and financial barriers in the use of direct acting antiviral drugs. We introduced a new stepwise combination of first generation fibrosis tests - aminotransferase-to-platelet ratio index (APRI) and Forns-followed by FibroMeter<sup>Virus3G</sup> whenever results remained unclassified after first generation tests to identify significant fibrosis. This combination presented similar accuracy to FibroMeter<sup>Virus3G</sup> used as the only test, reduced APRI and Forns grey zone, and spared FibroMeter<sup>Virus3G</sup> requirement in 50% of cases. This approach represents a lower-cost alternative to assess fibrosis, with no need for liver biopsy.

Fibrosis assessment using FibroMeter combined to first generation tests in hepatitis C. *World J Hepatol* 2017; 9(6): 310-317 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i6/310.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i6.310>

## INTRODUCTION

Fibrosis staging in chronic hepatitis C (CHC) has evolved in recent years with the introduction of blood tests for liver fibrosis as well as physical methods such as elastometry. Although liver biopsy has been classically considered the standard tool to evaluate fibrosis, it presents well-known inconveniences<sup>[1-3]</sup> and limitations<sup>[4-7]</sup> which make its use to assess fibrosis staging controversial amongst various authors<sup>[8-11]</sup>. However, even when considering the recent advances in CHC therapy, the diagnosis of significant fibrosis still represents a challenge to define which patients should have priority in treatment, mainly in resource limited countries. Thus, the development and improvement of alternative methods to identify candidates for an early treatment or intensive fibrosis monitoring is still recommended<sup>[11]</sup>. Most of the commonly used first generation non-invasive tests such as aspartate aminotransferase-to-platelet ratio index (APRI)<sup>[12]</sup>, FIB-4<sup>[13]</sup> and Forns index<sup>[14]</sup> have been constructed and evaluated as binary diagnosis tools aiming to predict or exclude significant fibrosis, advanced fibrosis or cirrhosis at specific cut-offs. Although they are all free of charge, easily accessible and well validated for CHC, these non-invasive tests are limited to classify all patients<sup>[12-14]</sup>.

The interest in detailed fibrosis class classification for non-invasive tests of fibrosis has recently grown<sup>[15-18]</sup>, representing a more comprehensive and sophisticated approach to assess liver fibrosis. In this line, FibroMeters are a group of blood tests providing classifications intended to evaluate liver fibrosis in chronic viral hepatitis, alcoholic liver disease and non-alcoholic fatty liver disease<sup>[19-21]</sup>. FibroMeter dedicated for viral aetiology has recently evolved from FibroMeter<sup>Virus2G</sup><sup>[20]</sup> to a less costly

hyaluronic acid free test FibroMeter<sup>Virus3G[21]</sup>, which discriminates seven different fibrosis classes. FibroMeters provide scores ranging from 0 to 1 which are correlated with METAVIR staging system<sup>[22]</sup>. Although this new non-invasive test represents a better strategy to evaluate fibrosis in CHC, it may signify an economic burden hindering easy access mainly in developing countries. Thus, in order to identify patients with significant fibrosis and optimize costs, we evaluated the performance of a stepwise combination using APRI and Forns followed by FibroMeter<sup>Virus3G</sup> in cases whose results remained unclassified after use of these first generation tests, always considering liver biopsy as reference.

## MATERIALS AND METHODS

### Patients

A cross-sectional study with prospective inclusion of compensated CHC patients submitted to percutaneous liver biopsy was performed at the Federal University of Rio de Janeiro, Brazil, as part of a pre-treatment routine evaluation. This group represented the derivation population of the study. Patients with concomitant human immunodeficiency virus infection, hepatitis B virus, alcohol abuse, metabolic, autoimmune or biliary diseases, liver transplantation or those who had previously undergone antiviral treatment were excluded. The validation population was composed by an independent cohort of CHC patients from Angers in France, who fulfilled the same inclusion and exclusion criteria. All patients signed an informed consent form and the study was approved by the Ethics Committee of both Institutions.

### Liver biopsy

In the derivation population, all consecutive biopsies were guided by ultrasonography using a 14 or 16 G disposable Tru Cut needle (Surecutw, TSK Laboratory, Akasaka, Japan) obtaining a maximum length of 20 mm for each pass. In validation population, Menghini needle was used. Samples were considered inappropriate when length presented < 10 mm or contained < 6 portal tracts. Serial sections 5 µm thick were cut from each paraffin block and routinely stained with hematoxylin and eosin, periodic acid-Schiff diastase, reticulin, Masson Trichrome and Picrosirius red. Liver fibrosis was staged from F0 to F4 according to METAVIR staging system<sup>[22]</sup> by an experienced hepatopathologist in each centre, blinded for biological and clinical results. METAVIR F ≥ 2 was considered significant fibrosis. This fibrosis stage classification was used as the reference for accuracy calculation of non-invasive tests.

### Blood fibrosis tests

Serum tests of fibrosis were performed with blood samples collected from fasting patients on the same day of biopsy procedure or within a maximum 3 mo interval and stored at -70 °C. APRI and Forns were selected due to their free accessibility and their good

accuracy to discriminate significant fibrosis. The values of APRI<sup>[12]</sup>, Forns<sup>[14]</sup> and FibroMeter<sup>Virus3G[21]</sup> tests were calculated according to the original studies: (1) APRI = AST level/ULN/platelet counts (10<sup>9</sup>/L) × 100; (2) Forns index = 7.811 - 3.131 × ln(platelet count) + 0.781 × ln(GGT) + 3.467 × ln(age) - 0.014 × cholesterol; and (3) FibroMeter<sup>Virus3G</sup> = patented formula including the biologic parameters prothrombin index, AST, ALT, Urea, GGT, alpha-2-macroglobulin and platelets. The calculations were performed by Echosens (Paris, France) laboratory.

### Statistical analysis

Quantitative variables were expressed as mean ± SD values or proportions. Student's *t* test or ANOVA were used to compare continuous variables, and McNemar  $\chi^2$  test to compare paired proportions. The performance of APRI, Forns and FibroMeter<sup>Virus3G</sup> to predict significant fibrosis was expressed by the AUROC. In order to evaluate the applicability of FibroMeter<sup>Virus3G</sup>, considering an economic approach, we determined the best cut-off point of FibroMeter<sup>Virus3G</sup> to discriminate significant fibrosis using the Youden index that maximizes sensitivity and specificity. The performance of APRI and Forns were separately assessed to exclude or predict significant fibrosis respectively, at cut-offs already established in literature as follows: APRI: cut-off of 0.5 and 1.5<sup>[12]</sup>; Forns: cut-off of 4.2 and 6.9<sup>[14]</sup>. FibroMeter<sup>Virus3G</sup> was then sequentially tested in a stepwise use, considering the results allocated in unclassified APRI values (between 0.5 and 1.5) and Forns values (between 4.2 and 6.9), using histology as reference. The overall accuracy of the aforementioned approaches was calculated considering the sum of true positive and negative cases as a proportion of the total. Sensitivity, specificity, predictive positive (PPV) and negative values (NPV) of first generation tests and sequential use of APRI + FibroMeter<sup>Virus3G</sup> and Forns + FibroMeter<sup>Virus3G</sup> were evaluated.

Data were analyzed using the statistics software programs SPSS version 20 for Windows and MedCalc version 14.8.1. A *P* value < 0.05 was considered statistically significant.

## RESULTS

### Patients' characteristics

The initial series of liver specimens in Rio population consisted of 231 biopsies, of which four (1.7%) were excluded, due to evidence of other hepatic diseases associated with hepatitis C, and five (2.0%) were considered inadequate for analysis. Thus, the final Rio population included 222 biopsies of CHC patients. The validation cohort was represented by 538 French CHC patients. Excepted for gender, demographic characteristics, laboratory data and histological features of derivation and validation cohort were similar and described in Table 1.

The mean length of liver fragments was 24 ± 5 mm in derivation population vs 22 ± 10 mm in validation cohort (*P* = 0.315). The prevalence of significant fibrosis

Total	5	91	55	54	17	222	190/222 = 86

was 57% vs 61% ( $P = 0.399$ ) comparing derivation population to validation cohort, respectively, considering liver biopsy as reference.

### Rio (derivation) population

FibroMeter<sup>Virus3G</sup> applied as a class classification test presented an overall rate of correct diagnosis of 86% considering any of the results reported in FibroMeter<sup>Virus3G</sup> stage class in accordance with fibrosis scored by METAVIR (Table 2). The AUROCs of both tests comparing METAVIR F0-F1 vs F2-F4 were similar between FibroMeter<sup>Virus3G</sup> and APRI [0.855 (0.801-0.898) vs 0.815 (0.757-0.864)] but the difference was at the limit of significance ( $P = 0.06$ ). The FibroMeter<sup>Virus3G</sup> AUROC was higher in comparison to Forns AUROC [0.855 (0.801-0.898) vs 0.769 (0.708-0.823);  $P < 0.001$ ]. The best cut-off that predicted significant fibrosis was 0.61, demonstrating an accuracy of 80% compared to liver biopsy. The PPV, NPV and accuracy of all tests were shown in Table 3. The stepwise combination of APRI or Forns followed by FibroMeter<sup>Virus3G</sup> provided an overall accuracy of 79% (Figure 1) and 78% (Figure 2), respectively ( $P = 0.791$ ), when identifying significant fibrosis. It also enabled 49% ( $n = 109$ ) and 54% ( $n = 120$ ) of the total sample, representing the grey zone of APRI and Forns for significant fibrosis, to be correctly classified in 73% and 77% of cases, respectively.

Thus, diagnostic accuracy did not differ comparing the use of FibroMeter<sup>Virus3G</sup> test alone or combined with APRI or Forns (80% vs 79% vs 78%, respectively,  $P = 0.79$ ), but represented a lower cost alternative since this procedure led to a 51% reduction of FibroMeter<sup>Virus3G</sup> test requirement using APRI + FibroMeter<sup>Virus3G</sup> and 46% reduction using Forns + FibroMeter<sup>Virus3G</sup> ( $P = 0.25$ ). Rates of well classified patients applying the algorithm APRI + FibroMeter<sup>Virus3G</sup>, using METAVIR score as reference, were as follows: 100% for F0, 81% for F1, 67% for F2, 80% for F3 and 94% for F4.

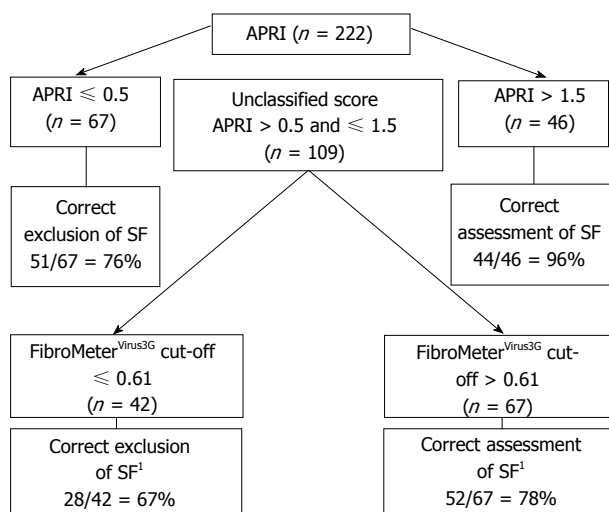

### Angers (validation) population

The cut-off of 0.61 found in derivation population presented an overall accuracy of 75% when discriminating significant fibrosis in the validation cohort in comparison to 80% in derivation population ( $P = 0.13$ ), considering histology as reference. The diagnostic accuracy of APRI + FibroMeter<sup>Virus3G</sup> combination in validation population to detect significant fibrosis and advanced fibrosis was respectively 69% and 74%. Rates of correct classification of this algorithm according to METAVIR score were as follows: 100% for F0, 88% for F1, 39% for F2, 64% for F3 and 85% for F4. When analysing the subgroup of false negative patients in this population we observed that 69% are represented by F2, 23% are F3, and only

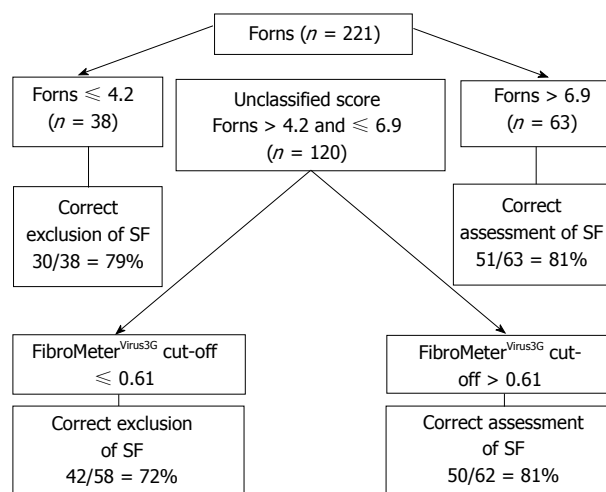

**Figure 1** Sequential algorithm of aminotransferase-to-platelet ratio index + FibroMeter<sup>Virus3G</sup> to predict significant fibrosis, in the Rio population. Accuracy of sequential use of aminotransferase-to-platelet ratio index (APRI) + FibroMeter<sup>Virus3G</sup> was determined considering: Number of correct assessments of SF (96) + number of correct exclusions of SF (79)/total of liver biopsies (222) = 175/222 = 79%. <sup>1</sup>Considering liver biopsy as reference.

8% are cirrhotic. The PPV, NPV and accuracy of APRI + FibroMeter<sup>Virus3G</sup> combination on validation population are shown in Table 3.

## DISCUSSION

Although new treatment regimens with very high rates of sustained virologic response are now available to treat hepatitis C patients, the logistical and financial barriers to treat all infected patients represent an important limitation, even in resource-replete countries<sup>[23]</sup>. Thus, it is necessary to determine an optimal and practical approach to prioritize these highly efficacious, but extremely costly therapies, for a selected population at risk of disease progression or for those who require immediate therapy. There is a consensus that non-invasive evaluation of liver

**Figure 2** Sequential algorithm of Forns + FibroMeter<sup>Virus3G</sup> to predict significant fibrosis, in the Rio population. Accuracy of sequential use of Forns + FibroMeter<sup>Virus3G</sup> was determined considering: Number of correct assessments of SF [(101) + number of correct exclusions of SF (72)]/total of liver biopsies (221) = 173/221 = 78%.

fibrosis may be useful to complement or even replace liver biopsy in CHC owing to its low risk of complications and good accuracy. However, non-invasive tests also present some limitations related to cost, fibrosis discrimination and accuracy.

The present study originally evaluated the combination of a more robust patented fibrosis test, FibroMeter<sup>Virus3G</sup>, with low cost first generation tests to enhance its applicability in the clinical practice. Although APRI and Forns are well established non-invasive tests to assess fibrosis in CHC, their main limitation is that when used alone, almost half of the patients could not be classified according to the possibility of presenting or not significant fibrosis. Thus, using a second test to improve discrimination would enhance the accuracy of these results in order to diagnose significant fibrosis. In the present study, the use of first generation tests combined with FibroMeter<sup>Virus3G</sup> demonstrated to be a lower cost strategy since it reduced

FibroMeter<sup>Virus3G</sup> requirement, without loss of accuracy, eliminating the requirement for liver biopsy procedure.

When analyzed as a class classification test, FibroMeter<sup>Virus3G</sup> presented an overall accuracy of 86% similar to the rate of 87% described in FibroMeter<sup>Virus3G</sup> original report<sup>[21]</sup>. The AUROC for significant fibrosis was 0.85, comparable to previous reports ranging from 0.84 to 0.86<sup>[16,17,21]</sup>. Analysing under a practical point of view, and considering significant fibrosis as the criteria to treat or not the patient, we presented important results that may help hepatologists on clinical decision-making. We found a cut-off of 0.61 as the best numeric value to discriminate significant fibrosis for FibroMeter<sup>Virus3G</sup>, which is close to the value displayed in the manufacturer's bar graph of FibroMeter<sup>Virus3G</sup> report of 0.63, representing the transition from F1 to F2 METAVIR stage<sup>[24]</sup>. The cut-off of 0.61 presented similar performance in comparison to manufacturer's cut-off of 0.63 in the French validation cohort.

FibroMeter<sup>Virus3G</sup> applied as a numeric score also enables its association to other scores. Sebastiani *et al.*<sup>[25]</sup> provided a sequential algorithm for fibrosis evaluation (SAFE) biopsy combining APRI and Fibrotest, another biomarker based on fibrosis class classification, resulting in a 46% reduction of liver biopsy requirement to identify significant fibrosis. In a more recent study performed with 1785 CHC patients, Boursier *et al.*<sup>[26]</sup> reported that the diagnosis of significant fibrosis using SAFE still required liver biopsy in 64% of the cases. To our knowledge, to date the stepwise combination of APRI or Forns with FibroMeter<sup>Virus3G</sup> has never been evaluated. The sequential algorithm of either APRI or Forns combined with FibroMeter<sup>Virus3G</sup> represents a lower cost method with similar accuracy when compared to the isolated use of FibroMeter<sup>Virus3G</sup> test. This represents an advantage when reducing the number of unclassified APRI and Forns patients in the grey zone, without the need for liver biopsy. This is a useful and alternative approach in countries with less financial resources, considering the easy applicability and low cost of APRI and Forns for significant fibrosis. This procedure may represent a more comprehensive proposal to apply these non-invasive tests in the clinical setting.

