BMI is the ratio between a person's stature and respective weight. In most cases, the higher is the BMI, the higher is the concentration of fat in the body. Persons with BMI higher than 30 are considered obese and individuals with BMI higher than 40 are considered morbidly obese. Obesity is associated with increased risks for metabolic derangements such as diabetes, hypertension, hypercholesterolemia and atherosclerotic diseases. Because of this association, obese patients are considered at higher risk of developing cardiopulmonary complications after LT and they absorb more resources when undergoing complex surgical interventions like LT.

Peer-review

This is a large retrospective study to attempt to answer if BMI affect outcomes of liver transplant patients. The study is well designed, performed, and written.

Abstract

AIM: To determine the general and transplant-specific risk factors for fractures in kidney transplant recipients.

METHODS: We conducted a cohort study of all adults who received a kidney-only transplant ($n = 2723$) in Ontario, Canada between 2002 and 2009. We used multivariable Cox proportional hazards regression to determine general and transplant-specific risk factors for major fractures (proximal humerus, forearm, hip, and clinical vertebral). The final model was established using the backward elimination strategy, selecting risk factors with a P -value ≤ 0.2 and forcing recipient age and sex into the model. We also assessed risk factors for other fracture locations (excluding major fractures, and fractures involving the skull, hands or feet).

RESULTS: There were 132 major fractures in the follow-up (8.1 fractures per 1000 person-years). General risk factors associated with a greater risk of major fracture were older recipient age [adjusted hazard ratio (aHR) per 5-year increase 1.11, 95%CI: 1.03-1.19] and female sex (aHR = 1.81, 95%CI: 1.28-2.57). Transplant-specific risk factors associated with a greater risk of fracture included older donor age (5-year increase) (aHR = 1.09, 95%CI: 1.02-1.17) and end-stage renal disease (ESRD) caused by diabetes (aHR = 1.72, 95%CI: 1.09-2.72) or cystic kidney disease (aHR = 1.73, 95%CI: 1.08-2.78) (compared to glomerulonephritis as the reference cause). Risk factors across the two fracture locations were not consistent (major fracture locations *vs* other). Specifically, general risk factors associated with an increased risk of other fractures were diabetes and a fall with hospitalization prior to transplantation, while length of time on dialysis, and renal vascular disease and other causes of ESRD were the transplant-specific risk factors associated with a greater risk of other fractures.

CONCLUSION: Both general and transplant-specific risk factors were associated with a higher risk of fractures in kidney transplant recipients. Results can be used for clinical prognostication.

Key words: Fracture; Risk factors; Kidney transplant recipient; Prognostication; Cohort study

Core tip: We examined risk factors for major and other fractures in adult kidney transplant recipients. Increasing age and female sex were associated with an increased major fracture risk, while diabetes or cystic kidney disease as the cause of end-stage renal disease and increasing age of the kidney donor were the transplant-specific risk factors associated with an increased major fracture risk. Risk factors were variable across fracture locations (major *vs* other fractures). General and transplant-specific risk factors for fracture

should be considered when assessing fracture risk in kidney transplant recipients. Different risk factors may need to be considered depending on the fracture location.

Risk factors for fracture in adult kidney transplant recipients. *World J Transplant* 2016; 6(2): 370-379 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i2/370.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i2.370>

INTRODUCTION

Kidney transplant recipients are at a higher risk of fracture compared to the general population^[1-4]. Reasons for the increased fracture risk are multifactorial, and may include perturbations in bone and mineral metabolism that occur in renal bone disease, and the administration of glucocorticoids after transplantation^[5]. However, the risk factors for fracture after transplant remain uncertain. In a recent systematic review many classical risk factors for fracture in the general population (*e.g.*, older age, female sex) were inconsistently associated with fractures in kidney transplant recipients^[6]. Unlike the transplant population, risk factors for fracture in the general population are well-established and are included in the World Health Organization's (WHO) Fracture Risk Assessment tool (FRAX). FRAX is used to guide treatment decisions in the general population by incorporating age, sex, clinical risk factors (body mass index, parental hip fracture, glucocorticoid use, rheumatoid arthritis, smoking, alcohol intake ≥ 3 units per day), and hip bone mineral density (optional) to predict the 10-year probability of hip fracture or major osteoporotic fracture (proximal humerus, forearm, hip, or clinical vertebral)^[7-9]. However, kidney transplant recipients may have different risk factors for fracture given the unique pathophysiology that underlies their bone disease^[10]. For example, in a recent cohort study the only classical risk factor for fracture that reached statistical significance in kidney transplant recipients was high alcohol use^[11]; however, this study had only 21 fracture events and may have had inadequate statistical power to identify other risk factors^[11]. The same study also found that FRAX may be a useful tool to predict fracture in kidney transplant recipients (area under the receiver operating curve 0.62); however, the authors hypothesized that incorporating transplant-specific risk factors for fracture may further improve the performance of FRAX^[11].

The WHO has called for a global strategy on fracture prevention and management^[12]. Such strategies require an understanding of well-validated fracture risk factors and prediction tools so populations at high risk can be targeted for diagnosis, treatment, and therapeutic trials.

Given that risk factors for fracture in kidney transplant recipients have not been well-established, we conducted this study to determine general risk factors (*e.g.*, age, sex, previous fracture, previous fall) and transplant-specific risk factors (*e.g.*, length of time on dialysis prior to transplant) associated with major fractures (proximal humerus, forearm, hip, and clinical vertebral) in kidney transplant recipients. In an additional analysis we assessed risk factors for other fracture locations (excluding major fractures, and fractures involving the skull, hands or feet).

MATERIALS AND METHODS

Design and setting

We performed a population-based cohort study using healthcare databases held at the Institute for Clinical Evaluative Sciences (ICES) in Ontario, Canada. Ontario residents have universal access to hospital and physician services. These datasets were linked using unique encoded identifiers and analyzed at ICES. This study was approved by the institutional review board at Sunnybrook Health Sciences Centre, Toronto, Canada.

Data sources

We used several databases to obtain our study cohort, characteristics, risk factors, and outcome data. Information on all kidney transplant recipients who received their transplant in Ontario was provided by the Canadian Organ Replacement Register. Information on provincial physicians' billing claims was provided by the Ontario Health Insurance Plan database. The Canadian Institute for Health Information Discharge Abstract Database provided information on diagnostic and procedural codes during Ontario hospitalizations and information on emergency room visits was provided by the National Ambulatory Care Reporting System. The Ontario Registered Persons Database provided information on vital status and demographics.

Cohort

We identified all first-time kidney-only transplants in Ontario from April 1st, 2002 to December 31st, 2009, restricting to individuals ≥ 18 years of age at the transplant date. We selected April 1st, 2002 as our cohort entry date as this was when Canada changed the International Classification of Disease (ICD) system from version 9 to 10. The cohort entry date (index date) was the date an individual received their kidney transplant.

Risk factors

We assessed several general risk factors for fracture (*e.g.*, age, sex, and prior major fracture) which are incorporated in FRAX. We also assessed other general risk factors found to increase fracture risk in the non-transplant population, including: A fall with hospitalization in the year prior to transplantation, race/eth-

nicity, and diabetes (only type 1 diabetes is included in FRAX)^[13-15]. We assessed several transplant-specific risk factors including: Length of time on dialysis prior to transplant (years), type of donor (living vs deceased), cause of end-stage renal disease [ESRD, *e.g.*, diabetes mellitus, glomerulonephritis, renal vascular disease, cystic kidney disease, or other (*i.e.*, any cause of ESRD not included in the aforementioned categories such as pyelonephritis)], pre-transplant dialysis modality (peritoneal, hemodialysis, or pre-emptive), and donor characteristics (age and sex).

Outcomes

We followed kidney transplant recipients from the date of transplant until first fracture, death, or end of follow-up (March 31st, 2013). We did not censor kidney transplant recipients if they returned to chronic dialysis or if they had another transplant during follow-up. Our primary outcome was major fractures which were defined as a composite of hip, forearm, proximal humerus, and clinical vertebral fractures. We chose to assess risk factors for major fractures with hospital presentation (emergency room visit or hospital admission) as these fracture locations are associated with excess morbidity and mortality in the general population^[16-18]. We also assessed other fracture locations, defined as: Lower leg (ankle, tibia, fibula, patella), femoral shaft, rib/sternum/trunk, scapula, clavicle, and pelvis fractures. These fractures as a whole were considered the secondary outcome as they may be more common in kidney transplant recipients^[10]. For example, in prior studies ankle fractures were common in kidney transplant recipients^[1,19]. We included both high and low trauma fractures because, similar to low-trauma fractures, high-trauma fractures occur more commonly when an individual has compromised bone strength^[20]. We identified fracture events using the 10th version of the ICD system. To increase accuracy, diagnosis codes for hip, forearm, and femoral shaft fractures had to be accompanied by procedural codes identified from hospital encounters and physician billing codes^[21].

Statistical analysis

We compared differences in baseline characteristics of recipients with and without a fracture using the Mann Whitney *U* test for continuous variables and the chi-square test for categorical variables. We calculated the incidence rate of fracture (per 1000 person-years) censoring the observation period on the date of death, first fracture, or end of follow-up (March 31, 2013). We used the Cox proportional hazards model to assess effects of risk factors on the hazard of the first fracture. Prior to obtaining the adjusted hazard ratio (aHR) to quantify the effect of each risk factor, model assumptions such as the proportional hazards assumption and linearity of continuous factors (Martingale residuals) were assessed with a *P*-value < 0.05 used as criteria for a violation^[22-24]. We used the backward elimination

Table 1 Characteristics of kidney transplant recipients classified by major fracture status¹ *n* (%)

	No fracture (<i>n</i> = 2591)	Major Fracture (<i>n</i> = 132)	<i>P</i> -value
General risk factors

Hemodialysis	1622 (62.6)	83 (62.9)	
Pre-emptive	268 (10.3)	14 (11.6)	
Donor characteristics			
Type of donor			0.47
Deceased (<i>vs</i> living)	1458 (56.3)	70 (53.0)	
Donor age (yr)	46 (36-54)	48 (41-55)	0.16
Donor sex			0.73
Women	1295 (50.0)	68 (51.5)	

Data are median (interquartile range) or *n* (%). ¹Major fracture events were comprised of forearm (*n* = 81), hip (*n* = 22), proximal humerus (*n* = 18), and clinical vertebral fractures (*n* = 13); ²Other was defined as a composite of: Indian Sub-Continent, Pacific Islander, Aboriginal, Mid East/Arabian, Latin American, Other/Multiracial; ³Due to the small number of recipients with a prior major fracture this risk factor was not able to be assessed; ⁴Includes individuals who received a pre-emptive transplant where the time spent on dialysis was defined as 0 years; ⁵Due to the small number of recipients with a major fracture who had renal vascular disease as the cause of their ESRD this category was combined into the other category; ⁶We defined hemodialysis and peritoneal dialysis based on the modality the recipient first received. We defined pre-emptive transplant as no evidence of hemodialysis or peritoneal dialysis prior to transplant. ESRD: End-stage renal disease.

strategy to select risk factors that would be entered into the final model, with recipient age and sex forced into the model. To decrease the possibility of missing important risk factors for fracture post-transplant, a priori we chose a *P*-value of ≤ 0.2 to select variables for inclusion in the final model^[25]. We assessed for multicollinearity among variables prior to entering variables into the backward elimination model. We found limited concern for multicollinearity, since all variance inflation factors were less than 2^[26]. There were missing data for the following variables: Donor age (2.2%), donor sex (< 1%), cause of ESRD (11.6%), race (10.7%), and donor type (< 1%). We handled missing data by assigning values randomly selected from observed values with the exception of donor age for which we supplemented missing values with the median age. In the final model we interpreted two-sided *P*-values < 0.05 as statistically significant. We performed all analyses using Statistical Analysis Software, version 9.4 (www.sas.com). The statistical methods of this study were reviewed by a biostatistician, Guangyong Zou, PhD.

RESULTS

Incidence of fracture

Of the 2723 kidney transplant recipients the total follow-up was 16274 person-years (average 6 years), during which 402 (14.8%) died and 132 (4.8%) sustained a major fracture (8.1 fractures per 1000 person-years, 95%CI: 6.8-9.6).

Baseline characteristics

Recipients who sustained a major fracture in follow-up compared to recipients with no major fracture had a significantly higher median age (56.5 years *vs* 50.5 years), were more likely to be women (48.5% *vs* 35.8%), and were less likely to have glomerulonephritis as their cause of ESRD (29.6% *vs* 36.7%) (Table 1).

Univariable analysis

We found older recipient age and female recipient sex were the general risk factors associated with an increased risk of major fracture (Table 2). For example,

¹Other was defined as a composite of: Indian Sub-Continent, Pacific Islander, Aboriginal, Mid East/Arabian, Latin American, Other/Multiracial; ²Due to the small number of recipients with a prior major fracture this risk factor was not able to be assessed; ³Includes individuals who received a pre-emptive transplant where the time spent on dialysis was defined as 0 years; ⁴Due to the small number of recipients with a major fracture who had renal vascular disease as the cause of their ESRD this category was combined into the other category; ⁵We defined hemodialysis and peritoneal dialysis based on the modality the recipient first received. We defined pre-emptive transplant as no evidence of hemodialysis or peritoneal dialysis prior to transplant. ESRD: End-stage renal disease; HR: Hazard ratio.

female recipients had almost a two-fold greater risk of major fracture (HR = 1.65, 95%CI: 1.18-2.33). Due to the small number of recipients with a prior major fracture this risk factor was not able to be assessed. Regarding transplant-specific risk factors, cystic kidney disease (HR = 1.93, 95%CI: 1.20-3.08) and diabetes (HR = 1.80, 95%CI: 1.15-2.82) as the cause of ESRD (compared to glomerulonephritis as the reference cause) were both associated with a higher risk of major fracture. Each 5-year increase in donor age was also associated with a greater risk of major fracture (HR = 1.11, 95%CI: 1.04-1.18).

Multivariable analysis

In the multivariable model, older recipient age (5-year increase) (aHR = 1.11, 95%CI: 1.03-1.19) and female recipient sex (aHR = 1.81, 95%CI: 1.28-2.57) were the general risk factors associated with a greater risk of major fracture (Table 2). Regarding transplant-specific risk factors diabetes (aHR = 1.72, 95%CI:

1.09-2.72) and cystic kidney disease (aHR = 1.73, 95%CI: 1.08-2.78) as the cause of ESRD (compared to glomerulonephritis as the reference cause), and older donor age (5-year increase) (aHR = 1.09, 95%CI: 1.02-1.17) were associated with a greater risk of major fracture.

Other fractures

When we assessed other fracture events (excluding the major fractures, and skull, hands, or feet) kidney transplant recipients had 141 fractures (8.7 fractures per 1000 person-years, 95%CI: 7.3-10.2). Recipients with vs without such fractures were significantly more likely to have diabetes (40.4% vs 25.4%) and were more likely to have had a fall with hospitalization in the year prior to transplant (7.1% vs 3.5%) (Table 3). In the multivariable model we found diabetes and a fall with hospitalization prior to transplantation were the general risk factors associated with an increased risk of fracture, while length of time on dialysis, and renal

Data are median (interquartile range) or *n* (%). ¹Other was defined as a composite of: Indian Sub-Continent, Pacific Islander, Aboriginal, Mid East/Arabian, Latin American, Other/Multiracial; ²Includes individuals who received a pre-emptive transplant where the time spent on dialysis was defined as 0 years; ³Other fracture events were comprised of pelvis (*n* = 15), ankle (*n* = 37), patella (*n* = 8), tibia/fibula (*n* = 37), rib/sternum (*n* = 34), and other (femoral shaft, scapula, clavicle; *n* = 16); ⁴We defined hemodialysis and peritoneal dialysis based on the modality the recipient first received. We defined pre-emptive transplant as no evidence of hemodialysis or peritoneal dialysis prior to transplant; ⁵Prior major fracture had to occur from 1991 to cohort entry (date of transplant).

vascular disease and other causes of ESRD were the transplant-specific risk factors associated with a greater risk of other fractures (Table 4).

DISCUSSION

Similar to the general population, we found increasing recipient age and female sex were associated with an increased major fracture risk in kidney transplant recipients. Unique to the kidney transplant population, we also found diabetes or cystic kidney disease as the cause of ESRD and increasing age of the kidney donor were associated with a significantly increased major fracture risk. However, risk factors were not consistent across fracture locations with increasing age and female sex not associated with an increased other fracture risk. Our findings suggest that both general and transplant-specific risk factors for fracture should be considered by clinicians when assessing fracture risk in kidney transplant recipients. However, different risk factors may need to be taken into account when considering different fracture locations.

We previously published a study of 321 kidney transplant recipients from Manitoba, Canada and found that FRAX was able to modestly predict fracture and may be a useful tool for clinicians to use to help guide treatment decisions; the area under the receiver operating curve value was 0.62 and there was concordance in the observed vs predicted 10-year major osteoporotic fracture probability (6.3% vs 5.6%, respectively)^[11]. However, the number of major osteoporotic fracture events was small (*n* = 21), with correspondingly wide 95% CIs^[11]. We hypothesized that a fracture prediction tool incorporating both general and transplant-specific risk factors may improve fracture prediction^[11]. However, model updating may not be needed as the absolute fracture rate found in the current study was lower than previously reported, similar to other recently conducted studies^[27,28]. Moreover, the strength of the transplant-specific risk factors was only moderate. Additionally, the large sample size needed to update a model and the reasonable performance of the original FRAX model in kidney transplant recipients further suggests model updating may not be needed. However,

¹Other was defined as a composite of: Indian Sub-Continent, Pacific Islander, Aboriginal, Mid East/Arabian, Latin American, Other/Multiracial; ²Includes individuals who received a pre-emptive transplant where the time spent on dialysis was defined as 0 years; ³We defined hemodialysis and peritoneal dialysis based on the modality they first received. We defined pre-emptive transplant as no evidence of hemodialysis or peritoneal dialysis prior to transplant.

to gain a more complete understanding of fracture risk, it is likely important for clinicians to consider some transplant-specific risk factors (*e.g.*, cause of ESRD) in isolation, when assessing fracture risk. Future research should assess other potential transplant-specific risk factors (unavailable in our current analyses), including: Change in body mass index after transplantation (weight changes found to increase fracture risk in the general population) and fibroblast growth factor 23 (suppresses mineralization of the bone matrix)^[29,30].

We found that risk factors for fracture may vary across fracture locations. For example, there were different risk factors for fracture between our two fracture classifications (major fracture locations *vs* other fracture locations). A possible explanation for this finding is that in the kidney transplant population risk factors for fractures are site specific. For example, similar to what some studies have found in the general population, in our study increasing recipient age and female recipient sex were both associated with an increased major fracture risk^[31-33]. However, increasing recipient age and female sex were not associated with an increased risk of other fractures. This provides a potential explanation for the results of a previous systematic review which found risk factors for fracture in kidney transplant

recipients were inconsistent; studies in the review included different fracture locations^[6]. However, we cannot discount the possibility that the differences in risk factors across fracture locations found in this study were the result of a type II error. Future studies with larger sample sizes should assess site-specific risk factors for fractures (*e.g.*, ankle) in kidney transplant recipients.

Of concern, several of the risk factors for fracture identified in this study are becoming more common in recent eras of kidney transplant recipients. For example, we found diabetes as the cause of ESRD and older recipient age were significant risk factors for major fractures. The number of recipients with diabetes and the average recipient age has been increasing^[34,35]. Similar to results found in a previous study^[36], increasing donor age was also associated with an increased risk of major fracture. This is concerning as there has been an increase in the number of recipients receiving a kidney from older donors^[37,38]. It is important to note that donor age may only be a surrogate measure for recipient age, with kidneys from older donors often being allocated to older recipients. Nevertheless, the increase in the aforementioned risk factors may have important implications for fracture risk in future recipients.

Unfortunately, none of the risk factors for major

fractures found in this study are easily modifiable. However, a hospitalized fall in the year prior to transplant was a significant risk factor for other fractures; falls are potentially modifiable through the use of fall prevention programs^[39-41]. This is an important finding given the commonality of falls in kidney transplant recipients with over 10% of women recipients aged ≥ 50 years sustaining a fall with hospitalization in the first 3-years after transplant^[4]. The paucity of modifiable risk factors is concerning as one of the best ways to prevent fractures in the general population is to provide therapy (*e.g.*, bisphosphonates); the efficacy of these therapies in kidney transplant recipients is unclear^[42]. However, given that not many recipients sustained a fracture the lack of modifiable risk factors may be less of a concern.

Limitations of the study are noted. First, we were unable to assess drug use (*e.g.*, glucocorticoids) as a potential risk factor for fracture; drug information in our databases was only available for a minority of kidney transplant recipients; therefore, our sample size would have been decreased, limiting statistical power. It is important to note that a previous study found that kidney transplant recipients who received early corticosteroid withdrawal had a 1.6% reduction in fracture compared to recipients who received standard corticosteroid based immunosuppression^[43]. Future studies should explore this further, including measuring glucocorticoid use as a continuous variable and assessing the impact of reduced dose on fracture risk, with a consideration given to the impact this may have on long-term immunological outcomes (*e.g.*, graft loss)^[44]. Second, we were unable to assess several risk factors, such as body mass index and estimated glomerular filtration rate, due to a high proportion of missingness (> 50%). Third, the small number of fracture events may have limited statistical power and increased concerns about the validity of the model. However, we selected a liberal *P*-value in our backward elimination analysis to ensure we were not excluding potentially important variables. Additionally, it is unlikely there were type I errors given there were at least 10 events per variable^[45]. Finally, due to the small number of fracture events we were also not able to assess several of the other risk factors included in the FRAX algorithm (*e.g.*, rheumatoid arthritis). Last, the generalizability of these results to other races/ethnic groups may be limited as the majority (72%) of our sample was White.

Both general and transplant-specific risk factors for fracture should be considered by clinicians when assessing fracture risk in this unique patient population; however, risk factors may be variable across fracture locations. Future studies with larger sample sizes should assess the ability of other transplant-specific risk factors to predict fracture.

COMMENTS

Background

Compared to the general population kidney transplant recipients are at an increased risk of fracture due to a multitude of factors, including: Chronic kidney disease-mineral and bone disorder and glucocorticoid administration post-transplant. However, risk factors for fracture are not well-established in the kidney transplant population. An understanding of risk factors for fracture is important to target high risk recipients for treatment and therapeutic trials.

Research frontiers

To determine the general and transplant-specific risk factors for fractures in kidney transplant recipients.

Innovations and breakthroughs

General and transplant-specific risk factors for fracture should be considered by clinicians when assessing fracture risk in kidney transplant recipients. However, different risk factors may need to be taken into account when considering different fracture locations. Unfortunately, none of the risk factors for major fractures found in this study are easily modifiable. However, a hospitalized fall in the year prior to transplant was a significant risk factor for other fractures; falls are potentially modifiable through the use of fall prevention programs. This is an important finding given the commonality of falls in kidney transplant recipients.

Applications

The risk factors for fracture identified in this study are useful for clinical prognostication.

Terminology

Major fractures were defined as a composite of hip, forearm, proximal humerus, and clinical vertebral fractures. Other fracture locations were defined as a composite of lower leg (ankle, tibia, fibula, patella), femoral shaft, rib/sternum/trunk, scapula, clavicle, and pelvis fractures.

Peer-review

This is a well written study on an important topic in transplantation as the risk of

bone fractures after transplantation. The statistical analysis is well conducted.

Abstract

AIM: To determine the outcome of orthotopic heart transplantation (OHT) in immunoglobulin light chain (AL) amyloidosis.

METHODS: The medical records of patients with AL who underwent orthotopic heart transplantation at the Mayo Clinic in Rochester Minnesota from 1992 to 2011 were reviewed. Patients met at least one of the following at: New York Heart Association class IV heart failure, ventricular thickness > 15 mm, ejection fraction < 40%. Selection guidelines for heart transplant included age < 60 years, absence of multiple myeloma and significant extra-cardiac organ involvement. Baseline characteristics including age, gender, organ

involvement, and New York Heart Association functional class were recorded. Laboratory data, waiting time until heart transplant, and type of treatment of the underlying plasma cell disorder were recorded. Survival from the time of OHT was calculated using Kaplan-Meier survival curves. Survival of patients undergoing OHT for AL was compared to that of non-amyloid patients undergoing OHT during the same time period.

RESULTS: Twenty-three patients (median age 53 years) with AL received OHT. There were no deaths in the immediate perioperative period. Twenty patients have died post OHT. For the entire cohort, the median overall survival was 3.5 years (95%CI: 1.2, 8.2 years). The 1-year survival post OHT was 77%, the 2-year survival 65%, and the 5-year survival 43%. The 5-year survival for non-amyloid patients undergoing OHT during the same era was 85%. Progressive amyloidosis contributed to death in twelve patients. Of those without evidence of progressive amyloidosis, the cause of death included complications of autologous hematopoietic stem cell transplantation for 3 patients, post-transplant lymphoproliferative disorder for 2 patients; and for the remaining one death was related to each of the following causes: acute rejection; cardiac vasculopathy; metastatic melanoma; myelodysplastic syndrome; and unknown. Eight patients had rejection at a median of 1.8 mo post OHT (range 0.4 to 4.9 mo); only one patient died of rejection. Median survival of seven patients who achieved a complete hematologic response to either chemotherapy or autologous hematopoietic stem cell transplantation was 10.8 years.

CONCLUSION: Our data demonstrate that long term survival after heart transplant is feasible in AL patients with limited extra-cardiac involvement who achieve complete hematologic response.

Key words: Heart transplantation; Autologous stem cell transplantation; Amyloidosis; Chemotherapy; Heart failure

Core tip: Heart failure due to immunoglobulin light chain (AL) amyloidosis is a devastating disease with poor prognosis. Orthotopic heart transplantation (OHT) is controversial. Twenty-three patients with AL amyloid underwent OHT at our institution over a twenty-year period. Median survival was 3.5 years following OHT. Median survival of seven patients who achieved a complete hematologic response to treatment for AL was almost 11 years. This study demonstrates that long term survival after heart transplant is feasible in AL patients with limited extra-cardiac involvement who achieve complete hematologic response.

INTRODUCTION

Immunoglobulin light chain (AL) amyloidosis is a systemic plasma cell disorder, characterized by the production of a kappa or lambda monoclonal light chain by a clonal population of bone marrow plasma cells^[1]. The monoclonal light chain misfolds into an insoluble beta-pleated sheet conformation. The aberrant protein subsequently accumulates in tissues, leading to organ dysfunction.