Some limitations may be discussed in this study. The prevalence of significant fibrosis in our population was higher than the prevalence reported in a meta-analysis including more than 30000 CHC patients which showed a rate of 48% of significant fibrosis histologically assessed<sup>[27]</sup>. Our prevalence is greatly influenced by the fact that this study was carried out in a tertiary-care setting. Another limitation is that derivation and validation populations came from different racial ethnic backgrounds. Nevertheless, most patients included in the derivation population were Caucasians and both populations shared similar characteristics regarding laboratorial results and distribution of significant fibrosis.

The diagnostic accuracy of the APRI and FibroMeter<sup>Virus3G</sup> combination in validation population was 69%. A decrease in diagnostic accuracy is usually expected in the validation population when compared to the derivation

population; however some points need to be emphasized. The PPV of the algorithm APRI and FibroMeter<sup>Virus3G</sup> in the validation population was high (87%). Consequently the algorithm enabled the selection of a subset of patients where very few false positive results were found. In other words, this algorithm allowed treatment to be given to those patients who really required antiviral drugs. The low sensitivity (57%) remains a limitation, since a considerable number of patients who need to be treated will not be correctly identified by the algorithm. Nevertheless, when analysing the subgroup of false negative patients in the validation population, we observed that the majority (69%) were represented by F2 and only 8% were cirrhotic. In the whole validation population, most of the F0 patients (100%), the F1 patients (88%) and the F4 (85%) were well classified by the algorithm, as well as two thirds of the F3. Therefore, the algorithm identifies the more severe patients (F3 and F4) while most of the misclassification concerns the F2 stage. In the derivation population, even though the accuracy of the algorithm was found to be better, the worst result was also observed in F2 stage. And lastly, even when considering a gold standard such as liver biopsy, there is a considerable misclassification of F2 patients<sup>[28]</sup>. In low income countries, where therapy is offered only to patients with advanced fibrosis, a close follow-up is required until these untreated patients fulfil the criteria for direct antiviral therapy. We may consider following the "missed" patients by reapplying the algorithm to better identify when patients change their fibrosis stage and require treatment<sup>[29]</sup>. Since most misclassified patients present F2 fibrosis stage, there is sufficient time before they become cirrhotic.

Our findings demonstrated that the association of a more robust non-invasive marker of fibrosis such as FibroMeter<sup>Virus3G</sup> and first generation tests may represent a useful alternative for fibrosis staging in CHC without loss of accuracy and without the need for liver biopsy. This might be an attractive approach mainly in limited resource countries.

## COMMENTS

### Background

Despite recent advances in chronic hepatitis C therapy, diagnosis of significant fibrosis still represents a challenge when defining which patients should have priority in treatment, mainly in resource limited countries. Although liver biopsy has been classically considered the standard tool to evaluate fibrosis, it presents well-known inconveniences and limitations which make its use controversial amongst various authors. Thus, the development and improvement of alternative methods to identify candidates for an early treatment or intensive fibrosis monitoring is still recommended. First generation non-invasive tests such as aminotransferase-to-platelet ratio index (APRI), FIB4 and Forns are free of charge, easily accessible and well validated for chronic hepatitis C, however are limited when classifying all patients. Therefore, in order to increase assessment availability for patients

with significant fibrosis, the authors evaluated the performance of a stepwise combination of first generation tests of fibrosis - APRI and Forns - followed by FibroMeter<sup>Virus3G</sup>, a more robust test, whenever results remained unclassified after first generation tests, always using liver biopsy as reference. This proposed combination allows costs to be optimized with no loss of accuracy and no need of liver biopsy, thus representing a favorable economic approach in resource limited areas.

### Research frontiers

This study introduces alternative approaches to evaluate significant fibrosis in chronic hepatitis C using a stepwise algorithm with first generation tests and FibroMeter<sup>Virus3G</sup> both to improve clinical decision-making and reduce costs. The authors considered this topic of great interest for clinicians and hepatologists in the daily practice management of chronic hepatitis C.

### Innovations and breakthroughs

The present study demonstrated that the association of a more robust non-invasive marker of fibrosis such as FibroMeter<sup>Virus3G</sup> and first generation tests such as APRI and Forns may represent a useful alternative for fibrosis staging in chronic hepatitis C. This might be an attractive non-invasive approach to evaluate liver fibrosis and to optimize the access to potent but expensive direct-acting antiviral agents. To our knowledge, to date the stepwise combination of APRI or Forns with FibroMeter<sup>Virus3G</sup> has never been evaluated.

### Applications

The sequential algorithm of either APRI or Forns combined with FibroMeter<sup>Virus3G</sup> represents an alternative approach to recognize and prioritize patients with chronic hepatitis C to antiviral therapy. It reduces the number of unclassified APRI and Forns patients allocated in the grey zone and reduces the total FibroMeter<sup>Virus3G</sup> requirement in 50%, representing an alternative approach in countries with less financial resources, without loss of accuracy, eliminating the requirement for liver biopsy procedure. This procedure may represent a more comprehensive proposal to apply these non-invasive tests in the clinical setting.

### Terminology

FibroMeter<sup>Virus3G</sup> is a non-invasive test to evaluate liver fibrosis in chronic hepatitis C represented by a patented formula including the biologic parameters prothrombin index, AST, ALT, Urea, GGT, alpha-2-macroglobulin and platelets.

### Peer-review

It is a carefully planned study, it takes in to consideration the Liver biopsy and the Fibrometer Virus2 and Virus3 and makes a head to head comparison of the three, as to discover the safety profile and the accuracy when it comes to clinical use especially for the group patients with cirrhosis and to evaluate the change in fibrosis stage in pts with cirrhosis that are unable to undergo liver biopsy with a non-invasive procedure. The Fibre meter requires more wide use in the clinical setting as to prove its self as a reliable and non-invasive method of estimating the fibrosis stage.

## Observational Study

# Thrombocytopenia in cirrhosis: Impact of fibrinogen on bleeding risk

Sonali V Thakrar, Susan V Mallett

Sonali V Thakrar, Susan V Mallett, Royal Free Perioperative Research Group, Department of Anaesthesia, Royal Free London, London NW3 2QG, United Kingdom

**Author contributions:** Thakrar SV and Mallett SV contributed equally to this work in designed and coordinated the research and writing the manuscript.

**Institutional review board statement:** This work was reviewed and approved by the Royal Free London Research and Development department and was deemed not to require ethics approval.

**Informed consent statement:** All data retrieved from our transplant database was anonymised. The data has been previously collected (prior to the study commencing), and was collected as part of standard care. Only those persons involved in clinical care had access to our database. No patient interventions were performed as part of this study. As a result, it was deemed unnecessary to require patient consent.

**Conflict-of-interest statement:** There are no conflicts of interest to declare.

**Data sharing statement:** Technical appendix, statistical code, and dataset available from the corresponding author at [s.thakrar1@nhs.net](mailto:s.thakrar1@nhs.net). Participant consent was not obtained but the presented data are anonymised and risk of identification is low.

**Open-Access:** This article is an open-access article which was selected by an in-house editor and fully peer-reviewed by external reviewers. It is distributed in accordance with the Creative Commons Attribution Non Commercial (CC BY-NC 4.0) license, which permits others to distribute, remix, adapt, build upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited and the use is non-commercial. ## Abstract

### AIM

To investigate the relationship between baseline platelet count, claus fibrinogen, maximum amplitude (MA) on thromboelastography, and blood loss in orthotopic liver transplantation (OLT).

### METHODS

A retrospective analysis of our OLT Database (2006-2015) was performed. Baseline haematological indices and intraoperative blood transfusion requirements, as a combination of cell salvage return and estimation of 300 mls/unit of allogenic blood, was noted as a surrogate for intraoperative bleeding. Two groups: Excessive transfusion (> 1200 mL returned) and No excessive transfusion (< 1200 mL returned) were analysed. All data analyses were conducted using IBM SPSS Statistics version 23.

### RESULTS

Of 322 OLT patients, 77 were excluded due to fulminant disease; redo transplant or baseline haemoglobin (Hb) of < 80 g/L. One hundred and fourteen (46.3%) were classified into the excessive transfusion group, 132 (53.7%) in the no excessive transfusion group. Mean age and gender distribution were similar in both groups.

Baseline Hb ( $P \leq 0.001$ ), platelet count ( $P = 0.005$ ), claus fibrinogen ( $P = 0.004$ ) and heparinase MA ( $P = 0.001$ ) were all statistically significantly different. Univariate logistic regression with a cut-off of platelets  $< 50 \times 10^9/L$  as the predictor and Haemorrhage as the outcome showed an odds ratio of 1.393 (95%CI: 0.758-2.563;  $P = 0.286$ ). Review of receiver operating characteristic curves showed an area under the curve (AUC) for platelet count of 0.604 (95%CI: 0.534-0.675;  $P = 0.005$ ) as compared with AUC for fibrinogen level, 0.678 (95%CI: 0.612-0.744;  $P \leq 0.001$ ). A multivariate logistic regression shows United Kingdom model for End Stage Liver Disease ( $P = 0.006$ ), Hb ( $P = 0.022$ ) and Fibrinogen ( $P = 0.026$ ) to be statistically significant, whereas Platelet count was not statistically significant.

### CONCLUSION

Platelet count alone does not predict excessive transfusion. Additional investigations, *e.g.*, claus fibrinogen and viscoelastic tests, provide more robust assessment of bleeding-risk in thrombocytopenia and cirrhosis.

**Key words:** Thrombocytopenia; Cirrhosis; Haemostasis; Fibrinogen; Liver transplantation

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Current literature describing bleeding risk in thrombocytopenia and cirrhosis does not take into account the impact of fibrinogen. The minimal platelet count to form a clot with normal strength is unknown, and would be influenced by fibrinogen. Viscoelastic testing, particularly maximum amplitude (MA, thromboelastography) or maximum-clot-firmness (MCF, thromboelastometry), reflects platelet-fibrinogen interaction and allows assessment of clot strength. Low platelet count and low fibrinogen levels lead to low MA/MCF and correlate strongly with increased bleeding tendency. Assessment of platelet count alone does not accurately predict bleeding, but is useful in conjunction with other indices such as claus fibrinogen and MA/MCF.

Thakrar SV, Mallett SV. Thrombocytopenia in cirrhosis: Impact of fibrinogen on bleeding risk. *World J Hepatol* 2017; 9(6): 318-325 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i6/318.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i6.318>

### INTRODUCTION

Thrombocytopenia is a common finding in patients with advanced liver disease. In most instances it is well tolerated but it is traditionally thought to increase the likelihood of surgical or traumatic bleeding. Moderate thrombocytopenia (defined as platelet count  $< 50 \times 10^9/L$ ) occurs in approximately 13% of those with liver disease and is associated with significant morbidity<sup>[1]</sup>. A number of factors contribute to thrombocytopenia in

liver disease, including low thrombopoietin levels, and sequestration of platelets in hypersplenism as a result of portal hypertension<sup>[2]</sup>.

Derangements of other haematological indices in cirrhosis include prolongation of prothrombin time (PT), prolongation of activated thromboplastin time (APTT) and dysfibrinogenaemia. Conventionally, these changes were thought to lead to an increased bleeding risk. Over the last 10 years, however, a new paradigm of haemostasis in liver disease has been described. There is now considered to be a "rebalancing" with a reduction in pro-coagulant molecules being accompanied by a reduction in anticoagulant molecules. Thrombin generation is normal, or even increased and patients with cirrhosis are now considered to have an elevated risk of thrombosis rather than have complications of bleeding<sup>[3]</sup>.

Standard tests of coagulation such as PT and APTT do not accurately reflect coagulation status *in vivo*, as they cannot assess cellular contributions or the effects of anticoagulant molecules. *In-vitro* studies in cirrhosis have shown a compensatory increase in levels of Von Willebrand Factor (vWF) - a platelet adhesion protein and reductions in ADAMTS-13, the cleavage enzyme responsible for the breakdown of vWF<sup>[4]</sup>. Additionally, platelet hyperactivity has been reported in cholestatic liver disease<sup>[5]</sup>. A systematic review evaluating platelet function concluded that in patients with cirrhosis, primary haemostasis is not defective<sup>[6]</sup>.

Whole blood viscoelastic testing provides valuable information about dynamic clot formation. It measures changes in clot tensile strength with time and is used in goal-orientated algorithms to target transfusion. Clot strength is assessed by maximum amplitude (MA) or maximum clot firmness (MCF) and is influenced by both platelet count and by fibrinogen level. MA or MCF can be maintained in the face of low platelet counts by normal or increased levels of fibrinogen<sup>[7]</sup>. Whole blood global viscoelastic tests such as thromboelastography (TEG®) or thromboelastometry (ROTEM®) may provide more clinically relevant information about coagulation profiles in liver disease. Increasingly observed blood transfusion free orthotopic liver transplantation (OLT) suggests that conventional tests of coagulation are inadequate in predicting bleeding.

Studies of low platelet count in cirrhosis suggest that thrombin generation may be reduced in cases of severe thrombocytopenia<sup>[8]</sup>. *In-vitro* studies, however, have shown that a platelet count of  $20-30 \times 10^9/L$  is likely to be adequate to initiate haemostasis and generate enough thrombin to allow normal MA on TEG<sup>[9]</sup>. Despite a reduction in thrombin production, clot strength is likely to be adequate if the appropriate substrates for clot formation are present. Moderate reductions in platelet count, therefore, do not necessarily indicate an increased risk of bleeding in liver disease.

British Haematology Society guidelines for the use of platelet transfusions and consensus guidelines for percutaneous image guided interventions<sup>[10,11]</sup> recommend the prophylactic transfusion of platelets to a count of  $> 50$

$\times 10^9/L$  prior to liver biopsy to prevent complications of bleeding. In view of current knowledge of coagulation and haemostasis in cirrhosis, the objectives of this study were to investigate the relationship between baseline platelet count, claus fibrinogen, MA on TEG and the volume of blood transfused in patients undergoing orthotopic liver transplantation.

## MATERIALS AND METHODS

### Study design

A retrospective study of patients who had undergone OLT at the Centre for Hepatobiliary Surgery, Royal Free London between 2006 and 2015 was conducted. The cohort of patients reviewed had transplantation for chronic end stage liver disease, with or without hepatocellular carcinoma. Data from their intraoperative course was retrieved from a database formed as part of standard care. Those with acute fulminant liver failure, paracetamol overdose or redo transplantation were excluded. Patients with starting haemoglobin of less than 80 g/L were also excluded in view of an increased risk of intraoperative blood transfusion. Data was anonymised and institutional research and development departmental approval was obtained for its use.

Patient demographic data, baseline haematological results, number of packed red cell units transfused intra-operatively and volume of cell salvaged blood returned to patients was retrieved electronically.

### Measurements

Baseline variables were retrieved from the OLT database and included patient characteristics such as age, gender, diagnosis and severity scoring with United Kingdom model for End Stage Liver Disease (UKELD score). Baseline clinical measurements were point-of-care (*i.e.*, Medical diagnostic testing at the point of care) samples taken at the time of anaesthesia for liver transplantation from arterial catheters and measurements included haemoglobin concentration (Hb) and platelet count by pocH-100i full blood count analyser (Sysmex Europe GmbH). TEG variables were from TEG<sup>®</sup> 5000 (Haemonetics, Braintree, MA, United States). United Kingdom TD in particular MA on heparinase TEG was assessed. Heparinase TEGs were used for analysis to remove any influence that may have been exerted by endogenous heparinoids and to standardize results. Laboratory Clauss fibrinogen levels using ACL-TOP 700 (Werfen, United Kingdom) were obtained prior to transplantation and did not exceed 24 h prior to anaesthetic start time. All assays are controlled and monitored using laboratory quality assurance processes.

As a surrogate for intraoperative blood loss, an estimation of 300 mL of blood in a packed red cell unit given to patients was made, and the volume summated with cell salvage return volume to give a total volume of blood returned. Patients were divided into 2 groups according to total volume of blood returned:  $\leq 1200$  mL

(no excessive transfusion) and  $> 1200$  mL (excessive transfusion).

### Statistical analysis

Descriptive statistics were performed on baseline variables and comparisons made between excessive transfusion (ET) and no excessive transfusion (NET) groups. Univariate logistic regression was performed for each variable independently as the predictor, and ET as the binary outcome. Receiver operating characteristic (ROC) curves for baseline platelet count and for baseline claus fibrinogen were also constructed and area under the curves calculated. Binomial logistic regression with each variable as the predictor and ET as the outcome was also performed. Predicted probabilities from the binomial logistic regression were used for further ROC analysis. The relationship between platelet count and blood volume returned as well as fibrinogen and blood volume returned was further investigated by linear regression modeling. All data analyses were conducted using IBM SPSS Statistics version 23. All statistical analyses were reviewed by Ms Fatima Jichi, a trained biostatistician with the department of Biostatistics, University College London.

## RESULTS

### Baseline demographics

Results for 323 patients were reviewed and of these 37 patients had either acute, fulminant liver failure or a redo-liver transplant and were excluded. A further 40 patients had a baseline Hb less than 80 g/L and were also excluded. Of the remaining 246 patients, 114 (46.3%) had excessive transfusion and 132 (53.7%) had no excessive transfusion.

Mean patient ages were 53 years ( $\pm 1$  SD 10.04 years) and were similar in ET and NET groups. The gender distribution of patients was 72.8% male and 27.2% female with a similar divide in both groups. Mean UKELD was 56 ( $\pm 10.55$ ) in the ET group and 51 ( $\pm 5.08$ ) in the NET group ( $P \leq 0.001$ ). Liver disease due to Infection (33.3%) or Alcohol (29.6%) was the commonest aetiology. Interestingly, primary sclerosing cholangitis (PSC) was more common in the NET group (18.9%) vs the ET group (7.9%).  $\chi^2$  analysis of aetiologies in both groups revealed  $\times \chi^2 = 18.81$ ,  $P = 0.016$ . Baseline Hb, platelet count, claus fibrinogen and hep MA were all statistically significantly different between the two groups (Table 1).

A comparison of patient demographics and baseline measurements between those with platelet count  $< 50$  and those  $\geq 50 \times 10^9/L$  is described in Table 2. Baseline fibrinogen was statistically significantly different between those with low platelet count (mean =  $1.78 \pm 0.62$ ) and those without ( $2.45 \pm 1.15$ ,  $P \leq 0.001$ ). Baseline hep MA was also significantly different in the 2 groups ( $35.28 \pm 9.49$  vs  $47.85 \pm 11.93$ ,  $P \leq 0.001$ ). The total volume of blood returned was not significantly different between

the 2 groups ( $P = 0.69$ ).

A logistic regression analysis (Table 3) was performed to ascertain the independent effects of age, gender, UKELD, baseline Hb, baseline platelet count, baseline platelet count <  $50 \times 10^9/L$  or  $\geq 50 \times 10^9/L$  as a binary value, baseline claus fibrinogen level and baseline heparinase MA on likelihood of excessive transfusion. UKELD ( $P \leq 0.001$ ), HB ( $P \leq 0.001$ ), platelet count ( $P = 0.007$ ), claus fibrinogen ( $P \leq 0.001$ ) and Hep MA ( $P = 0.001$ ) were all statistically significant. A cut off value of platelet count less than 50 was not a good predictor of excessive transfusion ( $P = 0.286$ ).

Review of ROC curves showed an area under the curve (AUC) for platelet count of 0.604 (standard error: 0.036; 95%CI: 0.534-0.675;  $P = 0.005$ ). AUC for fibrino-

SD: Standard deviation; UKELD: United Kingdom end stage liver disease score; ALD: Alcoholic liver disease; NASH: Non-alcoholic steato-hepatitis; PSC: Primary sclerosing cholangitis; PBC: Primary biliary cirrhosis; AIH: Autoimmune hepatitis; Hb: Haemoglobin; Hep MA: Maximum amplitude on heparinase thromboelastography.

gen level was 0.678 (standard error: 0.034; 95%CI: 0.612-0.744;  $P \leq 0.001$ ) (Figure 1).

A multivariate logistic regression with all covariates with  $P \leq 0.1$  from univariate logistic regression added to a model, shows UKELD ( $P = 0.006$ ), Hb ( $P = 0.022$ ) and Fibrinogen ( $P = 0.026$ ) to be statistically significant. Platelet count was not statistically significant (Table 4).

The AUC from ROC curve analysis of predicted probabilities from multivariate logistic regression was 0.749 (standard error: 0.032; 95%CI: 0.686-0.812;  $P \leq 0.001$ ), suggesting that variables need to be considered together to better predict excessive transfusion (Figure 2).

Further investigation of the relationship between baseline platelet count and total volume of blood returned to patients showed that for every 1 point increase in platelet count, a 4.9 mL ( $P = 0.19$ ) reduction in total

Platelets	0.999	0.994-1.004	0.700
Fibrinogen	0.682	0.487-0.955	0.026
Hep MA	0.986	0.957-1.015	0.338

OR: Odds ratio; UKELD: United Kingdom end-stage liver disease score; Hb: Haemoglobin; Hep MA: Maximum amplitude on heparinase TEG.

**Table 5** Relationship between baseline platelet count and baseline fibrinogen and blood returned to patients (linear regression)

Model	Regression coefficient B	95%CI	P value
Platelet count	2280.72-4.99	-9.142-0.829	< 0.001
Fibrinogen	3014.63-525.95	-776.88-275.02	< 0.001

blood volume returned was achieved. For every 1-point increase in fibrinogen level, however, a reduction of 525.95 mL ( $P \leq 0.001$ ) of blood returned to the patient was achieved (Table 5).

## DISCUSSION

### Principle findings

Guidelines recommend the prophylactic transfusion of platelets to achieve a count of  $50 \times 10^9/L$  prior to invasive procedures such as liver biopsy. Understanding of haemostasis in the cirrhotic population has altered with the concept of a "rebalanced" haemostatic profile in liver disease. This study evaluated differences in baseline platelet count, fibrinogen levels, viscoelastic tests and blood transfusion requirements in those undergoing OLT for chronic liver disease. Patients in our study were divided according to whether they received excessive blood transfusion or not. On comparison, the 2 groups were well matched for gender and age, although UKELD was found to be significantly different. Severity of liver disease, in the form of Childs-pugh score and Model for

**Figure 1** Receiver operating characteristics for baseline platelet count and baseline claus fibrinogen. A: Platelets; B: Fibrinogen; ROC: Receiver operating characteristic.

end stage liver disease (MELD) scoring, is associated with a prediction of increased intraoperative transfusion requirement<sup>[12]</sup>. This may explain the difference in UKELD between the 2 groups.

It was interesting to note a higher preponderance of PSC as the aetiology of liver disease in those not requiring excessive transfusion. Hypercoagulable haemostatic profiles have been described for those with biliary cirrhotic disease and in general this population does not have thrombocytopenia or low fibrinogen<sup>[5]</sup>.

A statistically significant difference in baseline Hb, platelet count, Clauss fibrinogen and MA on heparinase TEG was observed between those who received excessive transfusion vs those who did not. This highlights an association with bleeding risk and indicates that possibly all of these measurements would be useful in predicting increased blood transfusion requirements.

Logistic regression performed to evaluate the probability of excessive transfusion with each variable shows clearly that a platelet threshold value of  $50 \times 10^9/L$  is not a good predictor of blood transfusion in this population. Although there has been a previously described association between a reduction in thrombin generation with a reduction in platelet count<sup>[8]</sup>, the cut off value of platelets requiring transfusion in cirrhosis is likely to lie significantly below  $50 \times 10^9/L$  described in guidelines. One small prospective study of liver biopsy in severe thrombocytopenia associated

**Figure 2** Receiver operating characteristics with predicted probabilities from multivariate regression. ROC: Receiver operating characteristic.

with haematological malignancy suggests the likely cut off value lies below  $30 \times 10^9/\text{L}$ <sup>[13]</sup>.

Much of the literature describing bleeding risk in cirrhosis and thrombocytopenia does not take into account fibrinogen level. The minimal platelet count required for normal clot strength is unknown and is markedly affected by fibrinogen. MA on TEG is a composite reflection of platelet-fibrinogen interaction and can be used to assess clot strength. Assessment of MA shows that even in the face of a low platelet count, adequate clot strength may still be achieved if fibrinogen is normal or raised. A combination of low platelet count and low fibrinogen level always results in low MA and is strongly associated with an increased bleeding tendency<sup>[14,15]</sup>. Platelet count alone is not a true indicator of clot strength; therefore, if baseline platelet count is low, assessment of MA is useful in guiding whether to replace fibrinogen or to transfuse platelets. Thrombocytopenia predominately leads to a reduction in blood clot strength displayed as MA on TEG<sup>[16]</sup>, but fibrinogen also contributes to clot firmness. The effect of the administration of fibrinogen concentrates in thrombocytopenia, at a count of  $30 \times 10^9/\text{L}$ , in the pig model has been studied. Velik-Salchner *et al.*<sup>[17]</sup> showed an improvement in impaired clot formation and a reduction in blood loss in thrombocytopenia with the addition of fibrinogen.

The impact of fibrinogen on bleeding risk can be observed in the results of this study. Baseline claus fibrinogen level is likely to have a greater protective effect than the other baseline haematological variables (OR: 0.52; 95%CI: 0.388-0.705;  $P \leq 0.001$ ). Similarly, Odds ratios for fibrinogen on multivariate analysis are the lowest when compared with other variables (0.682, 95%CI: 0.487-0.955) (Table 4). On comparison of AUCs on ROC curve analysis, baseline fibrinogen level is a better predictor of excessive transfusion than platelet count. Interestingly, linear regression analysis shows a 525.95 mL reduction in blood returned to patients with each 1-unit increase in baseline fibrinogen level (*i.e.*, 1 g of fibrinogen factor concentrate) (Figure 1). In comparison, 1 pool of platelets (one adult therapeutic dose) increases platelet count by  $20 \times 10^9/\text{L}$ <sup>[11]</sup>, equating to a 99.8 mL reduction in blood transfusion if the linear

model is used. ROC analysis of predicted probabilities on multivariate analysis show an AUC greater than that of platelet count alone, indicating a better predictive value on assessing all the demographic and haematological variables simultaneously (Figure 2).

### Strengths and weaknesses of the study

Although there are a number of *in-vitro* investigations into the associations between thrombocytopenia and fibrinogen concentration and clot strength, there is a lack of evidence relating to the influence of the two *in vivo*. There is also a lack of substantial evidence to validate a cut off value for prophylactic platelet transfusion in the cirrhotic population. This study highlights the contribution of fibrinogen in reducing the risk of excessive blood transfusion, and therefore bleeding risk.

Excessive transfusion was used as a surrogate for intraoperative bleeding in this study. Measurement of blood loss in suction and weight of swabs would provide more accurate information with regard to blood loss, but this information was unavailable retrospectively. Furthermore, OLT is complex surgery with other influences on haemorrhage apart from the haemostatic picture. These include presence of portal hypertension and varices, difficult operative dissection with multiple adhesions, surgical technique (*i.e.*, Caval replacement surgery or "piggy back" technique for reperfusion) and the volume of fluid given to the patient<sup>[12,18]</sup>. Additionally, baseline low haemoglobin values increase the likelihood of requiring intraoperative blood transfusion. Low haematocrit also has an impact on laminar flow in blood vessels and therefore a disturbance in primary haemostasis may occur in anaemia<sup>[19]</sup>. We excluded those with baseline haemoglobin of  $< 80 \text{ g/L}$  for this reason.

Although the results of our study point to the usefulness of measuring baseline claus fibrinogen in conjunction with platelet count and assessment of TEG, we are unable to assess for specific cut off values for baseline platelet count and fibrinogen level. Results would require validation against external data sets to allow for cut off values, requiring further prospective research.

### Implications of study

The transfusion of platelets is not without risk. Complications of platelet transfusion include allergic or anaphylactic reactions, haemolytic and non-haemolytic transfusion reactions, transfusion related acute lung injury and septic transfusion reactions of bacterial origin<sup>[20]</sup>. Furthermore, in liver transplantation, platelets have been shown to be involved in ischaemic reperfusion injury by interactions with activated sinusoidal endothelium and induction of apoptosis. Perioperative platelet transfusion has been identified as an independent risk factor for adverse post-operative outcomes<sup>[21]</sup>. In a large retrospective analysis of patients undergoing cardiac surgery, those receiving platelets were at an increased risk of postoperative infection, stroke and multiorgan failure<sup>[22]</sup>.

The availability of platelets, largely due to short storage life, can also be limited. By demonstrating a lack

of association between excessive blood transfusion and a threshold platelet count of  $50 \times 10^9/L$ , the question of unnecessary prophylactic platelet transfusion arises. If an increase in fibrinogen levels by 1 g reduces the volume of blood transfused significantly, the usefulness of fibrinogen concentrate rather than platelet transfusion should be considered. Fibrinogen concentrate appears to have a better safety profile than cryoprecipitate and fresh frozen plasma, particularly when considering the risk of blood borne infection. Other advantages of its use include the accuracy and rapidity of its administration<sup>[23]</sup>.

In conclusion, further prospective evaluation to assess for the true baseline platelet count at which bleeding risk is increased needs to be performed. Studies have described an increase likelihood of bleeding associated with invasive procedure with low platelet counts ( $< 75 \times 10^9/L$ ), but it is important to note that these studies failed to assess the contribution of fibrinogen to clot strength in cases of thrombocytopenia<sup>[24]</sup>. Additional haematological indices such as Clauss fibrinogen and the use of viscoelastic testing may provide a more robust assessment of bleeding risk in thrombocytopenia associated with cirrhosis.

## ACKNOWLEDGMENTS

We would like to appreciate Dr. Eleanor Galtrey and Dr. Simon Goddard, Anaesthetic fellows, for their contribution in obtaining and processing data for this study. We also appreciate Felicity Blake, Point of Care laboratory manager for her continuing support in facilitating point of care assessment in patients undergoing OLT.

## COMMENTS

### Background

Thrombocytopenia is a common finding in patients with advanced liver disease. Concomitantly an increase in value of conventional tests of coagulation including prothrombin time and activated partial thromboplastin time occurs. A new paradigm of haemostasis in liver disease has been described and there is now considered to be a "rebalancing" of haemostasis in cirrhosis. As a result, the authors investigated the relationship between platelet count, Clauss fibrinogen, thromboelastography, and blood loss in orthotopic liver transplantation (OLT).

### Research frontiers

Much of the literature describing bleeding risk in cirrhosis and thrombocytopenia does not take into account fibrinogen level. There have been recent studies that show the effect of the administration of fibrinogen concentrates in thrombocytopenia, at a count of  $30 \times 10^9/L$ , in the pig model. Velik-salchner *et al* showed an improvement in impaired clot formation and a reduction in blood loss in thrombocytopenia with the addition of fibrinogen. Further studies evaluating the contribution of fibrinogen to clot strength in thrombocytopenia in humans are required.

### Innovations and breakthroughs

Currently, there are limited studies evaluating the contribution of fibrinogen to bleeding risk. The increased use of thromboelastography and in particular the evaluation of clot strength with other haematological indices could provide a more robust method of evaluating bleeding risk and requires further investigation.

### Applications

The transfusion of platelets does not come without risks to patients. The

availability of this valuable resource is also limited. The study highlights that platelet count alone is not a true indicator of clot strength and the threshold at which bleeding occurs in the face of a normal fibrinogen level needs further evaluation. Many current guidelines suggest prophylactic transfusion of platelets up to a count of  $50 \times 10^9/L$ , when in fact the threshold for bleeding risk is likely to be lower.

## Peer-review

Interesting study with respectable sample size. This article evaluated retrospectively the association between coagulation parameters and need for transfusion in patients undergoing OLT. The study is well written with a clear message.

### Abstract

#### AIM

To perform a systematic review to evaluate the incidence and prevalence of non-alcoholic fatty liver disease (NAFLD) in adult patients with sarcopenia.

#### METHODS

Randomized clinical trials, cross-sectional or cohort studies including adult patients (over 18 years) with sarcopenia were selected. The primary outcomes of interest were the prevalence or incidence of NAFLD in sarcopenic patients. In the screening process, 44 full-text articles were included in the review and 41 studies were excluded.

#### RESULTS

Three cross-sectional studies were included. The authors attempted to perform a systematic review, but due to the differences between the studies, a qualitative synthesis was provided. The diagnosis of NAFLD was made by non-invasive methods (image methods or any surrogate markers) in all three evaluated studies. All the studies suggested that there was an independent association between sarcopenia and NAFLD.

#### CONCLUSION

Sarcopenia is independently associated with NAFLD and possibly to an advanced fibrosis.

**Key words:** Metabolic syndrome; Obesity morbid; Sarcopenic obesity; Steatohepatitis; Skeletal muscle

**Core tip:** The aim of the present study was to perform a systematic review evaluating the incidence and prevalence of non-alcoholic fatty liver disease (NAFLD) in adult patients with sarcopenia. Randomized clinical trials, cross-sectional or cohort studies including adult patients (over 18 years) with sarcopenia were selected. The primary outcomes of interest were the prevalence or incidence of NAFLD in sarcopenic patients, and three cross-sectional studies were finally included. There was an independent association between sarcopenia and NAFLD in all the studies. In conclusion, sarcopenia is independently associated with NAFLD and possibly to an advanced fibrosis.