Cardiac involvement occurs in 50% of patients with systemic AL amyloidosis and is the most important risk factor for adverse prognosis and death^[2,3]. Amyloid fibrils infiltrate the extracellular space of the valves, atria and ventricles, as well as the perivascular spaces, resulting in biventricular wall thickening without ventricular dilation^[4]. As a result, atrial pressure increases, and atrial dilation occurs despite amyloid infiltration. Clinical features of cardiac amyloidosis include restrictive physiology, heart failure, dysrhythmias, and sudden cardiac death^[1,4,5]. In addition, there is evidence suggesting that the immunoglobulin free light chains are toxic to the myocardium^[6].

Patients with advanced heart failure due to AL have an extremely poor prognosis and often do not survive long enough to benefit from therapy for amyloidosis. Orthotopic heart transplantation (OHT) in AL has been limited due to the risk of disease progression in other organs and recurrence of amyloid deposition in the transplanted heart^[7,8]. Although earlier studies suggested inferior outcomes of OHT for compared with non-amyloid indications^[9,9], more recent reports have found survival similar to other forms of heart failure^[10]. Controversy regarding the role of OHT in AL remains^[11,12] and many centers consider amyloidosis to be a contraindication to OHT. The purpose of the current study was to determine the long term outcome and predictors of survival in a large single-center cohort of patients undergoing OHT for AL.

MATERIALS AND METHODS

Study population

Patients were identified from our institutional database of cardiac transplantation recipients. The diagnosis of amyloidosis was confirmed by demonstrating Congo red positivity in tissue samples. AL amyloid was confirmed by laser dissection mass spectrometry in all but two patients, who had typing performed by immunohistochemistry. During the period from May 31, 1992 to December 31, 2011, 3117 patients with

AL amyloidosis were seen at the Mayo Clinic. Twenty-one percent (668 patients) had overt congestive heart failure. One hundred and thirty-seven were referred for OHT evaluation, and 77 patients completed their evaluation for OHT. Of those completing the evaluation, 33 were deemed ineligible for OHT. Reasons for ineligibility included extensive amyloid in 29 and one instance of each of the following: Coexisting myeloma; coexisting lymphoma; improving cardiac status due to chemotherapy; and lack of financial approval. Forty-four patients (7% of patients with overt heart failure) completed evaluation and were listed for OHT, but only 23 were transplanted. Twenty-one were removed from the listing for the following reasons: Death ($n = 12$); further medical decline ($n = 5$); patient refusal ($n = 2$); myeloma ($n = 1$); and transplant elsewhere ($n = 1$). The median time to de-listing was 48 d (interquartile range 14, 111 d; range 0-341 d).

Throughout the 20-year period, all patients met at least one of the following at time of listing: New York Heart Association class IV heart failure, ventricular thickness > 15 mm, ejection fraction $< 40\%$. In 1998, additional selection guidelines were added: Age < 60 years; combination of the urine light chain, serum monoclonal protein and bone marrow plasmacytosis that does not infer the presence of multiple myeloma or related disorders including low bone marrow plasma cell labeling index; absence of renal involvement as defined by a 24-h urine total protein excretion of < 500 mg and creatinine clearance > 50 mL/min per square meter unless combined renal transplant planned; absence of liver involvement - if elevation of alkaline phosphatase was thought to be due to heart failure, liver biopsy was to be done to exclude interstitial amyloid deposits. The presence of vascular deposits in a biopsy of the rectum, fat or viscera was not an exclusionary criterion. Assignment of organ involvement was according to the consensus criteria from the 10th International Symposium on Amyloid and Amyloidosis^[13]. The modified body mass index (mBMI) was calculated as BMI multiplied by serum albumin level in gram per litre. For most patients the values used for listing and pre-operative BMI (and mBMI) were the same given the proximity of listing to OHT.

The autologous hematopoietic stem cell transplantation (AH SCT) protocol is as previously described, and 11 of the patients have been previously reported^[14]. Demographic, clinical and laboratory data were collected from the Mayo Clinic Transplant Center database, the Robert A Kyle Dysproteinemia database, and all medical records were reviewed. Because most of these patients were treated before era of the serum immunoglobulin free light chain assay, the ability to assign a hematologic response was limited. The determination of hematologic response was a hybrid of the two consensus guidelines. If patients had serum immunoglobulin free light chains measured ($n = 9$), then the 2012 consensus response criteria were applied^[15]; otherwise, the 10th consensus response criteria from the International Symposium

on Amyloid and Amyloidosis were applied^[13]. Two patients had measurable M-spikes, 8 had positive immunofixation of the serum or urine that could be followed, and 4 either had none of the aforementioned detected (or testing not performed prior to starting chemotherapy).

Immunosuppression

Post OHT, all patients received standard therapy for immunosuppression, according to our institutional protocol at the time of transplant. The first twenty-one patients received OKT3, cyclosporine, prednisone, and azathioprine or mycophenolate mofetil. A gradual taper of cyclosporine was done over the first year to baseline immunosuppression. Surveillance endomyocardial biopsies to monitor for rejection were used to help guide prednisone taper. The last two patients received prednisone, mycophenolate mofetil, and tacrolimus.

Statistical analysis

Medical records for the patients undergoing OHT for AL amyloidosis were reviewed. Survival from the time of OHT was calculated using Kaplan-Meier survival curves. Comparison of survival curves was done with the log-rank test. Baseline variables were tested for their impact on overall survival using Cox proportional modeling. The database was closed to follow up as of March 18, 2015. All statistics were calculated using JMP 10.0.0 (SAS, Cary, North Carolina).

RESULTS

Twenty-three patients with AL amyloidosis underwent OHT (Table 1). Fifty-two percent were female ($n = 12$), and all but two were Caucasian. Twenty-one patients had isolated cardiac involvement at baseline clinical evaluation; one patient (OHT#14) had mild peripheral nerve and gastrointestinal involvement, and one (OHT #15) had peripheral nerve involvement. Twenty-two patients had had a clonal lambda plasma cell disorder; one had a kappa clone. Three patients had renal transplantation, one simultaneous with the OHT and the others at 23 and 53 mo post OHT.

Twenty patients have died post OHT (Table 1 and Figure 1A). The baseline disease burden is outlined in Table 2. For the entire cohort, the median overall survival was 3.5 years (95%CI: 1.2, 8.2 years). The 1-year survival post OHT was 77%, the 2-year survival 65%, and the 5-year survival 43% (Figure 1A). Progressive amyloidosis contributed to death in twelve patients. Of those without evidence of progressive amyloidosis, the cause of death included post-AHSCT complications for 3 patients, post-transplant lymphoproliferative disorder for 2 patients; and for the remaining there was one death related to each of the following causes: Acute rejection; cardiac vasculopathy; metastatic melanoma; myelodysplastic syndrome; and unknown. Eight patients had rejection at a median of 1.8 mo post OHT (range 0.4 to 4.9 mo); only one patient died of rejection).

Table 1 Demographics and orthotopic heart transplantation outcomes

AL-OHT	M/F	Age at OHT	List to OHT (d)	Year OHT	PO FU (yr)	Major outcomes
8	F	52	62	1997	16.5	Alive, doing well
22	F	53	1160	2011	3.9	Alive, PTLD in remission, VGPR on bortezomib
23	M	58	13	2011	3.1	Alive, doing well
1	M	45	86	1992	14.1	Died, progressive amyloid; renal transplantation 53 mo post OHT
17	F	51	94	2003	10.8	Died, renal failure, debility; hematologic relapse and renal amyloid
9	M	56	16	1998	8.6	Died, metastatic melanoma
2	M	44	126	1993	8.4	Died, PTLD, sepsis, progressive amyloidosis
12	F	57	44	1999	8.2	Died, cardiogenic shock secondary to cardiac amyloid, required dialysis for renal amyloid post ASHCT#2
3	M	56	14	1994	7.5	Died, progressive amyloid
14	M	33	30	1999	6.3	Died, cardiac allograft vasculopathy
16	F	53	33	2000	5.4	Died, progressive GI amyloid and stroke; renal transplant 23 mo post-op
7	M	61	415	1997	3.5	Died, progressive amyloid autonomic and peripheral neuropathy
18	M	56	33	2004	3.1	Died, complications of myelodysplastic syndrome
5	F	47	68	1995	2.6	Died, PTLD, progressive multifocal leukoencephalopathy
10	F	54	5	1998	2.2	Died, progressive amyloid
19	M	62	18	2005	2.1	Died, progressive amyloid peripheral neuropathy and GI involvement, recurrent pneumonia
4	M	49	86	1994	1.2	Died, progressive amyloid
21	F	51	29	2007	1.2	Died, progressive GI amyloid, right heart failure, renal failure, steroid myopathy vs amyloid neuropathy
13	F	51	103	1999	0.9	Died, sepsis, multiorgan failure after AHSCT
11	F	48	31	1999	0.7	Died, disseminated fungal infection after AHSCT
15	F	60	33	1999	0.6	Died, progressive amyloid peripheral and autonomic neuropathy
20	F	52	33	2006	0.6	Died, progressive amyloid and overwhelming infection
6	M	56	99	1996	0.04	Died, refractory rejection; had combined renal and cardiac transplant

The first three rows are alive. IFE: Immunofixation of serum and/or urine; dFLC: Difference between involved and uninvolved immunoglobulin free light chains; Tx: Transplant; mBMI: Modified body mass index [albumin × weight/(height)²]; IVS: Interventricular septum; EF: Ejection fraction; BM PC: Bone marrow plasma cells; NA: Not available; IQR: Interquartile range.

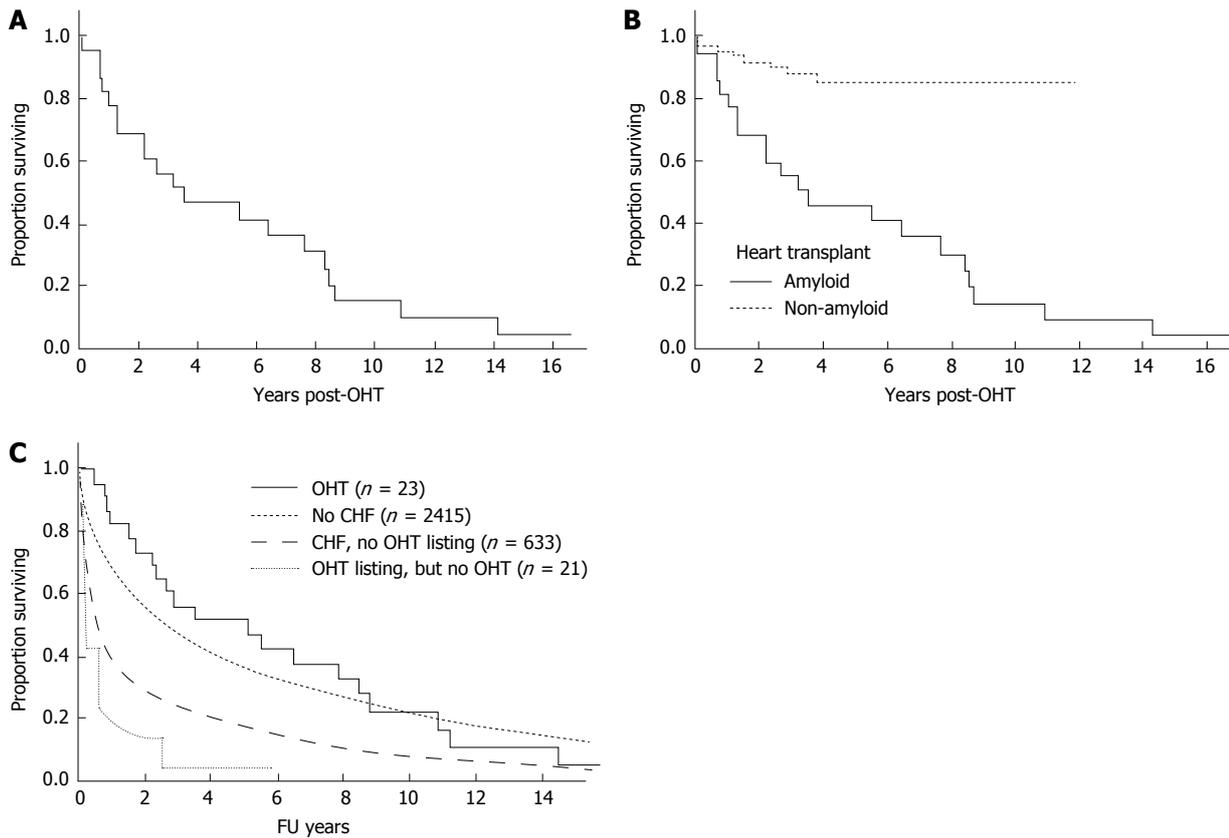

Figure 1 Overall survival. A: Overall survival from orthotopic heart transplant; B: Overall survival comparing OHT for AL amyloidosis to OHT from 1992 to 2011 for non-amyloid indications; C: Comparison of survival with non OHT subgroups. OHT: Orthotopic heart transplantation; CHF: Congestive heart failure; AL: Immunoglobulin light chain.

Figure 1B shows a comparison of this cohort to patients undergoing isolated OHT at our center for non-amyloid indications, where 1 year overall survival is $94.8\% \pm 2.1\%$ and 5-year survival $85.2\% \pm 4.4\%$. Given the small sample size, it is difficult to assess baseline factors that might predict for early death. Notably, no patient died within the immediate OHT peri-operative period. On univariate analysis none of the following factors were significant risk factors for poor overall survival: Age, gender, BMI or mBMI (at listing or at transplant), time from listing to OHT, serum creatinine, or bone marrow plasmacytosis.