Tovo CV, Fernandes SA, Buss C, de Mattos AA. Sarcopenia and non-alcoholic fatty liver disease: Is there a relationship? A systematic review. *World J Hepatol* 2017; 9(6): 326-332 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i6/326.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i6.326>

## INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is defined as a set of liver diseases that can range from simple steatosis to steatohepatitis (NASH), which can progress to fibrosis or even cirrhosis<sup>[1]</sup> and complications such as hepatocellular carcinoma<sup>[2,3]</sup>. It will soon become the most common liver disease worldwide<sup>[4]</sup>, with an estimated prevalence in the general population of Western countries about 20% to 30%<sup>[5]</sup>. In specific populations, its prevalence can be much higher and may reach 90% in morbidly obese patients eligible for bariatric surgery, 69% in type 2 diabetes mellitus patients and 50% in dislipidemic ones<sup>[4]</sup>. In our experience, the prevalence of NASH when obese individuals without diabetes mellitus with high aminotransferases levels were evaluated in a nutrition outpatient clinic was 88%<sup>[6]</sup>. On the other hand, when we evaluated morbidly obese patients submitted to bariatric surgery, the prevalence of steatosis was 90.4% and NASH 70.4%<sup>[7]</sup>. NAFLD patients present higher mortality than the general population, being the cardiovascular disease the most common cause of death. In patients presenting NASH, however, the mortality is associated more often to hepatic causes<sup>[4]</sup>.

Sarcopenia is well characterized by the progressive loss of strength and skeletal muscle mass, generally associated with functional limitations, morbidity, and mortality<sup>[3,8,9]</sup>. The European consensus on definition and diagnosis of sarcopenia recommends using the low muscle mass and muscle function (strength or performance)

for its diagnosis. Assessment of different stages of sarcopenia may help to establish the best treatment to be administered in different contexts and set appropriate recovery targets<sup>[9]</sup>.

There is some concern about whether NAFLD results in sarcopenia through the activation of myostatin in the skeletal muscle, or if is sarcopenia the initial abnormality resulting in the activation of the stellate cells with fibrogenic properties in the liver. Considering the hypothesis that myostatin increases adipose tissue mass that will result in the decrease of adiponectin secretion, the original defect may actually begin in the skeletal muscle<sup>[10]</sup>.

Sarcopenia may occur simultaneously with obesity, particularly the accumulation of visceral fat, which can be related to inflammation, insulin resistance (IR), and further reduction in the skeletal muscle mass, consequently causing muscle catabolism<sup>[11]</sup>. In some conditions, lean body mass is lost while fat mass may be preserved or even increased<sup>[12]</sup>; this state is called sarcopenic obesity<sup>[9]</sup>. The prevalence of sarcopenic obesity increases with age, depending on definitions and reference populations<sup>[13-15]</sup>.

Although sarcopenia has been independently related to an increased risk of NAFLD and advanced fibrosis, and that sarcopenia may be associated with worse liver related clinical outcomes, this is an understudied issue, and its role on NAFLD or NASH has not been fully established<sup>[16]</sup>. The aim of this study was to perform a systematic review identifying original studies that evaluated the association between sarcopenia and NAFLD in adults.

## MATERIALS AND METHODS

### Protocol and registration

This systematic review was registered at the international prospective register of systematic reviews platform (PROSPERO) (<https://www.crd.york.ac.uk/PROSPERO/>), number CRD42015027083. This study followed the recommendations of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses<sup>[17]</sup>.

### Eligibility criteria

Randomized clinical trials (RCTs), cross-sectional or cohort studies including adult patients (over 18 years) with sarcopenia were selected.

The primary outcomes of interest were the prevalence or incidence of NAFLD in sarcopenic patients, liver fibrosis and NASH activity index assessed by biopsy or non-invasive methods. Studies in which one or more of these outcomes were assessed were included in the present systematic review.

### Search and study selection

The search for eligible studies was performed in PubMed, Lilacs, EMBASE and Cochrane in October, 2016, without a limiting period. The search strategy included the following set of keywords: "Sarcopenia"(Mesh) OR "Sarcopenia"

Figure 1 Screening process.

OR "Loss of skeletal muscle" OR "Loss of muscle mass and strength" OR "Reduced muscle mass and strength" OR "Intra-abdominal fat" OR "Muscle wasting" OR "Sarcopenic obesity" and (additional keyword). The last gap was changed at each search using the keywords "Non-alcoholic fatty liver disease"(Mesh) OR "Non-alcoholic fatty liver disease" OR "NAFLD" OR "NASH" OR "Non-alcoholic fatty liver disease" OR "Nonalcoholic fatty liver disease" OR "Nonalcoholic fatty liver" OR "Nonalcoholic fatty livers" OR "Nonalcoholic steatohepatitis" OR "Nonalcoholic steatohepatitides" OR "Fatty liver index". The searches were performed without limiting the types of articles (RCTs, clinical trial, comparative study). The selection of eligible studies was performed by title and abstract reading. When abstracts regarding subjects or outcomes of interest were not clear, the full text of the article was read.

### Data collection process

Data was collected by two independent investigators for the following variables: Design of the study, age and sex of participants, and the presence of NAFLD. The methodological quality assessment criteria followed the guidelines according to the study design - CONSORT<sup>[18]</sup> or STROBE<sup>[19]</sup>.

## RESULTS

In the initial screening process (Figure 1), 44 full-text articles were included in the present review, of which 41 studies were finally excluded, remaining three cross-sectional studies for analysis. The authors attempted a systematic review with meta-analysis, but due to the variance amongst the three studies, a qualitative synthesis is provided. The main results of the studies with the respective comparisons within and between groups (when available) are shown in Table 1.

The diagnosis of NAFLD was made by non-invasive methods (image methods or any surrogate markers) in all three evaluated studies. The liver attenuation index (LAI) was evaluated by computed tomography in the study of Hong *et al.*<sup>[15]</sup>. The fatty liver index (FLI) was

calculated from waist circumference, body mass index, gamma-glutamyl transpeptidase and triglyceride levels in the study of Moon *et al.*<sup>[20]</sup>. The NAFLD fibrosis score (NFS), hepatic steatosis index and the liver fat score were non-invasive scores used in the studies of Lee *et al.*<sup>[16]</sup>.

The diagnosis of sarcopenia was defined by the skeletal muscle mass index (SMI) as follow: Total skeletal muscle mass (kg)/weight (kg) × 100, and was evaluated by dual energy X-ray absorptiometry (DXA) in three of the studies<sup>[15,16]</sup> or by bioelectric impedance analysis (BIA) in one<sup>[20]</sup>.

Moon *et al.*<sup>[20]</sup> evaluated the effects of skeletal muscle mass to visceral fat area ratio by BIA on NAFLD (diagnosed using FLI). Of all the 9565 individuals who underwent a routine health examination, 1848 (19.3%) presented NAFLD (FLI ≥ 60). The group with low FLI showed the lowest visceral fat area and highest skeletal muscle mass, and the SMI presented inverse correlations with FLI. In the multivariate analysis, skeletal muscle mass to visceral fat ratio was negatively associated with FLI. Considering the quartiles of the skeletal muscle mass to visceral fat ratio, the highest one showed the lowest risk of NAFLD, adjusted for age, gender, diabetes mellitus, hypertension, C-reactive protein and lipid profile (odds ratio, 0.037).

The study of Hong *et al.*<sup>[15]</sup> performed a cross-sectional analysis between sarcopenia and NAFLD in the Korean Sarcopenic Obesity Study, a prospective observational cohort study. The authors included 452 healthy adults by LAI (evaluated by computed tomography), used as a parameter for the diagnosis of NAFLD. Both SMI and LAI were negatively correlated with the homeostasis model assessment of insulin resistance ( $P < 0.001$ ). After using the multiple logistic regression analysis, the odds ratio for NAFLD was 5.16 in the lowest quartile of SMI (adjusting for potential confounding factors).

Lee *et al.*<sup>[16]</sup> used a representative sample of 15132 subjects from the Korea National Health and Nutrition Examination Surveys (2008-2011), a population-based study. Non-invasive scores as the body mass index, aspartate aminotransferase/alanine aminotransferase ratio and diabetes mellitus (BARD) and fibrosis-4 (FIB-4) were used to define advanced fibrosis in subjects with NAFLD. The prevalence of NAFLD in non-sarcopenic patients ranged from 4% to 14% (non-obese) and from 50% to 72% (obese), depending on the hepatic steatosis score employed. The prevalence of NAFLD in sarcopenic patients ranged from 9% to 30% (non-obese) and from 61% to 83% (obese). The SMI was inversely correlated with the NAFLD predicting scores ( $P < 0.001$ ). Sarcopenic subjects had an increased risk of NAFLD regardless of obesity (odds ratio 1.55-3.02;  $P < 0.001$ ) or metabolic syndrome (odds ratio 1.63-4.00;  $P < 0.001$ ) than those non-sarcopenic. Furthermore, it was demonstrated an independent association between sarcopenia and NAFLD when analysed by multiple logistic regression analysis.

**Table 1** Characteristics and outcomes of the included studies

Ref.	Year	Design of the study	Sample size	Mean age ( $\pm$ SD)	Gender	Method of diagnosis of sarcopenia	Independent variable	Method of diagnosis of NAFLD	Frequency of NAFLD	Results of the studies
Hong <i>et al</i> <sup>[15]</sup>	2014	Cross-sectional	452	49.5 $\pm$ 10.3	285 women (63.1%)	DXA	SMI/weight (quartiles)	CT (LAI)	Prevalence	OR of having NAFLD by quartiles of SMI after adjusting for potential confounding factors: OR = 5.16 (95% CI: 1.63-16.33)  $P$ = 0.041 after adjustment for age, sex, smoking status, physical activity, HOMA-IR, hsCRP and 25[OH]D levels
Lee <i>et al</i> <sup>[16]</sup>	2015	Cross-sectional	15132	49.7 $\pm$ 16.5	9515 women (62.9%)	DXA	SMI: < 32.2% for men and < 25.5% for women	HSI, CNS and LFS BARD and FIB-4 for advanced fibrosis	Prevalence: 22%-29%	Sarcopenic <i>vs</i> non-sarcopenic patients according to the NAFLD assessment method: OR = 1.18-1.22 (95% CI: 1.02-1.39)  $P$ < 0.001 when adjusted for age, sex, regular exercise, HOMA-IR, smoking and HT
Moon <i>et al</i> <sup>[20]</sup>	2013	Cross-sectional	9565	47 $\pm$ 10.3	5293 men (55.3%)	BIA multi frequencies	SVR (quartiles)	Surrogate marker: FLI $\geq$ 60	Prevalence: 19.32%	OR for NAFLD among the quartiles of SVR using multiple logistic regression analysis: OR = 0.037 (95% CI: 0.029-0.049)  $P$ < 0.001 when adjusted for age, sex, total cholesterol, low-density lipoprotein cholesterol, DM, HTN, hsCRP

BIA: Bioelectric impedance analysis; CNS: Comprehensive NAFLD score; CT: Computed tomography; DM: Diabetes mellitus; DXA: Dual energy X-ray absorptiometry; FLI: Fatty liver index; HOMA-IR: Homeostasis model of insulin resistance; hsCRP: High sensitivity C-reactive protein; HSI: Hepatic steatosis index; HTN: Systemic hypertension; LAI: Liver attenuation index; LFS: Liver fat score; NAFLD: Non-alcoholic fatty liver disease; 25[OH]D: 25-hydroxyvitamin D; OR: Odds ratio; SMI: Skeletal muscle mass index; SVR: Skeletal muscle mass to visceral fat area ratio.

Among the individuals with NAFLD, the lower the SMI, the more chance of advanced fibrosis when compared with the non-sarcopenic ( $P$  < 0.001).

## DISCUSSION

In the present review, all the studies<sup>[15,16,20]</sup> concluded that there was an independent association between sarcopenia and NAFLD. The association of sarcopenia with NAFLD seems to be independent of IR<sup>[15,16]</sup> or obesity<sup>[16]</sup>. However, it is not possible to establish whether the association between sarcopenia and NAFLD is a cause or an effect. The skeletal muscle is now recognized as an endocrine organ secreting myokines, and this fact may help to understand its role in the pathogenesis of NAFLD<sup>[21]</sup> as well as contribute to the development of effective therapeutic options<sup>[10]</sup>.

The association between fat accumulation in the liver and in the muscle has recently been established. The fat content in the paravertebral muscles analyzed by computed tomography may be correlated with aging and steatosis, and a reduction in muscle fat may be associated with an decrease of the liver fat content<sup>[22]</sup>.

Insulin resistance and metabolic syndrome has been consistently associated with sarcopenia and NAFLD, as both conditions may share pathophysiological mecha-

nisms<sup>[23-26]</sup>. However, the association between sarcopenia and NAFLD seems to be independent of IR, raising the possibility that the loss of muscle mass may contribute to the development of NAFLD<sup>[27]</sup>.

The study of Moon *et al*<sup>[20]</sup> showed that the FLI was lower in the group with higher skeletal muscle mass, and the group with NAFLD (high FLI) presented lower SMI and higher visceral fat area when compared with the lower FLI group, suggesting that the incidence of NAFLD increases as the muscle mass relative to visceral fat decreases. Therefore, this fact could support a favorable role for skeletal muscle in IR and in the development of NAFLD.

Hong *et al*<sup>[15]</sup> evaluated the relationship between sarcopenia and NAFLD, demonstrating a higher risk of NAFLD in those with lower muscle mass after adjusting for confounding factors as IR and inflammation. The individuals with sarcopenia presented more metabolic syndrome, higher C-reactive protein levels and higher body fat mass when compared to those without sarcopenia.

The study of Lee *et al*<sup>[16]</sup> compared sarcopenic and non-sarcopenic patients within obese and non-obese groups of patients. The analysis made it possible to control the effect of obesity on NAFLD and it was the only study that clearly presented an association of sarcopenia

and hepatic steatosis. The prevalence of NAFLD in non-obese sarcopenic patients was more than twice as high as in non-obese non-sarcopenic patients. The proportion of increase in the prevalence of NAFLD comparing obese sarcopenic patients and obese non-sarcopenic patients was remarkably lower. This demonstrates the strong association of sarcopenia and NAFLD in non-obese patients, as well as with fibrosis.

It is worth noting that all three studies included representative samples and performed differing methods of analysis of the outcome, *i.e.*, the relationship between sarcopenia and NAFLD. Even though all three presented multivariable logistic regression analysis, the predictive models were different in all of them, illustrating the complexity and lack of consensus on the factors affecting NAFLD risk. Regardless the model, all of them showed increased risk of NAFLD in the presence of sarcopenia.

More recently, Lee *et al.*<sup>[28]</sup> investigated whether sarcopenia was associated with significant liver fibrosis in the same population. Liver fibrosis was assessed by non-invasive scores as Forns, FIB-4 and NFS. It was observed that sarcopenia was significantly associated with significant liver fibrosis (odds ratio 0.52-0.67;  $P < 0.01$ ) in subjects with NAFLD, independently of obesity and IR.

As possible limitations of the studies, the use of a cross-sectional design limits the possibility to infer causality between skeletal muscle mass loss and NAFLD or NASH<sup>[15,16,20]</sup>, and there was no information regarding the use of smoking status or alcohol consumption<sup>[15]</sup>, which may allow for a bias. Also, no study performed liver biopsy to establish the diagnosis of NAFLD, considered the gold standard in the respective diagnosis<sup>[4,9,15,20]</sup>. Furthermore, the BMI of the patients included in the studies was not so high, varying from 21.4<sup>[20]</sup> to 27.9<sup>[16]</sup>, characterizing overweight and not obesity, and being lower than the BMI of the occidental population<sup>[29]</sup>. This point may be explained by the local ethnic characteristics (all three studies reviewed are Korean studies), limiting the external validity of such studies.

The European consensus<sup>[9]</sup> defined that the CT scan and the magnetic resonance imaging are considered the gold standard to estimate muscle mass. DXA is considered the preferred alternative method, and BIA is a portable alternative to DXA. All the three studies included in the present analysis used the gold standard methods for the diagnosis of sarcopenia, being BIA<sup>[20]</sup> or DXA<sup>[15,16]</sup>.

Of the three articles included in the present systematic review, only the one of Lee *et al.*<sup>[16]</sup> reported the exclusion of approximately 25% of the patients because of missing information about the main variables evaluated (skeletal muscle mass and NAFLD).

Two additional studies were published in 2016, however they were excluded of the present systematic review because of the different primary outcomes of interest. The first was the cross-sectional study of Kim *et al.*<sup>[30]</sup>, evaluating 3739 Korean people, showing that the risk of NAFLD is associated with a low SMI independent

of metabolic risk factors, and may differ according to the age or menopausal status. The other study, of Koo *et al.*<sup>[31]</sup>, evaluated 309 Korean subjects, where the prevalence of sarcopenia was 8.7%, 17.9% and 35.0% in subjects without NAFLD, with NAFLD and with NASH respectively ( $P < 0.001$ ).

There is an independent association between sarcopenia and NAFLD and possibly to an advanced fibrosis. A higher skeletal muscle mass may have a beneficial effect in the prevention of NAFLD, which might be explored by future standardized experimental studies.

## COMMENTS

### Background

Non-alcoholic fatty liver disease (NAFLD) is becoming the most common liver disease worldwide, presenting a higher mortality than the general population. Sarcopenia has been related to an increased risk of NAFLD and advanced fibrosis, and may be associated with worse liver related clinical outcomes. However, this is an understudied issue, and its role on NAFLD has not been fully established. The aim of this study was to perform a systematic review identifying original studies that evaluated the association between sarcopenia and NAFLD in adults.

### Research frontiers

Sarcopenia may occur simultaneously with obesity, particularly the accumulation of visceral fat, which can be related to inflammation, insulin resistance and further reduction in the skeletal muscle mass, consequently causing muscle catabolism. In some conditions, lean body mass is lost while fat mass may be preserved or even increased; this state is called sarcopenic obesity. The skeletal muscle is now recognized as an endocrine organ secreting myokines, and this fact may help to understand its role in the pathogenesis of NAFLD as well as contribute to the development of effective therapeutic options.

### Innovations and breakthroughs

In the present review, all the studies concluded that there was an independent association between sarcopenia and NAFLD. The association of sarcopenia with NAFLD seems to be independent of insulin resistance or obesity. However, it is not possible to establish whether the association between sarcopenia and NAFLD is a cause or an effect.

### Applications

The association between fat accumulation in the liver and in the muscle has just recently been established. The fat content in the paravertebral muscles analyzed by computed tomography may be correlated with aging and steatosis, and a reduction in muscle fat may be associated with an decrease of the liver fat content.

### Terminology

Dual energy X-ray absorptiometry and bioelectric impedance analysis are methods of diagnosis of sarcopenia. Computed tomography using liver attenuation index, as well as the comprehensive NAFLD score, the hepatic steatosis index, the liver fat score and the fatty liver index are non-invasive methods of diagnosis of NAFLD.

### Peer-review

This review is timely as there is emerging evidence and understanding of the association between NAFLD and sarcopenia.

## Abstract

### AIM

To assess vitamin E efficacy, defined as its ability to induce hepatitis B e antigen (HBeAg) seroconversion, in children with HBeAg-positive persistent hepatitis.

### METHODS

In July 2016, we extracted articles published in MEDLINE and the Cochrane Library using the following search terms: "chronic hepatitis B", "children", "childhood", "therapy", "treatment", "vitamin E", "tocopherols", "tocotrienols". Only randomized controlled trials (RCTs) published in English language were collected.

### RESULTS

Three RCTs met inclusion criteria and were considered in the present meta-analysis. Overall, 23/122 children in the treatment group underwent HBeAg seroconversion vs 3/74 in the control group (OR = 3.96, 95%CI: 1.18-13.25,  $P = 0.025$ ).

### CONCLUSION

Although our meta-analysis has several limits, including the very small number of available studies and enrolled children with HBeAg positivity-related hepatitis, it suggests that vitamin E use may enhance the probability to

induce HBeAg seroconversion in these patients. Further well designed and adequately sized trials are required to confirm or deny these very preliminary results.

**Key words:** Hepatitis B; Pediatric hepatology; Viral hepatitis; Immunology

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Treatment of chronic hepatitis B in children is still an area of uncertainty. Vitamin E, based on immunostimulatory anti-inflammatory activity, has been evaluated in the treatment of pediatric hepatitis B virus infection. These few experiences seem to be encouraging as they suggest a potential role of vitamin E in inducing HBeAg seroconversion, but they need to be confirmed in well-designed and adequately-sized trials.

Vitamin E for the treatment of children with hepatitis B e antigen-positive chronic hepatitis: A systematic review and meta-analysis. *World J Hepatol* 2017; 9(6): 333-342 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i6/333.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i6.333>

## INTRODUCTION

Chronic hepatitis B virus (HBV) infection continues to represent a very serious health problem worldwide, both in adults and in children<sup>[1]</sup>, despite several efforts to prevent its spread and to reduce its disease burden, such as vaccination programs<sup>[2]</sup>, the use of safe injection techniques and blood donor screening<sup>[3]</sup>, as well as the introduction, in our therapeutic arsenal, of new and more advanced and effective antiviral treatments<sup>[4]</sup>. The clinical relevance of this pathogen depends on its ability to insidiously induce, in a large proportion of infected individuals, a necro-inflammatory hepatic disease with different patterns of severity and course, including cirrhosis and hepatocellular carcinoma. Several factors have been demonstrated to influence the prevalence<sup>[5]</sup>, severity and outcome of patients with HBV-related chronic hepatitis. In particular, ethnicity, mode of acquisition and mainly, age at the time of HBV infection represent the major risk factors for the development of a persistent liver disease<sup>[6]</sup>. Whereas approximately 90%-95% of acutely HBV-infected immunocompetent adults experience a self-limiting hepatitis with the establishment of protective long-lasting immunity, and only the remaining 5%-10% develop chronic hepatitis, neonatal transmission of HBV causes a higher rate of chronic infection<sup>[7]</sup>. Approximately 90% of infected children in highly endemic countries, where vertical transmission from mother to child is predominant, become persistent carriers<sup>[8]</sup>. According to the current knowledge, the natural history of long-lasting HBV infection is chara-

cterized by three chronological phases, including immune tolerance, immune clearance and low replication status.

Despite a large series of available studies, long-term outcomes of HBV infection acquired in infancy are still unclear. However, the spontaneous or therapy-induced hepatitis B e antigen (HBeAg) seroconversion with HBe antibody development is generally considered a key event in patients with long-lasting HBV-related infection<sup>[9]</sup>, because it is often accompanied by remission of liver disease and confers a favorable course over a long-term follow-up<sup>[10]</sup>. After HBeAg loss, serum HBsAg persists, but serum aminotransferase levels usually decrease, reaching normal or low values and a significant reduction in HBV replication is observed in a large part of the subjects undergoing HBeAb development<sup>[11]</sup>. Nevertheless, in some of these patients, the achievement of HBeAg seroconversion is not associated with the improvement of hepatic disease, rather these individuals still present with liver damage with different grades of severity and course and they are at higher risk of developing complications later in life<sup>[12]</sup>. Persistent HBV-related infection is considered as the result of an impaired immune response against this pathogen, consequently the boosting of antiviral immune response has become an innovative strategy in the attempt to obtain the remission of the infection, which still occurs at very low rate<sup>[13,14]</sup>. Starting from this assumption, a randomized controlled pilot trial was performed in 2001 in adult patients with HBV-related hepatitis, showing beneficial effects in anti-viral activities in these individuals<sup>[15]</sup>.

Therefore, on the basis of these findings, we aimed to perform a systematic review and meta-analysis to identify and summarize the current evidence on the potential efficacy of vitamin E in the treatment of children with HBeAg-positive persistent hepatitis, defined as its ability to induce HBeAg loss and HBeAb development.

## MATERIALS AND METHODS

### Search strategy

A systematic computer-based search of published articles, according to the Preferred Reporting Items for Systematic reviews and Meta-Analysis Statement, issued in 2009<sup>[16]</sup>, was conducted through Ovid interface, in order to identify relevant studies on the vitamin E use for the treatment of children with HBeAg-positive chronic hepatitis. The literature review was performed in July 2016. The following electronic databases were used: MEDLINE (1950 to June 30, 2016), the Cochrane Library (until the second quarter of 2016) and EMBASE (1980 to June 30, 2016) for all relevant articles. The search strategy and the search terms were developed with the support of a professional research librarian. The text word used for the search were identified by means of controlled vocabulary, such as the National Library of Medicine's MESH (Medical Subject Headings) and Keywords. The used MESH terms and keywords were: "chronic hepatitis B", "children", "childhood", "therapy", "treatment", "vitamin E", "tocopherols", "tocotrienols". The PubMed "related articles"

feature as well as the reference lists of retrieved articles was also searched to find additional pertinent studies. If a study was considered potentially eligible by either of the two reviewers, the full-text of this study was further evaluated. Full-text assessment was performed according to eligibility criteria developed to systematically include studies into this review. Selected studies were considered eligible if all the following predefined criteria were met: (1) the research was designed to assess the tolerability and efficacy of vitamin E use for the treatment of children with HBeAg-positive chronic hepatitis; (2) the research studies were designed as randomized studies; (3) the studies were reported in the English language, as peer-reviewed, full-text publications, whereas articles that were not published as full reports, such as conference abstracts, case reports, and editorials were excluded; and (4) sufficient data for the evaluation of HBeAg seroconversion rate were available (Table 1).

### Study selection

Data extraction: Two authors (Leandri P and Loggi E), independently and in a parallel manner, performed the literature search, identified and screened relevant articles, based on title or title and abstract. If a study was considered potentially eligible by either of the 2 reviewers, the full article was collected for further assessment. Other two authors (Bacchi-Reggiani ML and Andreone P) independently extracted and tabulated all relevant data from included studies by means of a standardized method, according to the Cochrane handbook section 7.3a checklist of domains. The following information was obtained from each study, by means of a predefined data extraction form, including: First author's name, study design, inclusion and exclusion criteria, year of publication, country of origin, ethnicity, number of cases and controls, diagnostic methods for HBV markers and genome detection. We contacted the authors of the three studies to obtain additional information, including children's seroconversion rate by age groups and by HBV genotype. Unfortunately, access to patients' database was possible only for one study, whereas the above mentioned data, concerning the other two trials, were no longer available for the time period elapsed since their publication. The accuracy of data collection was checked by SF and any disagreements concerning the results were settled by consensus between all authors.

**Quality score assessment:** Three investigators (Fiorino S, Bacchi-Reggiani ML and Andreone P) independently evaluated the quality of the selected studies, on the basis of the Jadad scale<sup>[17]</sup> (Table 2). It includes the assessment of the following three items: Randomization (2 points as maximum score), blinding (2 points as maximum score) and an account for all patients (1 point as maximum score).

Any disagreement was resolved by discussion with the other authors. Total score ranges from 0 to 5. In-

cluded studies were classified into higher quality ( $\geq 3$ ) and lower quality ( $< 3$ ), on the basis of the total scores.

### Statistical analysis

Odds ratios (ORs) and 95% confidence intervals (CIs) were used as the summary statistic. The pooled OR was calculated with both fixed effect (inverse variance weighting) and random effect (Der Simonian and Laird) models. To avoid the exclusion of one among the eligible studies<sup>[18]</sup>, a 0.5 zero-cell correction was used. The variability, expressed in percentage across studies and attributable to heterogeneity beyond chance, was estimated with  $I^2$  statistic. We assessed the extent of small study effects by Egger's test.  $P$ -values  $\leq 0.05$  were considered significant for all included studies. Statistical analyses were carried out using STATA/SE version 14.1 (STATA Corp., College Station, TX, United States).

## RESULTS

### Study selection

We searched in MEDLINE, EMBASE, and Cochrane Library to retrieve works assessing vitamin E use in children with HBeAg-positive chronic hepatitis, our systematic review identified 2471 potential studies, and 2458 of them were excluded after a preliminary review of the titles and/or abstracts. The full texts of the remaining 13 articles were retrieved for a more detailed assessment. Of these, 10 studies did not meet the eligibility criteria, as described, because they were reviews, clinical studies carried out in adults or they were not published in the English language. Therefore, three studies were selected and included in the current meta-analysis. A flow-chart of the study search and selection process is shown in Figure 1.

### Study characteristics

Three randomized controlled studies, assessing the use of tocopherols in children with HBV-related chronic infection and rate of HBeAg seroconversion, met inclusion criteria and were considered in the present meta-analysis<sup>[18-20]</sup>.

Overall, the three trials involved 122 children, randomized to receive treatment according to an intention-to-treat protocol with different doses of vitamin E, and 74 controls. One study was performed in Turkey, one in Germany and one in Italy. The baseline characteristics of these included studies and their participants are summarized in Table 1. All considered studies described serological assays, which were employed to detect viral infection markers. Serum samples were tested for the presence of both viral antigens and host antiviral antibodies, using both enzyme-linked immunosorbent assay or radioimmunoassay, as well as of HBV-DNA, by means of liquid hybridization<sup>[18]</sup> or real time PCR<sup>[19,20]</sup>.

Overall, according to the Jadad scale, two trials were classified into higher quality<sup>[19,20]</sup> and one into lower quality<sup>[18]</sup> studies (Table 1).

The end-point of this meta-analysis was to estimate the potential antiviral efficacy of vitamin E, defined as its

<sup>1</sup>Identifies 1 patients undergoing HBeAb seroconversion in a subgroup of patients; <sup>2</sup>Identifies 2 patients, who underwent HBeAg seroconversion; <sup>3</sup>According to the Jadad scale. PRT: Prospective randomized trial; IT: Immune-tolerant; IR: immune-reactive; VE: Vitamin E; CVR: Complete virological response, defined as sustained HBeAg loss/anti-HBe seroconversion together with serum HBV-DNA reduction < 2000 IU/mL; ALT: Alanine-aminotransferase; NA: Not available; HBeAg: Hepatitis B e antigen; M: Male; F: Female.

ability to induce HBeAg loss and HBeAb development. A pooled estimate was performed on the basis of the considered studies. Overall, we observed that vitamin E use induced HBeAg seroconversion in 18.8% patients (23 seroconversion among 122 patients in the treated children vs 3 among 74 controls, OR = 3.96, 95%CI: 1.18-13.25,  $P = 0.025$ ,  $I^2 = 0.0\%$ ) (Figure 2). Children's seroconversion rates by age groups and by HBV genotype were available only for one of the three trials (Table 1).

### Sensitivity analysis and publication bias risk

To evaluate the effect of each individual study on the overall meta-analysis estimate, one study at a time was excluded, but the exclusion of any single research did not cause a significant alteration of the final decision and did not suggest the possibility of publication bias, but the number of considered studies is very small and this factor suggests caution in data interpretation.

## DISCUSSION

The natural history of HBV-related persistent infection in childhood as well as the indications for the appropriate use of the antiviral therapy still represent an area of considerable uncertainty in this subset of patients, although an expert panel consensus<sup>[21]</sup> and some meta-analyses<sup>[22,23]</sup> have been proposed to guide physicians in the treatment decision-making process. As no definitive guidelines exist,

according to available recommendations, the criteria for the management of these subjects in the real-life clinical setting have to be carefully evaluated before initiating any type of antiviral therapy. In particular, treatment is considered appropriate in HBeAg-positive children with persistently elevated (about 1.5-2.0 times the laboratory upper limit of normal), or exceeding 60 IU/L serum alanine aminotransferase and moderate/severe inflammation/fibrosis on liver biopsy<sup>[8]</sup>. Some drugs, such as interferon- $\alpha$  (IFN- $\alpha$ )<sup>[24]</sup>, lamivudine<sup>[25]</sup>, entecavir<sup>[26]</sup>, adefovir<sup>[27]</sup> and tenofovir<sup>[28]</sup> have been approved for these patients. However, their use is limited by important side effects, risk of resistance development, high costs and, mainly, age of the treated subjects<sup>[29]</sup>. Most of these antiviral compounds have been licensed for children over 12 years old and only IFN- $\alpha$  as well as entecavir have been approved for a pediatric population aged between 2 and 18 years<sup>[24,26]</sup>. In addition, to date, no therapy is considered appropriate in HBeAg-positive children in the immune tolerance phase. A risk of resistance development to antiviral drugs exists in this group of patients<sup>[21]</sup>. To date, on the basis of these results, a long-term follow-up is the only approach currently applied to these children and further therapeutic approaches or treatment schedules are required<sup>[30]</sup>.

Therefore, according to preliminary observations on the beneficial role of vitamin E as therapy in patients with chronic hepatitis B in a randomized controlled pilot

**Table 2** Jadad scale is a procedure for assessing the methodological quality or risk of bias in randomized controlled trials, adapted from Jadad *et al.*<sup>[17]</sup>

Item	Maximum points	Description
Randomization	2	1 point if randomization is mentioned 1 additional point if the method of randomization is appropriate 1 point has to be deducted if the method of randomization is inappropriate (minimum 0)
Blinding	2	1 point if blinding is mentioned 1 additional point if the method of blinding is appropriate 1 point has to be deducted if the method of blinding is inappropriate (minimum 0)
An account of all patients	1	The fate of all patients in the trial is known, if no data are reported the reason is stated

trial several years ago<sup>[15]</sup>, we had the aim to understand whether this compound could exert useful and safe therapeutic effects against HBV in childhood. We performed a systematic review and meta-analysis to search studies available in the literature assessing vitamin E ability to induce HBeAg seroconversion in children with HBeAg-positive persistent hepatitis. We found only three trials<sup>[18-20]</sup> meeting inclusion criteria for our meta-analysis, but, surprisingly, two of them reported high rates of HBeAg loss and HBeAb development<sup>[19,20]</sup>.

In particular, in Fiorino's trial a very high percentage of children (7/23, 30.4%), receiving vitamin E supplementation for 12 mo with a follow-up period of further 12 mo, obtained HBeAg clearance vs 1/23 (4.3%), in the control arm at the end of the follow-up period (24 mo)<sup>[20]</sup>. However, it has to be considered that a substantial percentage of HBeAg loss (23.2%) was also observed in the group of vitamin E-treated children for 6 mo with an additional follow-up period of 12 mo in comparison to the placebo arm (8.7%) in Gerner's research<sup>[19]</sup>. HBeAg seroconversion rates obtained in the above mentioned studies are higher in comparison to those observed in trials enrolling patients who were treated with nucleotide/nucleoside analogues. A recent research performed by Chan *et al.*<sup>[31]</sup>, using TDF (tenofovir disoproxil fumarate) or TDF + FTC (emtricitabine) in adult immune-tolerant patients, showed low percentage of HBeAg loss and HBeAb development (5% and 0% respectively) over 192 wk. The reasons explaining these high seroconversion rates in children supplemented with vitamin E in comparison to subjects treated with TDF analogs, mainly in Fiorino's study, are not completely understood and deserve further investigations. Nevertheless, some very interesting issues have to be considered: (1) different mechanisms of vitamin E and nucleotidic/nucleosidic analogue action; (2) duration of the treatment period; and (3) vitamin E dosage used.