Figure 1C shows the comparison of patients with AL who underwent OHT with AL patients without and with overt heart failure who did not undergo OHT, and with those who were listed but did undergo OHT.

Three patients had no therapy (chemotherapy or AHSCT) for amyloidosis and only four received treatment prior to OHT (Table 3). Reasons for no chemotherapy/AHSCT were: Inability to harvest stem cells for planned AHSCT; rejection two weeks after OHT; and death 7 mo after OHT. One patient received chemotherapy only prior to OHT, 4 received chemotherapy pre- and post-OHT, and 15 only post-OHT. The non-AHSCT first line therapies are shown in Table 3. Therapies beyond first line therapies included bortezomib, AHSCT, melphalan with corticosteroids, or an IMiD with dexamethasone; one patient received doxorubicin.

After their first line therapy, seven patients achieved a complete hematologic response (CR), 3 a very good partial response, 2 a partial response, and 11 remained immunofixation positive or were not assessed before death (Table 3). As shown in Figure 2A, patients achieving a CR fared much better than those who did not, achieving a median survival of 10.8 years.

Thirteen patients underwent AHSCT, performed at a median of 8 mo (range 3-24 mo) post OHT with one patient having a second AHSCT 82 mo post OHT. In two patients AHSCT was planned but could not be performed due to inability to harvest stem cells. The median survival of those undergoing AHSCT was 6.3 years (95%CI: 1.2, 8.6 years). Figure 2B demonstrates survival outcomes of those who received AHSCT vs those who did not. Among the patients who underwent AHSCT, 8 received full dose melphalan conditioning (200 mg/m^2), and 5 received attenuated doses. Two of the eight patients receiving full dose melphalan conditioning died within three years post AHSCT, and one is alive 33 mo at last follow-up. In contrast 3 of the 5 receiving attenuated melphalan conditioning died within 3-year post AHSCT. For the 2 who died within 100 d of AHSCT, the cause of death was disseminated fungal infection in one and sepsis leading to multi-organ failure in the other. Four of the AHSCT patients achieved a CR, 5 a very good partial response (PR) or PR, and 4 no significant response or not assessable.

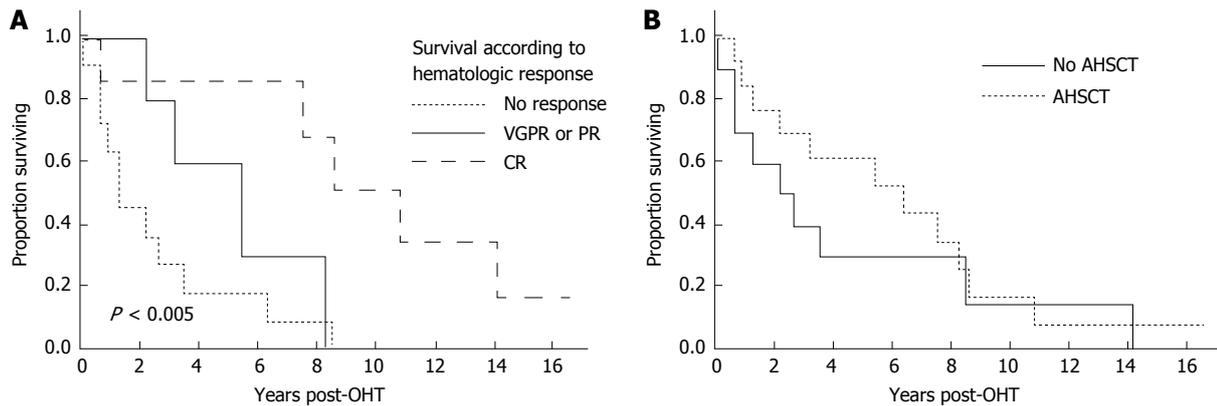

Figure 2 Influence of chemotherapy on overall survival. A: Overall survival (OS) based on hematologic response. The median OS for the 11 non-responders/non-evaluable patients was 1.2 years. The median OS for the 5 patients achieved VGPR or PR was 5.4 years. The median OS for the 7 patients achieving CR was 10.8 years; B: OS based on whether or not patient received AH SCT. The median OS for the 10 patients not undergoing AH SCT was 2.4 years; the median OS For the 13 patients undergoing AH SCT was 6.3 years. VGPR: Very good partial response; CR: Complete hematologic response; AH SCT: Autologous hematopoietic stem cell transplantation.

Table 3 Chemotherapy and response

AL-OHT	Rx relative to OHT	First amyloid directed therapy (Rx)	Response to 1 st Rx	Lines of Rx
8	Only Rx post-OHT	AH SCT ¹	CR	1
22	Rx pre- and post-OHT	Mel-Dex	CR	≥ 2
23	Rx pre- and post-OHT	Bortezomib-Dex ³	VGPR	≥ 2
1	Only Rx post-OHT	Mel-Pred	CR	≥ 2
17	Only Rx post-OHT	AH SCT ¹	CR	≥ 2
9	Only Rx post-OHT	AH SCT ¹	CR	≥ 2

¹Melphalan conditioning 200 mg/m²; ²Melphalan conditioning 140 mg/m² in all but OHT #12 who got 150 mg/m²; ³Patient had AH SCT as second line and received Melphalan conditioning 200 mg/m². Amyloid directed therapy: AH SCT: Autologous hematopoietic stem cell transplant; Mel: Oral melphalan; Pred: Prednisone; Bortez: Bortezomib; Dex: Dexamethasone; VBMCP: Vincristine, BCNU, melphalan, cytoxan, prednisone; NA: Not available; CR: Complete hematologic response; PR: Partial response; VGPR: Very good partial response; IFE: Immunofixation.

DISCUSSION

Given the limited supply of donor hearts, OHT in AL amyloidosis remains controversial due to the risk of recurrent amyloidosis in the graft or progression of other organ involvement. This long term follow-up study reports the largest single center experience of OHT in AL. Our results support the use of OHT in AL amyloidosis patients with predominant cardiac involvement and no evidence of myeloma, especially if they have achieved (or are able to achieve) a complete hematologic response.

Although the median overall survival of our cohort was only 3.5 years, those patients who achieved a complete hematologic response had a remarkably good overall median survival of more than 10 years.

Superior survival is reported in patients with AL amyloidosis and cardiac involvement who undergo OHT compared to patients who do not^[14,16]. In a report of 14 patients from the United Kingdom, median overall survival was 7.5 years from OHT; in 8 patients who underwent AH SCT and OHT, survival was increased to 9.7 years^[17]. These data are confounded by selection

Table 4 Orthotopic heart transplantation in patients with amyloidosis

Ref.	n	AHSCT	Outcomes
Current series	23	13	1-yr OS 77% 5-yr OS 43%
MGH ^[10]	18	14	5-yr OS 60%
United Kingdom 2004 ^[19]	17 ¹	3	1-yr 59% 5-yr approximately 37%
United Kingdom 2010 ^[17]	14 ¹	8	1-yr OS 86% 5-yr OS 45%
Spanish registry ^[28]	13	3	1-yr OS 43% 5-yr OS 36%
German group ^[29]	12	5	1-yr OS 83% 3-yr OS 83%
ISHLT Registry ^[8,30]	10 ²	None	1-yr 88% 4-yr 38%
Mauren ^[16]	10	8	1-yr 90%
Stanford ^[20]	9	5	1-yr 100%
French registry ^[31]	8	3	1-yr 89%

¹Unclear how much overlap between these two groups. Intervals for Dubrey series was 1982-2002 and for Sattianayagam series, interval was 1984-2004, but there was no reference of which patients had been previously reported; ²At least 8 were AL; unclear what other 2 were. ISHLT: International Society for Heart Transplant; OS: Overall survival; AHSCT: Autologous hematopoietic stem cell transplantation.

biases, but the fact remains that 30%-40% of patients with AL amyloidosis die within the first 6 mo of their diagnosis due to cardiac causes^[18] making consideration of aggressive strategies imperative.

Most series of heart transplantation in AL have reasonable 1-year survival rates (Table 4). In our study there was no perioperative mortality. The major causes of death in our and other series are infection and progressive amyloidosis. If performed without chemotherapeutic support, 5-year survival is just 20%^[19]. Improved survival rates have been seen in patients who undergo AHSCT, with 1- and 5-year survival of 82% and 65% respectively in our earlier report^[14]. Recent reports suggest improved short term outcomes with advances in chemotherapy and AHSCT, with the Stanford series reporting 1 year survival of 100%^[20].

In the MGH series of 18 AL patients undergoing OHT approximately 60% of patients were alive at 6 years^[10], and, in contrast to earlier studies^[8,9,21], was similar to that of non-amyloid patients. Although overall survival in our study was reduced compared with patients transplanted for non-amyloid indications, our series includes many early era patients who did not receive the benefit of current therapy for amyloidosis. Nevertheless, the long term survival of the patients in our series who achieved complete hematologic response was remarkably good.

Selecting patients with primarily cardiac involvement in AL is challenging. Subclinical extra-cardiac organ involvement may progress post heart transplant to clinically important disease. Perivascular intestinal amyloid is common and not viewed as a barrier to cardiac transplantation. However, in our experience, patients with significant mucosal intestinal involvement

do poorly and are often not able to tolerate aggressive treatment for AL. Clearly not all patients with cardiac involvement will require heart transplant; there are patients with significant cardiac involvement who can have cardiac improvement with effective chemotherapy alone^[22-25]. Perhaps cardiac biomarkers like ST-2 may lend insight to those with irreparable damage despite effective chemotherapy^[26].

"Better selection" also means choosing those patients in whom the underlying plasma cell clone can be controlled, since in our study and others effective chemotherapy has resulted in the best outcomes post-OHT^[10,16,20]. Most of the patients in our series did not receive chemotherapy prior to OHT because the only chemotherapies available at the time of their diagnosis were oral melphalan and prednisone and high dose melphalan with AHSCT. Newer treatment options^[27], especially bortezomib containing regimens, are less myelosuppressive, making pre-OHT therapy a possibility. Furthermore, the improvement in chemotherapeutic regimens makes hematologic response more likely in the current era.

Achieving a hematologic response pre-OHT is not a simple matter. Time is of the essence in these patients. In our experience and others, approximately 40% of AL patients listed do not undergo OHT either due to death or deterioration^[10]. This seems to be related to both delayed diagnosis, as well as inability to support these patients with traditional heart failure therapy and devices. In the MGH series, patients with amyloidosis had a mortality hazard ratio of 4.7 (95%CI: 2.8, 11.8) as compared to non-amyloidosis patients while on the waiting list^[10]. The only predictive factor of survival to OHT in that study was BMI - patients with lower BMI fared better than those with higher BMI, although this was not confirmed in our study.

The number of AL amyloid patients transplanted at our institution in recent years has declined. This reduction is multifactorial, and reflects patients receiving earlier and more effective bone marrow directed treatment, more rigorous selection, the availability of OHT for AL at other medical centers, and our own reluctance to offer OHT after some discouraging outcomes. However, the excellent long term survival in this study of patients achieving CR, coupled with markedly improved short term survival recently reported^[20] have prompted renewed enthusiasm for OHT in AL in highly selected patients.

We recognize that our study is limited by being a small series of highly selected patients, lacking currently available cardiac biomarkers and modern markers of clonal burden and access to current treatment regimens. Despite these limitations, in carefully selected patients, long term survival can be achieved. Moving forward the challenge will continue to be the selection of the appropriate patients. The patients likely to derive the most benefit are those who: (1) have plasma cells that are responsive to chemotherapy; (2) have clinically significant involvement of the heart only; and (3) are

not demonstrating significant cardiac response despite effective chemotherapy. The current lack of effective short term cardiac support and the rapidly progressive nature of AL cardiac amyloidosis warrant consideration of revised guidelines for organ allocation in these patients.

COMMENTS

Background

Cardiac involvement is present in approximately 50% of patients with immunoglobulin light chain (AL) amyloidosis and is associated with a dismal prognosis. Heart transplant for AL amyloid is controversial, due to concerns about amyloid deposition in the transplanted heart and the potential for increased morbidity and mortality from the underlying plasma cell disorder.

Research frontiers

The research goal was to review a single center experience with cardiac transplantation for AL amyloid and determine outcome.

Innovations and breakthroughs

This study demonstrates that long term survival is possible in highly selected patients with AL amyloid who undergo cardiac transplantation if the underlying plasma cell disorder can be controlled.

Applications

Patients with cardiac AL amyloid and limited extra cardiac involvement may be considered for cardiac transplantation. Long term survival is possible in those who achieve a complete hematologic response to chemotherapy or autologous stem cell transplantation.

Terminology

Immunoglobulin light chain AL is a plasma cell disorder which results in deposition of amyloid fibrils in the organs and tissues of the body. Autologous hematopoietic stem cell transplantation is a strategy to treat the underlying plasma cell disorder that causes AL amyloidosis.

Peer-review

The authors presented a good overview of patients with AL amyloidosis + advanced heart failure who received cardiac transplantation.

Abstract

AIM: To determine the incidence, etiology, risk factors and outcome of ventilator-associated pneumonia (VAP) in patients undergoing orthotopic liver transplantation (OLT).

METHODS: This retrospective study considered 242 patients undergoing deceased donor OLT. VAP was diagnosed according to clinical and microbiological criteria.