Nucleos(t)ide analogues exert antiviral activities by means of well-known direct as well as indirect mechanisms: (1) suppression of HBV replication mainly through the inhibition of reverse transcription process in the viral lifecycle<sup>[32]</sup>; (2) partial restoration of the impaired

immune response, as shown by significant reductions in the percentages of CD4<sup>+</sup>CD25<sup>high</sup> T regulatory cells, programmed death-ligand 1 (PD-L1) receptor expression on CD4<sup>+</sup> T cells and pro-inflammatory cytokine production<sup>[33,34]</sup>. Therefore, antigen-viral burden reduction is associated with the improvement of anti-HBV activity of immune cells. According to our current knowledge, vitamin E exerts its beneficial effects by means of similar mechanisms. It is well known that vitamin E plays critical roles for normal cellular functions<sup>[35]</sup>. This essential lipid-soluble compound, acting as a free radical "scavenger", exerts potent antioxidant effects<sup>[35]</sup> in all cellular membranes<sup>[36]</sup> and contributes to their protection from oxidative injury<sup>[37,38]</sup>. In addition, *in vitro* and *in vivo* studies have suggested that vitamin E is also able to improve immune-system functions<sup>[39]</sup>, mainly by increasing cell-mediated-immunity<sup>[40,41]</sup>. Mechanisms involved in these complex processes remain poorly understood, but, a recent systematic review has summarized its possible intracellular targets and suggested its potential direct antiviral or immunostimulating activities against HBV<sup>[42]</sup>. Vitamin E is able to influence the transcriptional function of some cellular genes by directly interacting with their promoter sequences<sup>[42-44]</sup> and it may modulate the post-transcriptional regulation of protein synthesis<sup>[45-47]</sup>. In particular, very preliminary studies have demonstrated that vitamin E is able to regulate the expression profiles of some microRNAs, but it is conceivable that it interacts with a larger number of these molecules<sup>[41,43,44]</sup>. In par-

**Figure 2** The relationship between vitamin E use and hepatitis B e antigen seroconversion in published studies. The area of each black square is proportional to the statistical size and the centre of the square is placed at the point of estimate. Error bars indicate 95% CIs for the estimate for each study. I + V: Inverse variance method; D + L: DerSimonian and Laird method.

particular, it has been reported that vitamin E increases the expression of 8 oxidative stress-associated miRs, including miR-16, miR-21, miR-122, miR-125b, miR-146a, miR-155, miR-181a, miR-223<sup>[44]</sup>. The tight modulation of the synthesis of these miRs, due to their pleiotropic effects, might increase the protective immune response against the virus. Some microRNAs, which are modulated by vitamin E, possess a double function. They are required not only to preserve the normal function of the immune system<sup>[48]</sup>, mainly of the cell-mediated arm<sup>[49]</sup>, and to prevent the development of a redundant and abnormal inflammatory response<sup>[50,51]</sup>, but they also exert a direct anti-HBV activity<sup>[52]</sup>. These premises may help us to explain the positive preliminary results of our meta-analysis. It is conceivable to think that vitamin E supplementation may contribute to the improvement of the anti-HBV activity of the immune system by means of a direct anti-viral action both by decreasing its replication abilities and by boosting the host's immune cell responses. The slow but progressive decline of HBV replication associated with HBeAg loss/HBeAb seroconversion, as described in 2 of the 3 studies included in our meta-analysis, corroborates the hypothesis that vitamin E acts as an immunomodulator resulting in a global antiviral activity. Interestingly, a delayed response has already been reported, with the use of immunomodulatory drugs for the treatment of adults with CHB<sup>[53]</sup>. In Fiorino's study, HBeAg seroconversion was also observed in additional 7 of 11 previously non-responder patients in the vitamin E supplemented group, with an extended follow-up for an additional period of 12 mo<sup>[20]</sup>. This observation underlines the importance of the duration of the treatment period and might contribute to explaining, at least in part, the absence of children responding to vitamin E therapy in Dickici's study<sup>[18]</sup>. In this trial, the period of supplementation with this compound was only three months long, in addition the dosage used was equal to 100 mg/d for three months, probably not enough to induce an improvement of anti-

viral immune responses. Therefore, both dosage and duration of vitamin E supplementation represent very important factors that must be considered when its anti-viral efficacy is evaluated. Taking into considerable account all the described factors, our study seems to suggest that vitamin E use may effectively enhance the probability to induce HBeAg seroconversion in these patients, even in children in the immune-tolerant phase. However, it has to be considered that our meta-analysis has several limits. First, the very small number of available studies enrolling children with HBeAg positivity-related hepatitis, as well as the small size of these trials may increase publication and selection biases; second, one research study has been carried out in Asia<sup>[18]</sup> and 2 studies in Europe<sup>[19,20]</sup>, it is not known whether differences in response rates, following vitamin E use, may exist among children belonging to different ethnicities or depending on the different prevalence of HBV genotypes; third, the study design did not include the use of placebo in control groups in two studies<sup>[18,20]</sup>; fourth, it has to be taken into account that HBeAg seroconversion rate in children in the immunetolerant phase is < 2% among children younger than 3 years and 4%-5% among older children<sup>[54]</sup> and that data concerning HBV genotypes as well as children's seroconversion rates by age groups were available only for one of the studies considered for the meta-analysis. Therefore, this limit precludes further proper assessments of the potential vitamin E benefits in children under 14 years as well as of its potential efficacious dose. However, in the study by Fiorino *et al.*<sup>[20]</sup>, patients who responded to vitamin E treatment were respectively 4 (1 child), 13 (2 children), 14 (2 children), and 17 (2 children) years old at the enrollment (Table 1).

In addition, it has to be considered that some meta-analyses<sup>[55,56]</sup> have reported that long-term administration of vitamin E, at dosages exceeding 150 UI once a day, is associated with serious negative outcomes, such as an increase in all-cause mortality. However, although the conclusions of these studies are rather questionable<sup>[57-60]</sup>

because of the meta-analytic approaches used and no severe side effects have been described in the three included trials, with the exception of some adverse events, represented by flares of transaminases, these results suggest caution in the generalization of vitamin E administration in the pediatric population before confirmation of the effectiveness and safety of this compound. Certainly, vitamin E, which was administered at high dosage to the children in the reported trials, has to be considered as a drug, with possible benefits as well as with potential risks. Therefore, to date these limiting factors prevent the formulation of definitive recommendations on the role of this type of treatment in children with HBeAg-positive hepatitis. However, to our knowledge this is the first attempt to quantitatively assess the therapeutic effects and efficacy of vitamin E in the treatment of these subjects. These patients suffer from a viral-related liver disease, a condition associated with a deficiency in immune system responses. Therefore, the use of vitamin E in patients with HBV chronic infection might represent an approach combining the direct antiviral effect of nucleoside/nucleotide analogues on HBV replication together with the immune-enhancing role of this fat-soluble compound. Therefore, further well-designed and adequately-sized trials are required to confirm or deny these preliminary, but apparently very interesting and promising, results with the aim to establish the potentially useful dose of vitamin E to induce HBeAg seroconversion.

## ACKNOWLEDGMENTS

The authors thank Dr. Simonetta Righi, Biblioteca Centralizzata, Policlinico S Orsola-Malpighi, Università di Bologna, Bologna, Italy for her support in the search of scientific bibliography and Dr. Cecilia Baroncini IRCCS - Institute of Neurological Sciences of Bologna, Italy for her support in the linguistic revision of the manuscript.

## COMMENTS

### Background

Hepatitis B virus (HBV) chronic infection in childhood continues to represent a very important clinical problem in several countries worldwide and the treatment indications for this subset of patients are still an area of considerable uncertainty. Clear-cut guidelines are lacking, therefore, to date, therapeutic decisions are only based on the consensus of expert panels.

### Research frontiers

A defective immune response is considered a crucial factor in maintaining a persistent infection in subjects with HBV. Drugs able to restore an adequate immune activity could contribute to promote an effective control of this infection.

### Innovations and breakthroughs

In the real-life clinical setting, a wide proportion of children with persistent HBV infection remain untreated and a conservative approach is generally applied in these subjects. Therefore, the introduction of additional therapies and different strategies in clinical practice is required. Since several years ago, vitamin E has emerged as a compound with a large spectrum of immune-stimulatory activities and its use could improve the defective immune activity detectable in several diseases, including chronic viral infections. This research field could be very

interesting, but this kind of application requires caution. Some reports, although rather questionable, report possible harmful effects, when this compound is used at high dose.

## Applications

Vitamin E administration could represent one among the options for the treatment of children with HBV-chronic infection, either as mono-therapy in the developing countries with limited economic resource or, for the future, in combination with standard antiviral drugs. The decrease in viral replication and antigen burden as well as the restoration of an adequate immune function might represent an effective approach for the management of patients with HBV persistent infection.

## Peer-review

The authors underwent a meta-analysis to evaluate the role of vitamin E administration to children with immune tolerant HBV infection. Results showed a nearly four-fold likelihood of achieving HBeAg seroconversion in those children receiving vitamin E. Sensitivity analysis showed that exclusion of any of the three studies did not change results.

### Abstract

Ornithine transcarbamylase deficiency (OTCD) is an X-linked disorder, with an estimated prevalence of 1 per 80000 live births. Female patients with OTCD develop metabolic crises that are easily provoked by non-predictable common disorders, such as genetic (private mutations and lyonization) and external factors; however, the outcomes of these conditions may differ. We resuscitated a female patient with OTCD from hyperammonemic crisis after she gave birth. Hyperammonemia after parturition in a female patient with OTCD can be fatal, and this type of hyperammonemia persists for an extended period of time. Here, we describe the cause and treatment of hyperammonemia in a female patient with OTCD after parturition. Once hyperammonemia crisis occurs after giving birth, it is difficult to improve the metabolic state. Therefore, it is important to perform an early intervention before hyperammonemia occurs in patients with OTCD or in carriers after parturition.

## INTRODUCTION

Urea cycle disorders (UCDs) are one of the most common inherited metabolic diseases in Japan, with an estimated prevalence of 1 per 50000 live births. The urea cycle is the metabolic pathway that eliminates excess endogenous and exogenous nitrogen from the body by modifying ammonia into urea, thereby reducing its toxicity. This cycle comprises 6 different enzymes, including ornithine transcarbamylase (OTC; EC 2.1.3.3).

OTC deficiency (OTCD; Mc Kusick No. 311250) is an X-linked disorder, with an estimated prevalence of 1 per 80000 live births<sup>[1]</sup>. The traditional treatment for OTCD is a low-protein diet. Sodium benzoate and/or sodium phenylbutyrate are significant as an alternative pathway therapy<sup>[2,3]</sup>.

In female patients with OTCD, metabolic crises can be easily provoked by non-predictable common disorders, such as genetic (private mutations and Lyonisation) and external factors, and sometimes may be fatal.

We resuscitated a female patient with OTCD, who maintained a relatively stable condition using a self-restricted protein diet, from hyperammonemic crisis after parturition. Hyperammonemia after giving birth in a female patient with OTCD can be fatal<sup>[4]</sup>, and this type of hyperammonemia persists for an extended period of time. If patients with OTCD develop hepatic coma with hyperammonemia  $\geq 300$   $\mu\text{mol/L}$ , hemodialysis as well as treatments that target alternative nitrogen metabolism pathways and arginine or/and citrulline treatments should be used to control blood ammonia levels immediately to avoid damage to the brain<sup>[5-7]</sup>. We discontinue hemodialysis and control blood ammonia levels using the alternative pathway therapy, and arginine or/and citrulline treatments when their blood ammonia levels decrease to  $< 180$   $\mu\text{mol/L}$ <sup>[8,9]</sup>. Hemodialysis is excellent for the removal of ammonia in the body; however, this treatment does not suppress the production of ammonia and removes useful medications

from the body. Moreover, although a high-caloric infusion that largely consists of glucose is important, the early administration of essential amino acids and low-protein is useful for preventing protein catabolism in the body and for controlling ammonia levels<sup>[10]</sup>.

Here, we discuss the cause and treatment of hyperammonemia in a female patient with OTCD after parturition.

## CASE REPORT

A 37-year-old female patient who was diagnosed with late-onset OTCD was followed by her doctor, and was introduced to our institute after pregnancy. She was the first child of nonconsanguineous parents and had no family history of hyperammonemia. She presented with seizures at the age of 7 and developed hyperammonemia following the administration of valproic acid as treatment for the seizure. She was diagnosed with OTCD by liver biopsy examination (liver OTC enzyme activity that was 30% the level of healthy patients) (Table 1). She had visited the emergency room previously due to hyperammonemia and had undergone hemodialysis for impaired consciousness at the age of both 18 years and 21 years. Despite this, she followed a self-restricted protein diet and L-carnitine treatment. She naturally became pregnant at the age of 37 years and delivered an unaffected male baby by vacuum extraction at 41 wk and 1 d of gestation. Her blood ammonia value was 68  $\mu\text{mol/L}$  at delivery, 59  $\mu\text{mol/L}$  at 10 h after delivery, and 54  $\mu\text{mol/L}$  at 24 h after delivery. She developed hyperammonemia (194  $\mu\text{mol/L}$ ) 4 d after delivery, but was discharged 6 d after delivery because her blood ammonia level decreased to 60  $\mu\text{mol/L}$  following arginine and citrulline treatment. Upon discharge, she consumed a hamburger at a fast food restaurant and 250 g of beef at her home. She was hospitalized on an emergency basis at midnight because of hyperammonemia (180  $\mu\text{mol/L}$ ) with impaired consciousness (Table 2). Blood ammonia levels instantly decreased to 82  $\mu\text{mol/L}$  by the continuous administration of arginine. She then underwent hemodialysis and continuous hemodiafiltration under respirator management in the intensive care unit because her blood ammonia level increased to 339  $\mu\text{mol/L}$ , with a grade III hepatic coma. Moreover, she received a high-calorie infusion (2500 kcal/d), arginine (80 mg/kg per day), citrulline (150 mg/kg per day), sodium benzoate (150 mg/kg per day), and sodium phenylbutyrate (140 mg/kg per day) as an alternative pathway therapy. Following this, her hyperammonemia improved.

Although extubation was attempted because of stable blood ammonia levels following these treatments (Figure 1), she was reintubated because she could not maintain respiration. Her ammonia levels increased again to 210  $\mu\text{mol/L}$  after experiencing physical stress during extubation, before gradually decreasing to 60  $\mu\text{mol/L}$ . She developed sepsis and was managed at the

intensive care unit for 43 d.

The cause of hyperammonemia for this case was considered to be: (1) physical stress experienced during vaginal parturition and fasting while withstanding pain for a prolonged period of time; (2) excessive protein intake after discharge; and (3) metabolic changes during puerperium following anabolism for the repair of the parturient canal, including the uterus, after delivery and

**Figure 1** Blood ammonia levels after delivery. The patient was admitted on emergency basis because of impaired consciousness 7 d after delivery (day 7) and was intubated. She then underwent HD and CHDF under ICU management (from day 8 to day 12). HD: Hemodialysis; CHDF: Continuous hemodiafiltration; ICU: Intensive care unit.

catabolism for producing maternal milk.

Presently, she uses medication and has been able to raise her child following hospital discharge despite her brain magnetic resonance imaging and single-photon emission computed tomography indicating atrophy of the bilateral frontal and temporal lobes with decreased bold flow (Figure 2).

## DISCUSSION

We resuscitated a female patient with late-onset OTCD who developed hyperammonemia crisis after giving birth. We previously reported the long-term outcome for patients with OTCD in Japan<sup>[8,9,11]</sup>. The expected survival rate at 35 years of age in late-onset OTCD patients was less than 30% for both male and female patients according to data obtained from 1978-1995<sup>[8]</sup>, and 89% for male patients and 84% for female patients according to data obtained from 1999-2009<sup>[9]</sup>. The more recent long-term outcome improved compared to previous outcomes due to improved medication, hemodialysis, and liver transplantation; however, the long-term survival of patients is not guaranteed. These patients always have the potential to develop hyperammonemia due to metabolic stress during infection, surgery or delivery, even if the hyperammonemia is resolved at the time of onset and their medical state is well controlled thereafter.

It has been reported that female patients with OTCD are likely to develop hyperammonemia that persists for 6 to 8 wk at 3 to 14 d after delivery<sup>[12,13]</sup>. Although the cause of hyperammonemia after delivery in female patients with OTCD is not clear, it is considered to be related to increased protein load for collagen catabolism following involution of the uterus<sup>[14]</sup>. We also consider that hyperammonemia is related to metabolic changes in

**Figure 2** Brain magnetic resonance imaging and single-photon emission computed tomography 7 mo after delivery. A and B: FLAIR demonstrates atrophy of the bilateral frontal and temporal lobes, and a high signal for the cortex and subcortex on both sides of insula, the ventral temporal lobe and the frontal lobe bottom. The signal is elevated bilaterally in the putamen, caudate nucleus, and front globus pallidus; C: Single-photon emission computed tomography shows bilaterally decreased blood flow in the frontal lobe, ventral temporal lobe, basal ganglia, and thalamus.

their bodies during puerperium.

She developed hepatic coma that required respiratory management, which required 40 d to resume breathing without assistance and to regain improved level of consciousness. She continued to produce maternal milk a month after the onset of hyperammonemia, and hyperammonemia persisted even after maternal milk production stopped. The cause of long-term hyperammonemia is not only puerperium. Mitochondrial abnormalities within the liver of patients with OTCD has been previously demonstrated<sup>[15]</sup>, and hyperammonemia itself disrupts the function of mitochondria<sup>[16]</sup>. Therefore, it has been considered that the impaired mitochondria in cases of hyperammonemia aggravates OTCD and results in long-term hyperammonemia.

In this case, her blood ammonia levels remained at 60  $\mu\text{mol/L}$  from during pregnancy to 3 d after delivery and elevated at 4 d after delivery. She did not receive sodium benzoate or sodium phenylbutyrate, which are utilized as alternative pathway therapies, because her blood ammonia levels soon decreased after arginine and citrulline treatment. We consider that even female patients with OTCD who do not receive sodium benzoate or sodium phenylbutyrate therapy are recommended to start receiving sodium benzoate or sodium phenylbutyrate treatment from the start of labor to immediately after delivery, if they have developed severe hyperammonemia<sup>[17]</sup>. Benzoate is conjugated with glycine to form hippurate, which is rapidly excreted in the urine. For each mole of benzoate administered, 1 mole of nitrogen is removed. Phenylbutyrate is activated to the CoA ester, which is metabolized by  $\beta$ -oxidation in the liver to form phenylacetyl-CoA, which is then conjugated with glutamine. The resulting phenylacetylglutamine is excreted into the urine, and 2 moles of nitrogen are excreted for each mole of phenylbutyrate<sup>[5]</sup>.

Therefore, it is effective for OTCD patients who have never received sodium phenylbutyrate or sodium benzoate to preliminarily receive such a medication when the blood ammonia level is expected to increase

during excessive stress, such as during delivery. Because ammonia is a final product in amino acid metabolism, it is believed that there is a time lag from stress load to the increased blood ammonia levels. It may be effective to measure blood glutamine levels to predict whether the blood ammonia levels will increase or to estimate the change in body condition in patients with OTCD because glutamine is a supplier of ammonia and one of the markers of the medical condition<sup>[18,19]</sup>. Furthermore, the blood value is high, even in OTCD carriers<sup>[20]</sup>. Moreover, it may be useful to adjust the amount of sodium phenylbutyrate or sodium benzoate based upon blood glutamine levels.

The patient should have been monitored without discharge from our hospital because hyperammonemia crisis was likely to develop anytime within 2 wk after parturition and she could not consume protein-rich food in our hospital. Moreover, we consider that hyperammonemia crisis could have been avoided if she had received sodium benzoate or sodium phenylbutyrate therapy immediately after delivery. Caesarean section and the halting maternal milk production might contribute to preventing a hyperammonemia crisis.

Moreover, this patient was a candidate for liver transplantation (LT) since she was susceptible to developing hyperammonemia crisis for non-predictable common disorders. If female patients with OTCD who have had hyperammonemia crisis are going to be married and give birth, LT before pregnancy may be a treatment option because LT prevents recurrent hyperammonemia attacks and contributes to improved quality of life in patients with UCD<sup>[21-24]</sup>.

In conclusion, we treated a female patient with late-onset OTCD, who developed hyperammonemia crisis after delivery. Hyperammonemia crisis after delivery in patients with OTCD is often fatal and difficult to predict. It is important to perform early intervention before hyperammonemia occurs in patients with OTCD or carriers after delivery. Once hyperammonemia crisis occurs following parturition, it is difficult to improve the

metabolic state of the patient.

## COMMENTS

### Case characteristics

Hyperammonemia crisis with hepatic coma after delivery.

### Clinical diagnosis

Hyperammonemia crisis with hepatic coma.

### Differential diagnosis

Carbamoyl-phosphate synthetase 1 deficiency, arginosuccinate synthetase deficiency, arginosuccinate lyase deficiency and arginase 1 deficiency were considered to be a differential diagnosis.

### Laboratory diagnosis

Increased blood glutamine and urinary orotic acid levels as well as impaired liver ornithine transcarbamylase enzyme activity.

### Imaging diagnosis

Atrophy of the bilateral frontal and temporal lobe, as indicated by brain magnetic resonance imaging.

### Treatment

Arginine, citrulline, sodium benzoate, sodium phenylbutyrate, and hemodialysis.

### Related reports

A peak ammonia concentration less than 180  $\mu\text{mol/L}$  was shown to be a marker of a good neurodevelopmental prognosis, and a peak ammonia concentration of more than 360  $\mu\text{mol/L}$  was a marker of a bad prognosis.

### Term explanation

UCDs: Urea cycle disorders; OTCD: Ornithine transcarbamylase deficiency; LT: Liver transplantation.

### Experiences and lessons

It is important to perform early intervention before hyperammonemia occurs in patients with OTCD or carriers following parturition.

### Peer-review

Hyperammonemia after delivery in a female patient with OTCD can be fatal. In this case report, authors have discussed the cause and treatment of hyperammonemia in a female patient with OTCD after delivery. This case indicates that it is important to perform early intervention before hyperammonemia occurs in patients with OTCD or carriers after delivery.

## Contents

Three issues per month Volume 9 Number 7 March 8, 2017

### EDITORIAL

- 349 Parkin in cancer: Mitophagy-related/unrelated tasks  
*Eid N, Kondo Y*

### REVIEW

- 352 Future of liver disease in the era of direct acting antivirals for the treatment of hepatitis C  
*Ponziani FR, Mangiola F, Binda C, Zocco MA, Siciliano M, Grieco A, Rapaccini GL, Pompili M, Gasbarrini A*

### ORIGINAL ARTICLE

#### Basic Study

- 368 Characterization of a new monoclonal anti-glypican-3 antibody specific to the hepatocellular carcinoma cell line, HepG2  
*Vongchan P, Linhardt RJ*

#### Case Control Study

- 385 Risk factors for hepatocellular carcinoma in cirrhosis due to nonalcoholic fatty liver disease: A multicenter, case-control study  
*Corey KE, Gawrieh S, deLemos AS, Zheng H, Scanga AE, Haglund JW, Sanchez J, Danford CJ, Comerford M, Bossi K, Munir S, Chalasani N, Wattacheril J*

#### Retrospective Study

- 391 Features of hepatocellular carcinoma in Hispanics differ from African Americans and non-Hispanic Whites  
*Venepalli NK, Modayil MV, Berg SA, Nair TD, Parepally M, Rajaram P, Gaba RC, Bui JT, Huang Y, Cotler SJ*

#### Prospective Study

- 401 Phase angle obtained by bioelectrical impedance analysis independently predicts mortality in patients with cirrhosis  
*Belarmino G, Gonzalez MC, Torrinhas RS, Sala P, Andraus W, D'Albuquerque LAC, Pereira RMR, Caparbo VF, Ravacci GR, Damiani L, Heymsfield SB, Waitzberg DL*

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Ahmet Gurakar, MD, Associate Professor, Department of Medicine, Division of Gastroenterology and Hepatology, Johns Hopkins University, Baltimore, MA 21205, United States

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

**FLYLEAF**

### Abstract

Dysfunctional mitochondria may produce excessive reactive oxygen species, thus inducing DNA damage, which may be oncogenic if not repaired. As a major role of the PINK1-Parkin pathway involves selective autophagic clearance of damaged mitochondria *via* a process termed

mitophagy, Parkin-mediated mitophagy may be a tumor-suppressive mechanism. As an alternative mechanism for tumor inhibition beyond mitophagy, Parkin has been reported to have other oncosuppressive functions such as DNA repair, negative regulation of cell proliferation and stimulation of p53 tumor suppressor function. The authors recently reported that acute ethanol-induced mitophagy in hepatocytes was associated with Parkin mitochondrial translocation and colocalization with accumulated 8-OHdG (a marker of DNA damage and mutagenicity). This finding suggests: (1) the possibility of Parkin-mediated repair of damaged mitochondrial DNA in hepatocytes of ethanol-treated rats (ETRs) as an oncosuppressive mechanism; and (2) potential induction of cytoprotective mitophagy in ETR hepatocytes if mitochondrial damage is too severe to be repaired. Below is a summary of the various roles Parkin plays in tumor suppression, which may or may not be related to mitophagy. A proper understanding of the various tasks performed by Parkin in tumorigenesis may help in cancer therapy by allowing the PINK1-Parkin pathway to be targeted.

**Key words:** Cancer; Ethanol; Liver; Mitophagy; Parkin; PINK1; 8-OHdG

**Core tip:** A large number of studies have found that the impaired Parkin function or downregulation of expression may induce cancer initiation and progression *via* mitophagy-related/unrelated mechanisms. Thus, there is a growing belief that Parkin may have tumor suppressor effects. Based on literature and on the authors' recent publications regarding animal models of alcohol abuse, this paper highlights the various roles of Parkin in the suppression of oncogenesis. Proper understanding of Parkin functions may have therapeutic implications in the treatment of various cancers.

Eid N, Kondo Y. Parkin in cancer: Mitophagy-related/unrelated

tasks. *World J Hepatol* 2017; 9(7): 349-351 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v9/i7/349.htm> DOI: <http://dx.doi.org/10.4254/wjh.v9.i7.349>

Mutations in the Parkin gene are frequently associated with Parkinson's disease (PD). They lead to defects in autophagic clearance of damaged mitochondria *via* mitophagy, resulting in the characteristic neuronal loss observed in PD<sup>[1]</sup>. Parkin-mediated mitophagy is characterized by accumulation of PINK1 on the outer mitochondrial membrane (OMM) of damaged mitochondria and subsequent mitochondrial translocation of Parkin and ubiquitination of numerous OMM proteins, followed by clearance of these organelles *via* the microtubule-associated protein light chain 3 (LC3)-mediated autophagic machinery<sup>[1,2]</sup>. Parkin-mediated ubiquitination of OMM proteins stimulates the recruitment of different LC3 interacting region-containing autophagy receptors which bind ubiquitin-tagged OMM proteins, including p62, optineurin and NBR1<sup>[2]</sup>. Dysfunctional mitochondria can transform cells and promote tumorigenesis, suggesting that mitophagy may function as a tumor suppressor mechanism<sup>[2]</sup>. A number of recent studies have investigated the involvement of mitophagy in tumor suppression, with results including the finding that insufficient mitophagy resulted in oncogenic formation in heterogeneous thyroid Hürthle cell tumors<sup>[3]</sup>. However, a growing body of evidence suggests that Parkin also plays a role in cancer as a putative tumor suppressor. Parkin<sup>-/-</sup> mice exhibited enhanced hepatocyte proliferation associated with upregulation of endogenous follistatin, resulting in the induction and progression of hepatocellular carcinoma (HCC)<sup>[4]</sup>. Upon autophagy activation the Atg4 cysteine protease first cleaves pro-LC3 at the C-terminus, thus forming LC3- I. Induction of Atg7 conjugates phosphatidylethanolamine (PE) to LC3- I, forming LC3- II (essential form of LC3 for mitophagosome formation). The Atg5/12/16 complex also acts as an E3 ligase, promoting PE conjugation to LC3<sup>[2]</sup>. Mice with systemic mosaic deletion of Atg5 and liver-specific Atg7<sup>-/-</sup> mice develop benign liver adenomas<sup>[5]</sup>. Parkin deficiency results in overexpression of its substrates, mitotic defects, genomic instability and tumorigenesis<sup>[6]</sup>. Downregulation of Parkin protein has been observed in HCC, whereas Parkin overexpression inhibits the migration and invasion of multiple cancer cells<sup>[7]</sup>. Parkin has been reported to contribute to the functions of p53 - another tumor suppressor - *via* regulation of the energy metabolism (especially the Warburg effect) and antioxidant defense<sup>[8]</sup>. Paradoxically, in some cases Parkin activity may be required for KRAS-driven tumors to maintain mitochondrial quality control and buffer oxidative stress, making it a pro-survival protein<sup>[7]</sup>. KRAS mutant pancreatic adenocarcinoma has been reported to rely on autophagy and mitophagy to supply bioenergetic intermediates for the TCA cycle. Mitophagy

also appears to be a prosurvival mechanism in immortal baby mouse kidney epithelial cells ectopically expressing oncogenic HRAS or KRAS by removing damaged mitochondria<sup>[9]</sup>.

Seitz and Stickel<sup>[10]</sup> reported that animal models of alcohol abuse have clearly identified ethanol as a hepatic carcinogen *via* mechanisms related to excessive reactive oxygen species and acetaldehyde production, altered methylation and reduction of retinoic acid in hepatocytes. Recently the authors<sup>[11,12]</sup> and others<sup>[13]</sup> investigated Parkin-mediated hepatic mitophagy in animal models of acute and chronic alcoholism. The authors found that acute ethanol administration (5 g/kg) to adult rats enhanced hepatocyte mitophagy, which was associated with Parkin mitochondrial translocation and colocalization with accumulated 8-OHdG - a marker of oxidative nuclear and mitochondrial DNA (mtDNA) damage and mutagenicity<sup>[11,12,14,15]</sup>. Accordingly, Parkin co-localization with accumulated 8-OHdG in hepatocyte mitochondria of acute ETRs may be a signal for mitophagy induction *via* the triggering of Parkin mitochondrial translocation<sup>[12,16]</sup>. It may also be a stimulus for DNA repair and prevention of oncogenesis, as endogenous Parkin has a reported physical association with mtDNA<sup>[12,17]</sup> and translocates to nuclei interacting with proliferating cell nuclear antigen in cultured neuronal cells affected by oxidative DNA damage<sup>[18]</sup>. In addition, Parkin-deficient mice have been reported to show increased 8-oxoguanine in the cerebral cortex. Parkin's promotion of DNA repair may therefore be an important mechanism in the suppression of cancer and neurodegenerative diseases<sup>[18,19]</sup>. The authors' findings in animal models of ethanol-induced mitophagy may support the above-mentioned literature regarding the tumor suppressor roles of Parkin, which may or may not be mitophagy-related. Parkin has additionally been reported to regulate two additional cytoprotective mechanisms on cellular exposure to oxidative stress: (1) induction of mitochondrial-derived vesicle formation<sup>[12,16,20]</sup>; and (2) suppression of mitochondrial spheroid formation<sup>[11,21,22]</sup>. Further studies are needed to determine whether Parkin regulates these two mechanisms in cancer cells and to evaluate the impact of any such regulation on tumorigenesis<sup>[23]</sup>.

The authors believe that their recent publications on animal models of alcoholism and the work of others may provide evidence for Parkin-mediated oncosuppression, which may have implications in cancer therapy.

### Abstract

Hepatitis C virus (HCV) infection has been a global health problem for decades, due to the high number of infected people and to the lack of effective and well-tolerated therapies. In the last 3 years, the approval of new direct acting antivirals characterized by high rates of virological clearance and excellent tolerability has dramatically improved HCV infection curability, especially for patients with advanced liver disease and for liver transplant recipients. Long-term data about the impact of the new direct acting antivirals on liver fibrosis and liver disease-related outcomes are not yet available, due to their recent introduction. However, previously published data deriving from the use of pegylated-interferon and ribavirin lead to hypothesizing that we are going to observe, in the future, a reduction in mortality and in the incidence of hepatocellular carcinoma, as well as a regression of fibrosis for people previously affected by hepatitis C. In the liver transplant setting, clinical improvement has already been described after treatment with the new direct acting antivirals, which has often led to patients delisting. In the future, this may hopefully reduce the gap between liver organ request and availability, probably expanding liver transplant indications to other clinical conditions. Therefore, these new drugs are going to change the natural history of HCV-related liver disease and the epidemiology of HCV infection worldwide. However, the global consequences will depend on treatment accessibility and on the number of countries that could afford the use of the new direct acting antivirals.

**Key words:** Direct acting antivirals; Hepatitis C; Liver transplantation; Liver fibrosis; Cirrhosis; Hepatocellular carcinoma

## INTRODUCTION

Since its discovery, hepatitis C virus (HCV) has been a constant burden for global health, with 3 to 4 million new infections each year and an overall number of 130-170 million infected people in the world<sup>[1]</sup>. The prevalence of HCV infection has a large geographical variability, ranging from less than 1% to more than 10% in different regions<sup>[2,3]</sup>. In particular, 2.3 million of the chronically infected subjects have been estimated to reside in the United States, 1.5 in Japan and 11.5-19 in Europe<sup>[4]</sup>.