RESULTS: VAP occurred in 18 (7.4%) patients, with an incidence of 10 per 1000 d of mechanical ventilation (MV). Isolated bacterial etiologic agents were mainly *Enterobacteriaceae* (79%). Univariate logistic analysis showed that model for end-stage liver disease (MELD) score, pre-operative hospitalization, treatment with terlipressin, Child-Turcotte-Pugh score, days of MV and red cell transfusion were risk factors for VAP. Multivariate

analysis, considering significant risk factors in univariate analysis, demonstrated that pneumonia was strongly associated with terlipressin usage, pre-operative hospitalization, days of MV and red cell transfusion. Mortality rate was 22% in the VAP group *vs* 4% in the group without VAP.

CONCLUSION: Our data suggest that VAP is an important cause of nosocomial infection during post-operative period in OLT patients. MELD score was a significant risk factor in univariate analysis. Multiple transfusions, treatment with terlipressin, preoperative hospitalization rather than called to the hospital while at home and days of MV constitute important risk factors for VAP development.

Core tip: Ventilator associated pneumonia (VAP) is a serious perioperative complication in liver transplant recipients, and its etiology and risk factors are still poorly understood. Therefore, we conducted this retrospective study in a big sample of patients to evaluate the incidence, risk factors, etiological agents and outcome of VAP considering 242 consecutive liver transplant recipients. VAP occurred with an incidence of 10 per 1000 d of mechanical ventilation (MV). Multivariate analysis demonstrated that VAP was strongly associated with terlipressin usage, pre-operative hospitalization, days of MV and red cell transfusion. Mortality rate was 22% in the VAP group *vs* 4% in the group without VAP.

Siniscalchi A, Aurini L, Benini B, Gamberini L, Nava S, Viale P, Faenza S. Ventilator associated pneumonia following liver transplantation: Etiology, risk factors and outcome. *World J Transplant* 2016; 6(2): 389-395 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i2/389.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i2.389>

INTRODUCTION

Ventilator-associated pneumonia (VAP) is the main hospital acquired infection in intensive care unit (ICU) and correlates with increased duration of mechanical ventilation (MV), length of ICU and hospital stay, and healthcare costs^[1]. The reported rates vary significantly depending on the population, the specific ICU, the preventive strategies and the definition^[2].

Liver recipients have high risk for prolonged post-operative MV due to multiple causes: Slow resolution of hepatic encephalopathy, muscle atrophy caused by pre-transplant poor nutrition and postoperative diaphragmatic dysfunction related to upper abdominal

surgery.

The risk of pneumonia may be increased because of the presence of alveolar oedema and pleural effusion, as a consequence of low serum protein concentration, large amount of blood product transfusions, immunosuppression and pre-existing risk factors like cardiac or renal failure.

The reperfusion damage has an important role in delaying extubation, which seems to be caused by the increased tumor necrosis factor (TNF) release from Kupffer cells. TNF leads to a histological damage in liver and lung tissue and could be a cause of alveolar oedema, haemorrhage and leukocyte invasion of the parenchyma.

Our study aimed to determine the incidence, etiology, risk factors and outcome of VAP in patients receiving orthotopic liver transplantation (OLT) from a deceased donor.

MATERIALS AND METHODS

Study design

After institutional review board approval, this retrospective study involved the patients who were admitted to our liver transplantation center from December 2006 to December 2010 and survived for at least 48 h. All patients had a diagnosis of end stage liver disease (ESLD) and underwent deceased donor OLT at the Transplantation Center of St. Orsola-Malpighi Policlinic in Bologna.

ESLD referred to the 4th stage or cirrhosis and was defined as the development of either a first major clinical complication of cirrhosis (variceal bleeding, ascites, jaundice, encephalopathy or spontaneous bacterial peritonitis) or hepatocellular carcinoma (HCC)^[3]. Clinical evaluation of those patients used the model for end-stage liver disease (MELD) score reporting the value of the day of the transplantation.

The exclusion criteria were acute liver failure, simultaneous kidney/liver or liver/heart transplantation.

We analyzed the incidence, etiology, risk factors and impact of VAP on clinical outcome. All patients were evaluated, at the moment of the admission, to confirm the absence of pneumonia. Patients were followed until hospital discharge or death.

Definitions

The suspicion of VAP was based on clinical criteria (new or progressive radiological pulmonary infiltrates plus two or more of the following: Temperature > 38.3 °C or < 36 °C, leukocyte count > 10 × 10⁹/L or < 4 × 10⁹/L and purulent respiratory secretions)^[4] appearing 48-72 h post intubation and initiation of MV.

A microbiologic strategy was then followed for diagnosis: Microbiologic lower respiratory tract samples were obtained with bronchoalveolar lavage (BAL) or endotracheal aspirate.

VAP diagnosis was defined in case of positive results

Table 1 Etiologic agents of ventilator-associated pneumonia

Microorganism	Total (n = 18)
<i>Klebsiella pneumoniae</i>	5/18 (28%)
<i>Escherichia coli</i>	5/18 (28%)
<i>Klebsiella oxytoca</i>	2/18 (11%)
<i>Enterobacter</i> spp.	1/18 (6%)
<i>Citrobacter</i> spp.	1/18 (6%)
<i>Pseudomonas aeruginosa</i>	8/18 (44%)
<i>Staphylococcus aureus</i>	4/18 (22%)
<i>Corynebacterium striatum</i>	4/18 (22%)
<i>Xantomonas</i> spp.	2/18 (11%)
<i>Acinetobacter</i> spp.	2/18 (11%)

The *Enterobacteriaceae* are written in bold. Note that in some patients more than one microorganism was found.

of quantitative culture of specimens from BAL or tracheoaspirate with protected brush (considering a threshold of 1×10^5 cfu/mL in a BAL fluid specimen, and 1×10^6 cfu/mL in an endotracheal aspirate specimen^[5].

Postoperative management

Immunosuppressive induction was achieved by administering 1 g of methylprednisolone at the time of reperfusion; the immunosuppressive regimen consisted of a combination of calcineurin-inhibitor and prednisone.

Postoperative interventions according to the European guidelines since 2002^[6] for VAP prevention consisted of semi-recumbent patient positioning, sedation resolution and use of a weaning protocol, strict hand hygiene, non-invasive ventilation, oral care with chlorhexidine, no ventilatory circuit tube changes unless specifically indicated, appropriately educated and trained staff, cuff pressure control every 24 h, enteral feeding, use of heat moisture exchangers and unit-specific microbiological surveillance.

Data collection

Pre-operative, intra-operative and post-operative data were recorded.

Preoperative data included age, weight, height, body mass index (kg/m²), body surface (m²), etiology of cirrhosis, presence of HCC at pre-operative investigation, MELD score at the transplantation day, Child-Turcotte-Pugh (CTP) score, serum bilirubin (mg/dL), serum creatinine (mg/dL), international normalized ratio, glycated haemoglobin (%), serum urea (mg/dL), serum glucose (mg/dL), serum albumin (g/dL), transjugular intrahepatic portosystemic shunt presence, ongoing therapy with diuretics, and terlipressin (instead of its indications as the clinical and laboratoristic parameters are included in other scores) at the time of transplantation, patient preoperative hospital stay rather than called to the hospital while at home.

Intra-operative data included length of surgery, anhepatic phase duration, number of packed red blood cells (RBC), fresh frozen plasma and platelets transfusions (units), duration of cold ischemia (h),

vasopressors usage in pre and post-reperfusion phase, donor age and gender. Quality of liver allograft was classified on the basis of Donor risk index (DRI)^[7] as low risk (DRI < 1.8) or high risk graft (DRI > 1.8)^[8].

Postoperative data considered: VAP incidence and etiology, duration of MV, time between intubation and VAP clinical manifestation, length of ICU stay and hospital mortality.

Statistical analysis

Statistical analyses were performed with SPSS 16.00. Continuous data are expressed as medians (25-75 interquartile range) while discrete data are represented by numerosity and relative frequencies. Patients were divided into two subgroups on the basis of presence or absence of VAP. Incidence of VAP is reported as episodes per 1000 d of MV. Differences between groups were assessed using χ^2 test or Fisher exact test for categorical variables and student's *t*-test or Mann-Whitney test for continuous variables. Variables which were significantly different between the two groups were individually analyzed with a univariate logistic regression model, considering VAP insurgence the dependent variable. Predictor variables found in univariate analysis were included into a multivariate logistic regression model using the Enter method, considering VAP insurgence the dependent variable. Results are expressed as hazard ratios, and *P* values with 95% CIs.

RESULTS

During the study period from 2006 to 2010, 284 patients underwent OLT at the Transplant Center of St. Orsola-Malpighi Hospital. Forty-two patients were not included in the analysis because they had: Combined liver/kidney or liver/heart transplantation (29 cases), transplantation for acute liver failure (6 cases) and other causes without concomitant cirrhosis (7 cases). The final analysis considered 242 patients with ESLD related to histologically proven liver cirrhosis.

Microbiologically confirmed VAP occurred in 18 (7.4%) patients, with an incidence of 10 episodes per 1000 d of MV, and none of these patients presented any criteria of pneumonia, from the in-hospital admission to the time of transplantation. The 18 patients received a diagnosis of VAP after positive BAL culture, and all of them were extubated within 48 h since pneumonia detection.

Isolated microbes belonged mainly to the group of *Enterobacteriaceae* (79%, 14 patients), including *Klebsiella pneumoniae*, *Escherichia coli*, *Klebsiella oxytoca*, *Enterobacter* spp. and *Citrobacter* spp. The remaining bacterial etiologic agents were represented by *Pseudomonas aeruginosa* (*P. aeruginosa*) and *Staphylococcus aureus* (*S. aureus*) (Table 1).

We observed that 25% of VAP episodes involved more than one microorganism.

VAP: Ventilator-associated pneumonia.

general preoperative, intraoperative and postoperative characteristics are reported in Table 2 and the donor variables in Table 3.

Significant differences in MELD score were observed between the two groups; VAP patients had a mean MELD score of 23 vs 20 of control patients. Treatment with terlipressin was associated with a higher risk of pneumonia (39% of VAP episodes receiving terlipressin vs 5.8% in the control group).

Intraoperative data (Table 2) showed statistically significant differences between the two groups in red cell transfusion (red cell transfusion refers to the large amount of red cell transfusion): A median of 16 units per patient in the VAP group vs 7 in controls. Postoperative data (Table 2) showed that ICU stay of VAP patients was significantly longer (16 d vs 5 d) and was associated with a higher hospital mortality (22% of VAP patients died vs 4% of controls). VAP was

Table 4 Variables associated with ventilator-associated pneumonia in multivariate analysis

Variable	OR	95%CI	P-value
MELD score	0.98	0.8-10	0.670

MV (d)	1.10	1.03-1.15	< 0.001
Terlipressin therapy	31.49	4.7-49.2	< 0.001
Preoperative hospital stay (d)	1.8	1-1.9	< 0.05

Statistical significance was defined as $P < 0.05$. MELD: Model for end-stage liver disease; CTP: Child-Turcotte-Pugh; RBC: Packed red blood cells; MV: Mechanical ventilation.

documented after a median of 72 h post intubation. Median intubation duration among all studied patients was 0.42 d, patients without VAP required a median of 0.38 (0.208-0.864) d of MV, while VAP patients required a median MV duration of 1.13 (0.375-11.75) d. This interval ran from the first intubation to the extubation or need for reintubation. The time from the second intubation to the extubation/exitus was not considered in the study.

Univariate logistic regression analysis found that MELD score, treatment with terlipressin, CTP score, days of MV, preoperative hospitalization and red cell transfusion were significantly associated with VAP (data not shown).

The multivariate logistic regression model constructed considering the variables which resulted significantly associated with VAP in univariate analysis resulted in a significantly increased risk of VAP for terlipressin use, red cell transfusion, duration of MV and preoperative hospitalization (Table 4).

DISCUSSION

It has been reported that the rate of VAP is usually 1 to 3% per day of intubation and MV and the rates of pneumonia are increased 6- to 21-fold for intubated patients and show a further rise with the duration of MV. It has been estimated that the overall rates are most commonly 10 to 15 cases per 1000 ventilator days for ICU patients, depending on the population studied. The National Nosocomial Infections Surveillance System reports a median occurrence of VAP of 4.6 -5.1 for 1000 ventilator days either in medical or surgical ICUs. Also, rates are generally higher in surgical ICU patients than in medical ICU patients^[9,10].

Data about the incidence of VAP in OLT patients are poor and highly variable, the incidence rates range from 5% to 48% and the rates of the VAP-related mortality from 36% to 53%^[11]. A recent monocentric Italian study was not able to detect increased frequency of VAP in a small population of OLT patients compared to a control group of non-OLT patients admitted to the same surgical ICU^[12]. Another study^[13] on the infections after OLT reported the occurrence of VAP in 17.5% of their

samples.

Our results show a higher incidence of VAP than previous results from similar patients. We have to underline that our patients presented a higher MELD score (mean values 20-23) than those considered in other studies (mean values 14-15), which could reflect worse general preoperative conditions predisposing to infections, although the mortality rate was comparable (22%).

As stated before, MELD score has already been associated with postoperative complications, and this association is concordant with the correlation between MELD score and the seriousness of the post-operative complications^[9].

The early identification of clinical predictors of severe prognosis, *i.e.*, the MELD score, could help to identify patients at major risk and to take appropriate measures, earlier intensive treatment and several strategies including the use of non-invasive ventilation when possible to reduce the rate of VAP^[14,15].

The quality of the liver graft, which has an important role in determining prognosis of transplanted organs, does not seem to play a role in early infectious complications like VAP. In fact, high risk grafts were equally distributed in the two groups, and this result has been corroborated in the literature^[11].