HCV infection becomes chronic in up to 50%-80% of cases, establishing a damage that may lead to cirrhosis and its complications [e.g., hepatocellular carcinoma (HCC), portal hypertension, liver decompensation and insufficiency] in approximately 10%-20% of patients<sup>[5,6]</sup>. Nevertheless, chronic HCV infection may be associated with extrahepatic manifestations, such as cryoglobulinemia and non-Hodgkin lymphoma, mainly caused by the continuous stimulation of the immune system<sup>[7,8]</sup>.

Non-pegylated interferon (IFN) or pegylated IFN (PEG-IFN) in combination with ribavirin (RBV) have been the main pharmacological agents for the treatment of HCV infection. However, only 30%-40% of subjects with genotype 1 HCV and 70%-90% of those with genotype 2 and 3 treated with PEG-IFN in association with RBV were able to reach a sustained virological response (SVR), defined as the absence of detectable levels of HCV-RNA 24 wk after the end of treatment<sup>[9-14]</sup>. In 2011 the association of the first-generation direct acting antivirals (DAAs) boceprevir and telaprevir with PEG-IFN and RBV increased the overall SVR rates to 68%-75% for naive patients and to 59%-88% for treatment-experienced patients, even if these regimens were dedicated just to the treatment of genotype 1 HCV infection<sup>[12,14,15]</sup>. However, the suboptimal response

rates, the long duration of treatment (24-48 wk) and the scarce tolerability of boceprevir and telaprevir, especially by cirrhotic patients, has heavily affected their clinical use and has led to search for new drugs<sup>[16]</sup>.

## SECOND-GENERATION DAAs

The second-generation DAAs are characterized by elevated SVR rates, good safety profiles, and more comfortable types of administration. They can be used or not in combination with RBV, depending on virological and disease-associated characteristics<sup>[17]</sup>. Sofosbuvir (SOF) has been the first new agent approved by the Food and Drug Administration (FDA) in December 2013 (Table 1 and Figure 1)<sup>[18]</sup>.

SOF targets HCV-RNA replication with a pangenotypic efficacy since it blocks the nucleotide polymerase NS5B, which is highly preserved among different HCV genotypes<sup>[19]</sup>. Treatment with SOF, either in combination with PEG-IFN plus RBV or with RBV alone has shown SVR rates above 85% at 12 wk after the end of treatment (SVR12)<sup>[20]</sup>. Successively, new DAAs for the treatment of HCV infection in association with SOF have been approved: Simeprevir (SMV, a NS3/4A protease inhibitor) and ledipasvir (LDV, a NS5A inhibitor) for genotype 1, and daclatasvir (DCV, a NS5A inhibitor) for genotype 3, reporting SVR12 rates > 90%<sup>[21-24]</sup>. More recently, the pangenotypic NS5A inhibitor velpatasvir has also been approved for HCV treatment in combination with SOF<sup>[25,26]</sup>.

The first antiviral regimen SOF-free was approved in July 2015 and includes paritaprevir (a NS3/4A protease inhibitor), ritonavir (a CYP3A inhibitor, used as a pharmacologic booster) and ombitasvir (a NS5A inhibitor), in association with dasabuvir (a non-nucleoside NS5B polymerase inhibitor), and is indicated for the treatment of genotype 1 (with dasabuvir) and 4 (without dasabuvir) HCV infection<sup>[27,28]</sup>. Successively, the FDA has approved another SOF-free antiviral regimen including elbasvir and grazoprevir<sup>[29]</sup>, and new drugs with pangenotypic efficacy are in final phase of study and will soon be available<sup>[30]</sup>.

The main advantage of the new DAAs-based antiviral regimens is the achievement of high SVR rates for all HCV genotypes within a short treatment period, together with the infrequent occurrence of side effects, usually of mild grade. Resistance-associated variants (RAVs) of the virus may exist prior to treatment, may persist for years after treatment and affect most frequently the NS3/5A viral protein; RAVs are associated with (but do not inevitably result in) treatment failure, which may occur in about 10%-15% of patients<sup>[31,32]</sup>.

The most ambitious result we might expect from the use of DAAs would be the reduction of liver cirrhosis-related complications, such as HCC development, and in the long-term period a decreased progression towards end-stage liver disease and a decreased need for liver transplant (LT), as well as the prevention of post-LT HCV infection recurrence<sup>[33]</sup>. Indeed, according to the latest data published by the World Health Organization in 2013, 5%-7% of infected subjects died from a

Figure 1 Second-generation direct acting antivirals molecules.

disease related to HCV<sup>[34]</sup>, with an estimated risk of liver failure of 10.4% and 26.5% in patients with F3 and F4 fibrosis, respectively<sup>[35]</sup>. HCV-associated liver disease represents the most common indication for LT and, in developed countries, is the most common etiological factor

of HCC, which is the third leading cause of cancer death worldwide<sup>[36-40]</sup>.

However, due to the relatively recent introduction of these new drugs, data about their impact on liver disease progression, complications and liver-related mortality are

**Table 1** Main features of antiviral targets and clinical indications of second-generation direct acting antivirals<sup>[17]</sup>

Molecule	Class	Target	Genotype	Associations
Sofosbuvir	Nucleotide polymerase inhibitor	NS5B RNA-dependent RNA polymerase	Pangenotypic	Ledipasvir Daclatasvir Simeprevir Velpatasvir
Dasabuvir	Non-nucleoside polymerase inhibitor	NS5B RNA-dependent RNA polymerase	Genotype 1	Ombitasvir + paritaprevir + ritonavir
Ombitasvir		NS5A	Genotype 1, 4	Paritaprevir + ritonavir with or without dasabuvir
Daclatasvir		NS5A	Genotype 1, 2, 3	Sofosbuvir
Ledipasvir		NS5A	Genotype 1, 4	Sofosbuvir
Velpatasvir		NS5A	Pangenotypic	Sofosbuvir
Elbasvir		NS5A	Genotype 1, 4	Grazoprevir
Paritaprevir		NS3/4A protease	Genotype 1, 4	Ombitasvir + ritonavir with or without dasabuvir
Simeprevir		NS3/4A protease	Genotype 1, 4	Sofosbuvir
Grazoprevir		NS3/4A protease	Genotype 1, 4	Elbasvir

scarce. Therefore, previously published data about the impact of SVR achieved with PEG-IFN-based regimens are the only available reference to evaluate the future positive effects that DAAs might produce on liver disease outcomes.

## IMPACT OF VIRAL ERADICATION ON LIVER CIRRHOSIS-ASSOCIATED MORBIDITY AND MORTALITY

Published data have demonstrated a correlation between the achievement of SVR and the reduction of HCV-related complications, liver disease severity and mortality (Table 2).

Veldt *et al.*<sup>[41]</sup> reported that among 286 subjects who achieved SVR and were followed-up for 5 years, only 1% experienced liver failure, with a survival similar to that of the general population. Another study including 721 patients with chronic hepatitis C reported a significantly lower annual mortality rate in subjects who had previously achieved SVR after IFN therapy compared to those who had not (0.44%/year, 1.98%/year and 3.19%/year for SVR, non-SVR and untreated patients, respectively;  $P < 0.0001$ ). The study also showed that viral clearance was able to reduce the hazard ratio for total deaths by 0.173<sup>[42]</sup>.

A meta-analysis including 129 trials for a total amount of 15067 patients has demonstrated that SVR achievement reduces the risk of LT requirement by 90%, and the risk of death by 60%-84%<sup>[43]</sup>. Nevertheless, viral clearance leads to a lower incidence of liver-related morbidity and death (0.62 and 0.61 among SVR patients, respectively, and 4.16 and 3.76 among non-SVR patients, respectively;  $P < 0.001$ )<sup>[44]</sup>. Recent data further confirmed that HCV infection resolution allows reduction in the incidence of liver decompensation<sup>[45]</sup>, all-cause mortality<sup>[46,47]</sup> and annual deaths rate (8.9% in SVR patients vs 26.0% in non-SVR patients;  $P < 0.001$ )<sup>[48]</sup>. This evidence was confirmed by an extensive review by Szabo *et al.*<sup>[34]</sup>; moreover, survival rates comparable to general population have been

reported after the achievement of SVR even in patients with well-compensated cirrhosis<sup>[49]</sup>. Although useful to figure out the long-term benefits expected from DAAs, the interpretation of data emerging from the use of IFN- or PEG-IFN-based regimens is limited by the selection of patients, since those affected by comorbidities were usually not suitable for treatment and were not included in outcomes analyses; moreover, the lack of homogeneous design and patients' stratification make it difficult to deduce general conclusions.

## IMPACT OF VIRAL ERADICATION ON LIVER FIBROSIS

Despite the positive impact of HCV infection eradication on patients' prognosis, few data about liver cirrhosis/fibrosis regression are available.

Regression of liver fibrosis as a result of viral clearance is supported by the reduction of inflammatory mediators that leads to apoptosis of myofibroblasts, and occurs by the inactivation of stellate cells. The down-regulation of inflammation, as well as microvascular remodelling, degradation of extracellular matrix and hepatocyte repopulation leads to the generation of new hepatic tissue<sup>[50,51]</sup>.

Cirrhosis regression has been reported in about 61% of cases after a median time of 3 years from the achievement of SVR (Table 2)<sup>[52]</sup>. Mallet *et al.*<sup>[53]</sup> observed the evolution of liver fibrosis in 96 patients treated with IFN or PEG-IFN with or without RBV, for a median follow-up of 118 mo. Although statistical significance was not reached, 18 subjects obtained a regression of fibrosis from METAVIR stage 4 to stage  $\leq 2$ . In another study, among 153 cirrhotic patients treated with IFN or PEG-IFN in combination or not with RBV for 24 or 48 wk, 75 (49%) had a regression of fibrosis after a mean time of  $21 \pm 4$  mo. In addition to SVR, factors independently associated with histology improvement were age  $< 40$  years ( $P < 0.001$ ) and body mass index  $< 27$  kg/m<sup>2</sup> ( $P < 0.001$ )<sup>[54]</sup>.

Other small studies reported variable rates of fibrosis regression after different time periods from viral

Pts: Patients; IFN: Interferon; PEG: Pegylated; SVR: Sustained virological response; HCC: Hepatocellular carcinoma; RBV: Ribavirin.

However, the neo-formed parenchyma derived from the generation of new liver tissue is different from the healthy one and is characterized by architectural and structural alterations<sup>[63]</sup>. At present, little is known about its functionality.

In HCV-infected subjects, the development of liver cirrhosis is the main oncogenic trigger for HCC<sup>[5,64,65]</sup>, though not the only one. Indeed, direct and indirect viral-related mechanisms may contribute to the growth of cancer cells, including the expression of viral proteins with oncogenic effect from infected cells, messy proliferation of non-infected hepatocytes responsive to the apoptotic boost and the oxidative stress caused by inflammation<sup>[66]</sup>.

HCV eradication may also reduce the risk of HCC recurrence after surgical treatment. A 63.4% cumulative recurrence rate has been reported in non-treated patients, compared to 63.2% in treated patients who did not achieve SVR and to 41.7% in the SVR group (non-treated vs SVR,  $P = 0.008$ ; SVR vs treated without SVR,  $P = 0.035$ )<sup>[69]</sup>. Mazzaferro *et al*<sup>[70]</sup> also found SVR as the only factor significantly reducing HCC late recurrence in HCV-pure (hepatitis B antiretrovirus negative) patients. A subsequent meta-analysis also reported a reduced rate of early recurrence in 51 patients undergoing surgical resection or percutaneous ablation, reporting a 30% reduction in HCC recurrence rate<sup>[71]</sup>. In addition, IFN therapy seems to exert beneficial effects, even when started before HCC curative treatments<sup>[72]</sup>.

DAAAs may likely modulate the expression of genes involved in the production of endogenous IFN $\gamma$ . In patients treated with SOF in association with RBV a reduction in

types I and II IFN in liver tissue and an increase of IFN- $\alpha$ 2 have been observed<sup>[75]</sup>. Conversely, other authors have reported a loss of intrahepatic immune activation by IFN- $\gamma$ , associated with normalization of the natural killer cells phenotype and function, consequent to DAAs treatment<sup>[76]</sup>. How these findings may be associated with DAAs treatment outcome still needs to be further elucidated.

Although the risk of HCC development is significantly reduced by viral clearance it is not completely eliminated, especially in cases of persistence of other cofactors promoting carcinogenesis. Toyoda *et al.*<sup>[77]</sup> reported that 18/522 patients who achieved SVR after IFN treatment developed HCC after a median follow-up of about 7.2 years (1.0-22.9 years), with an incidence of 1.2% and 4.3% at 5 years and 10 years, respectively. In the analysis, the presence of diabetes mellitus and advanced fibrosis (FIB-4 index  $\geq 2$ ) at 24 wk after SVR were correlated to an increased risk of developing HCC. Other data identified type 2 diabetes mellitus and total alcohol intake as independent risk factors for HCC development (HR = 2.77, 95%CI: 2.13-3.60,  $P < 0.001$  and HR = 2.13, 95%CI: 1.74-2.61,  $P < 0.001$ , respectively)<sup>[78]</sup>. In another study, among 232 SVR patients who underwent liver biopsy between 1992 and 2009, the development of HCC was definitively lower in the group with low-intermediate grade fibrosis (F0-F2 according to Metavir) than in that with F3-F4 grade (1.6% and 8%, respectively)<sup>[79]</sup>.

Data about the impact of DAAs treatment on HCC recurrence in previously treated patients and on the development of new HCC nodules have been recently published. It seems to be clear that these new antivirals are not able to modify the natural history of HCC in cirrhotic patients, and it has also been postulated that they may act as promoters, although other studies have not supported this hypothesis<sup>[80-87]</sup>. Probably, an investigation focused on the immunologic changes and the microenvironmental hepatic tissue alterations consequent to DAAs treatment may be worthwhile to quell this debate<sup>[88]</sup>.

## DAAs AND LT

HCV infection-associated cirrhosis and HCC account for 40% of all cases on the LT waiting list in the United States and for about 1/3 of LTs in cirrhotic patients<sup>[39,40]</sup>. HCV infection recurrence of the graft is universal and leads to cirrhosis in up to 20%-30% of recipients, being one of the most important causes of death and retransplantation<sup>[89,90]</sup>. The time course of post-LT HCV reinfection is faster than among immunocompetent individuals; cirrhosis can be histologically documented within 5 years after LT, and from that point on the first episode of decompensation may occur within less than 1 year<sup>[91]</sup>.

After HCV infection eradication, a 62%-84% decrease in 5-year mortality as well as a reduction by 90% of the risk of receiving LT have been reported<sup>[43]</sup>. This im-

provement in survival was observed in both sustained virological responders and relapsers<sup>[92]</sup>. The new available DAAs account for response rates higher than 90% and are better tolerated than either IFN and PEG-IFN, allowing for treatment of patients for whom the previous antivirals were contraindicated and who had low chances of response due to unfavourable virological or clinical conditions<sup>[93]</sup>. As patients who achieve SVR have a reduced risk of progression to cirrhosis and of developing its complications, the widespread use of the new DAAs will probably change the scenario of LT, potentially reducing the need for liver organs.

## DAAs treatment before LT

The aim of antiviral treatment in patients on the waiting list is to prevent the recurrence of HCV infection after LT. To reduce the risk of post-LT recurrence, the achievement of at least 30 d of HCV-RNA negativity before LT has been suggested<sup>[94,95]</sup>. However, whether it is necessary to continue antiviral therapy after LT in patients who received a very short course of therapy before transplantation is not yet clear<sup>[96]</sup>.

Furthermore, achieving SVR in waiting-list patients may directly impact the severity of liver disease, with possible delisting after treatment. A recent real-life multicentre study<sup>[97]</sup> including 103 decompensated cirrhotic patients listed for LT and treated with second-generation DAAs reported HCV eradication rates of 16% at 24 wk and of 35% at 48 wk after the beginning of treatment (Table 3). This was associated with delisting of 20% of patients at 48 wk from the end of treatment. The evidence of a significant improvement of liver function also comes from the SOLAR-1 study cohort A<sup>[98]</sup>, including cirrhotic patients with decompensated disease treated with LDV and SOF plus RBV. For this study, similar SVR rates (from 86% to 89%) were reported for Child-Pugh class B and C patients regardless of treatment duration, and this was associated with the improvement of model for end-stage liver disease (MELD) and Child-Pugh scores.

Other studies confirmed liver function amelioration after viral eradication in decompensated cirrhotic patients<sup>[26,98-104]</sup>; although in cases with more advanced liver impairment (Child-Pugh C, albumin lower than 3.5 g/dL, MELD > 20) and in the elderly worsening of liver function has also been reported<sup>[105,106]</sup>.

Delisting due to clinical improvement may therefore become frequent in the era of DAAs, making it possible to reserve LT only to patients who do not show significant benefit. Munoz<sup>[107]</sup> estimated that DAAs-induced reduction in MELD score down to the threshold of LT benefit may occur in 592-993 listed patients/year during the first year after treatment, and that approximately 213-515 donated livers/year may become available for redistribution to other patients.

The future impact of DAAs on indications for LT and on organ allocation policy may depend not only on the decreased number of HCV-infected recipients but also on the potential use of anti-HCV positive donors<sup>[108]</sup>. Indeed, DAAs might introduce a new era, in which anti-