The microorganisms associated with VAP vary widely depending on the characteristics of the patients, the different ICUs and the length of in-hospital stay. Common pathogens include *Enterobacteriaceae*, *P. aeruginosa* and *S. aureus*^[16]. In our series, the microorganisms associated with VAP, after liver transplantation, are not different from those in non-OLT patients in ICU^[17]. The *Enterobacteriaceae* predominated over *P. aeruginosa* and *S. aureus*.

Our study confirmed previous finding that multiple blood transfusions were associated with VAP insurgence. This is because longer duration of significant bleeding during OLT may lead to more alveolo-capillary membrane damage and prolonged postoperative intubation.

Our study shows that patients receiving terlipressin for hepatorenal syndrome had an odds ratio of 31.49 times higher for VAP, in the multivariate analysis. Further studies may investigate if hepatorenal syndrome (HRS) or its treatment with terlipressin is the effective risk factor for VAP. That is a limitation of the current study. Terlipressin therapy for HRS requires hospital admission and this could influence the outcome, but it has a notorious detrimental effect on splanchnic microcirculation. We suppose that the vasoconstricting action could damage intestinal barrier and foster bacterial migration through haematic and lymphatic circulation to pulmonary parenchyma, and this mechanism could also explain the high incidence of *Enterobacteriaceae* among etiologic agents in our case series. Westphal *et al*^[17] showed in an animal study that terlipressin treatment induced important alterations in pulmonary circulation, decreased cardiac index, and

diminished systemic oxygen delivery and consumption.

Despite the mentioned results, this study presents some limitations. We reported a low number of pneumonia cases due to its globally low incidence and the limited sample size, since our data came from a single center.

In conclusion, this study was designed to investigate the incidence, the risk factors and the outcome of VAP after OLT. Incidence has been estimated to be 10 per 1000 d of MV. Our study confirms some of the risk factors for VAP found in other studies: RBC transfusion, duration of MV and preoperative hospitalization rather than direct admission from home. MELD score is higher in the VAP group and it represents a significant risk factor in univariate analysis, reflects worse general conditions and prospects higher postoperative complications. The adoption of MELD score could rationalize VAP prevention practice in patients at major risk, earlier intensive treatment to increase the ventilator-free days and several strategies including the use of non-invasive ventilation. Among the risk factors, we found the therapy with terlipressin, used for the treatment of hepatorenal syndrome. This drug exhibited, in animal models, some effects on pulmonary circulation and has a detrimental effect on splanchnic blood flow that could contribute to bacterial migration. Also hepatorenal syndrome could have contributed to this effect. Further studies are needed to clarify this correlation.

COMMENTS

Background

Patients undergoing orthotopic liver transplant (OLT) represent a special subpopulation at risk for nosocomial infections, in particular ventilator-associated pneumonia (VAP) is the main hospital acquired infection in intensive care unit and it is a serious perioperative complication in liver transplant recipients.

Research frontiers

VAP's etiology and risk factors are still poorly understood.

Innovations and breakthroughs

The authors conducted this retrospective study in a big (considering the peculiar population) sample of patients, 242 consecutive liver transplant recipients. Of course, none of the patients who developed VAP presented signs or symptoms of infection before liver transplantation. Model for end-stage liver disease score was a significant risk factor in univariate analysis, and probably it reflects worse general conditions. In multivariate analysis the authors found a statistically significant association with terlipressin therapy. Patients who were taking terlipressin received the last dose until the OLT to treat the hepatorenal syndrome that could be a risk factor by itself. The authors did not refer to clinical and laboratory parameters as they are included in other scores. Some patients received other vasopressors during the OLT, but there were no statistically significant differences between the two groups. As the authors remarked in the discussion, further studies are needed to clarify this finding.

Applications

The application of the authors' results aims to individualize patients at major risk, to apply earlier intensive treatment and several strategies to prevent VAP.

Peer-review

The authors performed a study on a very important infectious complication in

post-operative OLT setting. The paper is well written and the aim is clear.

Abstract

AIM: To examine the results of orthotopic liver transplantation (OLT) for hepatocellular carcinoma (HCC) in Ireland over a 14-year period.

METHODS: Cases of HCC receiving OLT between January 1995 and September 2009 in the Irish Liver Transplant Unit were reviewed from a prospectively maintained database. Outcome measures included overall and recurrence free survival, alpha-fetoprotein (AFP) and tumour pathological features.

RESULTS: On explant pathology, 57 patients had HCC. The median follow-up time was 42.7 mo. The overall 1, 3 and 5 years survival was 87.7%, 72.1% and 72.4%. There was no difference in survival when compared

to patients undergoing OLT without malignancy. The tumour recurrence rate was 14%. The Milan criteria were exceeded in 32% of cases but this did not predict overall survival or recurrence. On multivariate analysis pre-operative AFP > 100 ng/mL was an independent risk factor for recurrence (RR = 5.2, CI: 1.1-24.3, $P = 0.036$).

CONCLUSION: Patients undergoing OLT for HCC had excellent survival even when conventional listing criteria were exceeded. Pre-operative AFP predicts recurrence independent of tumour size and its role in selection criteria should be investigated in larger studies.

Core tip: We have shown good survival from a medium volume transplant centre in a small cohort of patients exceeding Milan criteria. We show an association between a pre-operative alpha-fetoprotein (AFP) > 100 and hepatocellular carcinoma (HCC) recurrence, independent of tumour size. Our study supports other single centre experience on survival after transplant for HCC with low AFP and indicates that AFP needs to be interrogated in large, multi-centre studies to see if it can be included in transplant listing criteria to augment the current radiology based dimensional criteria.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the 5th most common cancer and 3rd leading cause of cancer-related death worldwide^[1]. The incidence and related mortality are increasing, particularly in Western countries^[2]. It is now well accepted that the optimal treatment for small HCC in the setting of cirrhosis is orthotopic liver transplantation (OLT)^[3]. Since the publication and adaptation of the Milan criteria^[4] the outcomes have improved dramatically compared to results from the era prior to established selection criteria^[5]. Patients undergoing OLT for HCC within the Milan criteria achieve outcomes comparable to non-malignant transplant cohorts. However, recurrence is the most important cause of post-transplant death^[6]. Appropriate patient selection is crucial as patients with large or biologically

unfavourable tumours have unacceptable recurrence and overall survival rates^[7]. It is essential that centres which provide OLT for HCC audit their results to ensure outcomes compare to international survival rates thus enabling appropriate patient prioritisation and organ allocation.

The aim of the current study was to determine the outcomes of OLT for HCC in a single, national institution over a 14-year period. Overall and recurrence free survival rates were compared to clinical and pathological factors using multivariate analysis to identify independent predictors of recurrence.

MATERIALS AND METHODS

All patients undergoing OLT with HCC proven on explant pathology between January 1995 and September 2009 were included in the study. All OLT in the Republic of Ireland are carried out in the Liver Unit of St Vincent's University Hospital. The Liver Unit maintains a prospective database containing patients' clinical details. Tumour characteristics are recorded on a computerised pathology database. A retrospective review of this data was performed. Patient characteristics recorded included age at OLT, sex, aetiology of underlying liver disease, pre-operative alpha-fetoprotein (AFP), survival, and recurrence status. Tumour data recorded included size and number of tumours, compliance with the Milan and University of California San Francisco (UCSF) criteria and microvascular invasion. The study was approved by the St Vincent's University Hospital ethics review board.

Patient selection and transplant protocol

All patients listed were classified clinically as cirrhotic. HCC diagnosis was based on a combination of ultrasound, computed tomography (CT) and double-contrast magnetic resonance imaging (MRI). After 1996 patients were listed for OLT if they met Milan criteria on pre-operative imaging. Patients in Ireland listed for OLT for HCC receive an adjusted Model for End-Stage Liver Disease (MELD) score^[8]. All OLT were from deceased donor transplants and organs were retrieved before cardiac death. Patients were followed up at a dedicated transplant clinic every three months. In general, post-transplant immunosuppression consisted of a reducing dose of corticosteroids and a calcineurin inhibitor (tacrolimus) or azothioprine. Follow up included annual abdominal ultrasound and CT where appropriate.

Survival and recurrence

Overall patient survival was determined from date of OLT until the most recently attended clinic. HCC recurrence free survival was determined by the date of the most recently available radiological imaging. Deaths from recurrence were prospectively recorded in the database. Patients without recurrence that died were documented free of recurrence only if the most recent available imaging or post-mortem report excluded recurrence. Two investigators (O'Connor DB

and Cooney A) independently reviewed the database to ensure accuracy of the survival and recurrence data. Patients were censored in September 2009 to ensure a minimum of 5-year follow-up.

Tumour characteristics

All explants were examined by a histopathologist experienced in HCC pathology (Nolan N). Tumour size, number of lesions, presence of macro or microvascular invasion, and condition of the non-tumour bearing liver were recorded. Tumours were graded as well, moderate or poorly differentiated. Compliance with Milan or UCSF criteria was based on size and number of lesions and was determined by explant pathology rather than pre-operative imaging.

Statistical analysis

Patients were divided into groups based on meeting or exceeding listing criteria, presence or absence of vascular invasion, tumour grade, and pre-operative AFP levels to determine impact on overall overall and recurrence free survival. Data is presented as median (interquartile range). Factors affecting survival were determined by a Cox Proportional Hazard Model and significant factors were incorporated into a multivariate analysis. Kaplan-Meier analysis and the log-rank test were used to illustrate differences between recurrence free and overall survival according to clinical factors. Comparisons between the HCC and control cohort were

made using Fisher's Exact test. All calculations were done using SPSS version 12.0 (SPSS, Inc., Chicago, IL). $P < 0.050$ was set as the threshold for statistical significance.

RESULTS

During the 14-year study period 57 patients underwent OLT for HCC confirmed on explant pathology. One patient received OLT in 1995 and 56 patients were transplanted between 1998 and 2009. This represented 11.3% of the 504 patients undergoing OLT in the Liver Unit during that time. HCC was diagnosed radiologically in 52 cases pre-operatively and 5 cases were incidental findings in cirrhotic patients. HCC was absent on explant pathology in 4 additional patients transplanted for presumed HCC, representing false positives who were excluded from the analysis. Pre-operative AFP, tumour histopathology and clinical follow up data were available for all 57 patients. Median follow up was 42.7 (14.6-67.6) mo.

The median age at OLT was 59 years. The most common underlying causes of cirrhosis were alcoholic liver disease (30%), hepatitis C (30%) and Haemochromatosis (23%). The Milan criteria were exceeded in 16 (28%) and 8 patients (14%) exceeded UCSF criteria. Median largest tumour size was 3 (2.5-4.5) cm. Micro-vascular invasion was present in 24 (42%) tumours. The mean time to OLT following diagnosis was 3 mo. Bridging therapy was not routinely used. Only 4 patients underwent trans-arterial chemo-embolization and this was not included in statistical analysis. Patient and tumour characteristics are outlined in Table 1.

Survival

Overall survival at 1, 3 and 5 years was 87.7% (50/57), 72.1% (31/43) and 72.4% (21/29) respectively. The HCC transplant group were compared to a cohort of 313 patients undergoing OLT between 1998 and 2008 who underwent their primary, non-emergent, transplant during that period. There was no statistical difference between the HCC and control cohort in 1 (87.7% vs 89.1%, $P = 0.450$), 3 (72.1% vs 84.2%, $P = 0.050$) and 5 years (72.4% vs 80.9%, $P = 0.211$) overall survival rates. No clinical or pathological variable significantly affected overall survival in those undergoing OLT for HCC (Table 2). Overall survival was not affected by patients exceeding the Milan (Figure 1A) or UCSF (Figure 1B).

Recurrence

Recurrence free survival was 86%, 69.7% and 69.5% at 1, 3 and 5 years respectively. There were 8 recurrences in total (14%) and 5 patients died from recurrence. Recurrence occurred within 1 year in 3 patients, within 2 years in 3 and beyond 3 and 5 years in one patient each. The location of recurrent disease was hepatic in 3 (including 2 patients with additional

HCC: Hepatocellular carcinoma; UCSF: University of California San Francisco.

extra-hepatic metastases), porta-hepatis lymph nodes in 2, and in one patient multiple recurrence occurred in lung, omentum and sacrum. Hepatic recurrences were diagnosed on CT and extra hepatic disease was confirmed by biopsy. Recurrence free survival was similar between patients meeting or exceeding the Milan (Figure 1C) and the UCSF criteria (Figure 1D). Underlying liver disease, tumour size or vascular invasion did not affect recurrence free survival. On univariate analysis only poorly differentiated tumours and AFP levels > 100 ng/mL were associated with reduced disease free survival (Table 3) and a shorter time to recurrence (Figure 2). On multivariate analysis, pre-operative AFP > 100 ng/mL remained an independent predictor of recurrence free survival (HR = 5.2, $P = 0.036$).

Patients exceeding Milan and UCSF criteria

Eight patients exceeded both Milan and UCSF criteria. Five were alive at 5 years and one patient with recurrence was alive after 3 years follow-up. Recurrence only occurred in 2 cases. One patient died from recurrence after 14 mo and one died from a separate malignancy at 2 years. Micro-vascular invasion was present in 4 cases. AFP exceeded 100 ng/mL in the patient who died from recurrence.

DISCUSSION

The current study confirms that OLT for HCC is an effective treatment modality and that survival rates are comparable to those undergoing OLT for non-malignant disease. Patients exceeding the Milan or UCSF criteria were not at increased risk of reduced overall survival or increased recurrence. Pre-operative serum AFP is an

HCC: Hepatocellular carcinoma; UCSF: University of California San Francisco.

independent risk factor for recurrence.

The landmark Milan publication in 1996 established listing criteria based on a single HCC of less than 5 cm or up to 3 tumours, each less than 3 cm^[4]. This was validated in other single-centre studies and together demonstrated a 5-year survival of 70% and recurrence rates of less than 15% which became the gold standard outcome in OLT for HCC^[9-11]. These criteria continue to be used in Ireland and many centres worldwide. Our institution is a medium volume centre performing approximately 60-70 OLT per year. The outcomes of our patient cohort compare favourably to recently published series' from higher volume centres^[12,13]. Our patient demographic is different to most centres as in over 50% of patients the underlying liver pathology was alcoholic liver disease or haemochromatosis. Worldwide, the main causes of HCC are hepatitis B and C virus but in this study they only accounted for 33% of HCC^[14]. However aetiology of HCC did not significantly impact on overall or disease free survival.

The majority of patients with HCC present with disease beyond the Milan criteria^[15]. Acceptable 5-year survival and recurrence rates observed in a subgroup of patients with larger tumours led to the publication of the UCSF criteria which proposes listing patients with a single tumour up to 6.5 cm or up to 3 lesions, none larger than 4.5 cm and total tumour burden not exceeding 8 cm^[16]. This has been reproduced in single-centre studies with short follow up but never in multi-centre or nationwide population studies but in recent years several units have called for an extension of the criteria. Patients beyond the Milan criteria did not experience inferior survival in our centre but our numbers are too small to support calls for extension of the criteria based simply

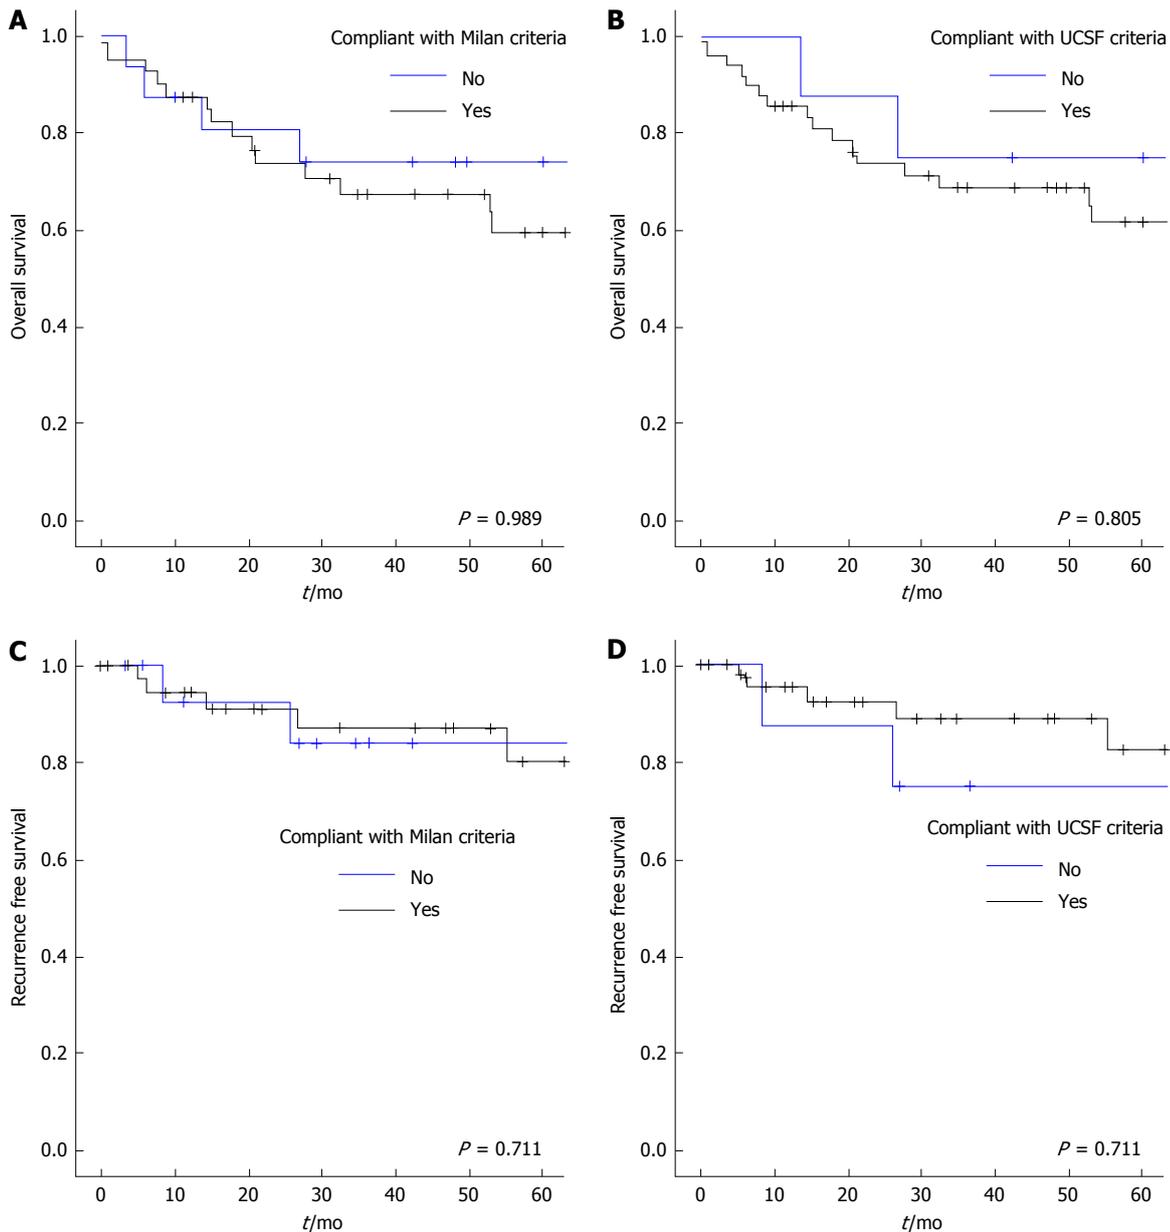

Figure 1 Kaplan-Meier estimates of overall survival (A and B) and recurrence free survival (C and D) in relation to compliance with the Milan and University of California San Francisco criteria. UCSF: University of California San Francisco.

on size and number of tumours. The limitations of pre-operative imaging for staging in the setting of cirrhosis also impede raising the threshold. One large study showed pre-operative imaging to under stage over 40% of patients^[17]. In the current study almost 30% were not compliant with Milan criteria on explant pathology. Interval tumour growth is a possible explanation for patients who meet criteria on imaging and then exceed them on pathology. However our cohort experienced a short waiting period of 3 mo and relatively small tumours (median 3 cm) which makes tumour doubling unlikely. Even with advances such as double-contrast MRI, extending the criteria based solely on size risks transplanting patients with tumours too large to benefit.

The limitation of established criteria is that they are based on tumour dimensions. While results from single

centre studies have justified its use for organ allocation, in a North American population study, a subgroup of patients with larger tumours within the Milan criteria had significantly poorer survival outcomes than those without HCC^[18]. It is imperative that any selection criteria be accurate in predicting prognosis to justify the large proportion of transplants undertaken for HCC in the setting of a shortage of organs. For example 25% of all United States OLT have been for HCC since the introduction of priority MELD scores for HCC in 2002^[18] and 11% of OLT in Ireland are for patients with HCC.

There is growing evidence that the biological behaviour of the tumour rather than size dictates recurrence. Patients with larger tumours beyond the Milan criteria but without micro-vascular invasion can have excellent survival, such as outlined in the “up-to-seven-criteria”,

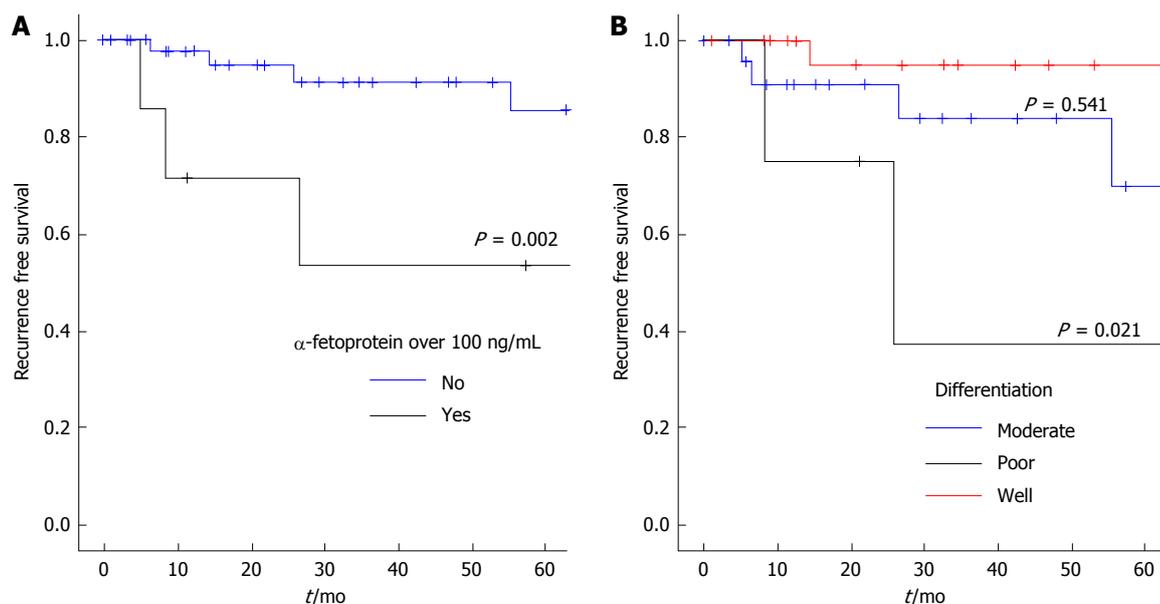

Figure 2 Kaplan-Meier estimates of recurrence free survival in relation to pre-operative α -fetoprotein (A) and tumour differentiation (B).

but this cannot be diagnosed pre-operatively^[19]. The impact of micro-vascular invasion was not found to be statistically significant in our cohort but in large studies it has been shown to double the risk of death^[7]. Pre-operative AFP may be the best available surrogate marker for micro-vascular invasion and the biological aggressiveness of the tumour. Several studies have identified a high pre-operative AFP as a risk factor for recurrence and reduced survival^[18,20-22]. We have shown AFP predicted reduced disease free survival, independent of both tumour size and micro-vascular invasion. Furthermore, patients exceeding Milan or even UCSF criteria experienced excellent overall and recurrence free survival with a pre-operative AFP < 100 ng/mL. This supports the finding of another group where an AFP level < 30 ng/mL predicted disease free survival in patients beyond Milan criteria^[23]. Both studies are limited by the small number of patients exceeding Milan criteria. Recent large studies have not examined the impact of AFP in the context of tumours beyond the Milan criteria. The largest study reporting survival in patients with tumours exceeding the Milan criteria (1112 patients) unfortunately did not examine the impact of AFP level^[7]. Analysis from the United Network for Organ Sharing on 2253 patients demonstrated a significant survival advantage in patients with low pre-transplant AFP (< 20 ng/mL) but this effect wasn't explored in patients with tumours outside Milan criteria^[24]. It would therefore be intriguing if AFP could be examined in a large population database or multicentre study to determine if patients with large tumours but low pre-operative AFP had higher survival rates. Only then can AFP be used to augment existing eligibility criteria to safely expand the pool of patients suitable for OLT.

In conclusion, in appropriately selected patients with HCC undergoing OLT, survival was comparable to non-HCC patients. A subgroup of patients with larger

tumours and low AFP may benefit from OLT but this association should be examined in larger, multicentre studies.

COMMENTS

Background

Orthotopic liver transplantation (OLT) is the most effective treatment for hepatocellular carcinoma (HCC) in the setting of cirrhosis. Survival in well selected patients with a small burden of tumour is similar to patients undergoing OLT for non-cancer related indications.

Research frontiers

Existing selection criteria are based on the size and number of the tumour. Several datasets have demonstrated good survival outcomes in patients exceeding these criteria. The biological characteristics, for example micro-vascular invasion may just as important as the tumour dimensions. However these cannot be reliably detected pre-operatively.

Innovations and breakthroughs

This study also demonstrates that patients with larger tumours can still have good survival outcomes. Pre-operative alpha-fetoprotein (AFP) predicted tumour recurrence. AFP may be a useful surrogate marker for less favourable biological characteristics of the tumour.

Applications

The prognostic value of AFP could be evaluated in large, multi-centre datasets to determine its potential as an adjunct to existing selection criteria.

Terminology

OLT: Orthotopic liver transplant involves fully explanting the diseased liver immediately prior to the transplant; HCC: Hepatocellular carcinoma is the most common primary liver tumour. Because most cases occur in the setting of cirrhosis, it is often not amenable to resection; AFP: Alpha-fetoprotein has no known function in adults but it has clinical significance as a tumour marker in

the diagnosis of HCC.

Peer-review

This is an interesting attempt to evaluate the results of liver transplantation for HCC with regard to potential relation with pre-operative values of AFP. The paper is well written and results are clarified.

Abstract

AIM: To analyze the association between plasma bilirubin levels and veno-occlusive disease (VOD) in non-adult patients undergoing hematopoietic stem cell transplantation (HSCT) during cyclosporine therapy.

METHODS: A total of 123 patients taking cyclosporine

were evaluated using an electronic medical system at the Seoul National University Children's Hospital from the years 2004 through 2011. Patients were grouped by age and analyzed for incidence and type of adverse drug reactions (ADRs) including VOD.

RESULTS: The HSCT patients were divided into three age groups: G#1 ≥ 18 ; $9 \leq$ G#2 ≤ 17 ; and G#3 ≤ 8 years of age). The majority of transplant donor types were cord blood transplantations. Most prevalent ADRs represented acute graft-*vs*-host disease (aGVHD) and VOD. Although the incidences of aGVHD did not vary among the groups, the higher frequency ratios of VOD in G#3 suggested that an age of 8 or younger is a risk factor for developing VOD in HSCT patients. After cyclosporine therapy, the trough plasma concentrations of cyclosporine were lower in G#3 than in G#1, indicative of its increased clearance. Moreover, in G#3 only, a maximal total bilirubin level (BILmax) of ≥ 1.4 mg/dL correlated with VOD incidence after cyclosporine therapy.

CONCLUSION: HSCT patients 8 years of age or younger are more at risk for developing VOD, diagnosed as hyperbilirubinemia, tender hepatomegaly, and ascites/weight gain after cyclosporine therapy, which may be represented by a criterion of plasma BILmax being ≥ 1.4 mg/dL, suggestive of more sensitive VOD indication in this age group.

Key words: Hematopoietic stem cell transplantation; Veno-occlusive disease; Cyclosporine; Adverse drug reaction; Total bilirubin

Core tip: This study analyzed the association between plasma bilirubin and veno-occlusive disease (VOD) in childhood undergoing hematopoietic stem cell transplantation (HSCT) during cyclosporine therapy. Here, we report that age of 8 or under may be a risk factor for VOD in CsA-treated patients who underwent HSCT with differential clearance of CsA. Another finding is that a criterion of 1.4 mg/dL of plasma maximal total bilirubin level or higher content alone closely represents the incidence of VOD in early childhood patients with HSCT in CsA therapy. Information shown in this study would be of great help to understand VOD occurring during CsA medication and to find optimal pharmacotherapy in HSCT patients.

Higher plasma bilirubin predicts veno-occlusive disease in early childhood undergoing hematopoietic stem cell transplantation with cyclosporine. *World J Transplant* 2016; 6(2): 403-410 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i2/403.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i2.403>

INTRODUCTION

Cyclosporine is a major immunosuppressant for organ transplantation, and is widely used for the prophylactic treatment of acute graft-*vs*-host disease (aGVHD) after hematopoietic stem cell transplantation (HSCT)^[1]. However, the morbidity and mortality resulting from acute, or subsequently following chronic GVHD, and veno-occlusive disease (VOD), as indicated by hyperbilirubinemia, tender hepatomegaly, and ascites, are obstacles to the use of cyclosporine alone or in combination with other agents^[2]. Clinical studies on cyclosporine therapy demonstrated differences between neonate, child and adult populations in the incidence of adverse drug reactions (ADRs)^[3]. Since these events are closely linked to the metabolic burden and/or clearance of the drug, ADRs should be monitored and avoided depending on the types of transplantation, age groups and pharmacokinetic profiles. In particular, the dose regimens and therapeutic concentrations need to be appropriately adjusted for optimal efficacy and/or minimized ADRs.

Cyclosporine therapy should be carefully monitored as a therapeutic drug monitoring system^[4]. Monitoring of pharmacokinetic profiles, including oral bioavailability, has been claimed in the context of successful pharmacotherapy because intestinal absorption of cyclosporine varies depending on the type of transplantation, age, and other parameters of patients^[5-9]. In general, patients of a young age seem to be more at risk for ADRs to cyclosporine, and exhibit different ADR profiles^[10]. Therefore, the oral dose of cyclosporine required for the maintenance of therapeutic blood levels is significantly augmented in childhood patients^[5]. In addition to the narrow therapeutic range of cyclosporine, the types and incidences of cyclosporine-induced ADRs vary depending on the types and severities of diseases, as well as patient age^[11].

It has been recognized that wide variations exist in the plasma concentrations of cyclosporine among HSCT patients^[12]. A limited number of studies have been performed in cyclosporine-treated neonates and children who underwent HSCT in the context of ADR monitoring^[13]. In Seoul National University Hospital, the administered dose of cyclosporine was equally determined by the post-surgical day of HSCT, which frequently resulted in cyclosporine plasma concentrations being out of therapeutic range (150-250 ng/mL). Although the normalized doses of cyclosporine for transplant patients of childhood age were usually higher than those for adults, the plasma concentrations were significantly lower^[3]. This raised the contention that biotransformation and/or excretion of cyclosporine is accelerated in childhood patients, which may be linked to ADRs, such as GVHD, nephrotoxicity, and neurotoxicity^[13].

Age-different effects of cyclosporine therapy on the types and incidences of ADRs in HSCT patients are

known^[14-16]. Nevertheless, more sensitive indicator(s) would be of great help to avoid or minimize serious ADRs and to accomplish successful pharmacotherapy, especially in patients of the childhood population who would be more prone to drug-induced harmful effects. This study analyzed the association between plasma bilirubin levels and VOD in non-adult patients undergoing HSCT during cyclosporine therapy. Here, we report that marginally high levels of total plasma bilirubin reliably indicate VOD during cyclosporine therapy in the HSCT patient of early childhood.

MATERIALS AND METHODS

Datasets

This study was approved by the Institutional Review Board of Seoul National University Hospital (SNUH; H-1112-087-390, 2012.3.17), a 1961-bed medical center, on March 17, 2012. The data collected had anonymous codes representing patient files comprising the following medical information: Age, gender, medical diagnosis codes, date of HSCT, absolute neutrophil count, post-transplantation day, donor types (cord blood and related donor), body weight, body surface area, body temperature, types of ADRs, peak

and trough concentrations of cyclosporine, serum hematocrit, alanine aminotransferase (ALT), aspartate aminotransferase (AST), serum total bilirubin levels, dates of labs drawn, medications (generic and brand name, prescription date), and duration of chemotherapeutic agent along with co-prescribed drugs.

Patients

The database contained records of 123 patients (ages ranging from 2 to 24 with 68 males and 55 females) who had been hospitalized in SNUH from September 15, 2004 to December 31, 2012 and had undergone measurements of plasma cyclosporine levels using a radioimmunoassay kit. Cyclosporine concentrations were monitored on day 1, 4, 11, 18, 24 and 28 after HSCT and at intervals of three or seven days after day 28 of HSCT in SNUH. Laboratory data were obtained from 123 patients, with three of them having HSCTs twice in this period. The total number of cyclosporine measurements was 2149, with an average of 17.5 measurements per patient.

HSCT patients who had been administered cyclosporine were divided into three groups based on age: G#1, 18 years of age or older; G#2, between 9 and 17 years of age; and G#3, 8 years of age or under. The median ages in G#1, G#2, and G#3 were 20, 13 and 6, respectively. Each group was additionally split into four subgroups by the levels of a maximal total bilirubin level (BILmax) [*i.e.*, BILmax (-), lower than 1.4 mg/dL of total plasma bilirubin; and BILmax (+), 1.4 mg/dL of total plasma bilirubin or higher] and VOD incidence [*i.e.*, VOD (-), no existing VOD; and VOD (+), existing VOD].

Statistical analysis

The Fisher exact test was chosen to determine differences in the frequency of BILmax \geq 1.4 mg/dL between VOD (-) and VOD (+) groups. Multivariate analysis was performed to find risk factors for drug therapy. Data represent the median (0.5-24.0 mg/dL). Results were considered statistically significant if the *P*-value was less than 0.05. Statistical analyses were conducted using the Duncan and Fisher's tests in SPSS Version 12.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

The characteristics of HSCT patients treated with cyclosporine (*n* = 123) are summarized in Table 1. Of the patients examined, cord blood transplantation constituted the majority of the transplant donor type (G#1, 60.0%; G#2, 58.6%; and G#3, 75.0%). The most prevalent ADR event observed was aGVHD (G#1, 61.9%; G#2, 46.4%; and G#3, 54.2%), whereas the second most frequent ADR event was VOD (9.5%-29.2%). Although the incidences of aGVHD, diagnosed as cytopenia and delayed immune reconstitution, did not vary much between the groups, the frequency ratios of VOD were significantly higher in G#3. Thus, being 8 years of age or under at the time of transplantation

Table 2 Median trough plasma concentrations and doses of cyclosporine in hematopoietic stem cell transplantation patients

Contents		G#1 (n = 25)	G#2 (n = 70)	G#3 (n = 28)
iv	Trough plasma concentration ^b (ng/mL)	535.6 (264.0-1214.0) ^a	448.9 (184.5-1070.0)	333.1 (152.5-819.0)
	Dose (mg/kg)	5.8 (3.9-7.7)	6.1 (3.5-14.2)	6.0 (3.8-9.3)
PO	Trough plasma concentration ^b (ng/mL)	345.9 (166.0-686.5)	247.7 (40.0-496.5)	204.4 (33.0-302.5)
	Dose (mg/kg) ^c	8.2 (3.4-11.4)	8.2 (1.6-17.5)	10.6 (6.0-24.6)

^aThe values in parenthesis represent the minimum and maximum trough plasma concentrations of cyclosporine; ^bG#1 was significantly different from G#2 or G#3 using Duncan test; ^cG#3 was significantly different from G#1 or G#2 using Duncan test. *iv*: Intravenous administration; *PO*: Per Os, which means oral administration.

Table 3 Two by two analyses between maximal plasma bilirubin contents and veno-occlusive disease in hematopoietic stem cell transplantation patients

	G#1 (n = 25)		G#2 (n = 70)		G#3 (n = 28)	
	BILmax (-)	BILmax (+)	BILmax (-)	BILmax (+)	BILmax (-)	BILmax (+)
VOD (+)	0	2	4	9	0	7
VOD (-)	5	18	28	29	17	4
P-value	1.00		0.356		0.0001	

BILmax (+): 1.4 mg/dL or higher; BILmax (-): Lower than 1.4 mg/dL. Data were analyzed using Fisher's test program. BILmax: A maximal total bilirubin level; VOD: Veno-occlusive disease.

would be a possible risk factor for VOD in patients who underwent HSCT from cord blood donors. In types of diseases, acute lymphoblastic leukemia and acute myeloid leukemia highly occurs in all three groups of patients, but there was no significant difference of the disease incidence rate depending on the age. Also the liver functions (*i.e.*, ALT and AST activities) were comparable in all groups of patients.

After intravenous administration, the trough plasma concentrations of cyclosporine were significantly lower (83.8% and 62.2% in G#2 and G#3, respectively, vs G#1) in G#2 or G#3 than in G#1, although the injected dose of cyclosporine was normalized to the patient body weight (Table 2). The trough plasma concentrations of cyclosporine were approximately 40% lower in G#3 than in G#1, indicative of its accelerated clearance in G#3. The trough plasma cyclosporine levels were similarly changed in the groups examined after oral administration; in this case, the oral dose was approximately 30% greater in G#3 than in G#1 (or G#2), suggesting the possibility that the bioavailability of cyclosporine was significantly lower in G#3 (Table 2). These results indicate that the clearance and/or turnover rate of cyclosporine in plasma might be augmented in G#3, whereas the oral bioavailability was lower in this group, implying the potential of increased detoxifying burden in the patients presumably due to accelerated biotransformation and excretion of cyclosporine.

Given the distinct difference in plasma cyclosporine concentrations and the potential of increased cyclosporine clearance in G#3, we next asked whether the incidences of VOD statistically correlated with total bilirubin levels in plasma among the patients examined. Setting the BILmax cutoff level at 2.0 mg/dL demonstrated an obvious increment in VOD incidences in

high BILmax groups when G#2, G#3 or the total population was analyzed, although it failed in demonstrating increased VOD incidences when G#1 was solely analyzed (data not shown). More importantly, setting the BILmax cutoff level at 1.4 mg/dL (a minimal significant value obtained empirically) revealed an augmented incidence of VOD in the high BILmax group in G#3 ($P < 0.0001$), but not in G#1 or G#2, as determined by two-by-two analyses (Table 3).

DISCUSSION

ADR-related admissions are a problem with a high prevalence^[17,18]. Pérez Menéndez-Conde *et al.*^[18] reported that 19.4% of admissions were direct consequences of ADRs, 65% of which were preventable^[19]. In particular, cyclosporine therapy causes various ADRs (*e.g.*, 20% of infectious complications during the therapy and 5% of severe GVHD)^[20,21], with approximately 6% of admissions eliciting permanent damage, including seizures or death^[22]. In general, the dose of cyclosporine is calculated for transplant patients primarily on the basis of body weight^[23]. However, this approach has limitations, such as the development of aGVHD, cGVHD, hepatotoxicity, gastrointestinal disorders, infections and hemorrhagic cystitis^[24]. Large variations in plasma cyclosporine concentrations exist in individuals (*i.e.*, 5-8 fold differences)^[25]. Since the biotransformation capacities of endogenous and exogenous substances vary depending on the stage of development and maturation, attention should be directed to cyclosporine clearance. The results of this study demonstrated the impact of age differences on the incidence and type of ADRs during cyclosporine therapy in HSCT patients of early childhood as compared to adolescent patients.

A major advantage of HSCT is the potential for therapeutic benefits from graft-vs-leukemia effects, which are mediated by donor T and natural killer cells^[26]. Unfortunately, graft-vs-leukemia effects are closely linked to aGVHD as the major limiting toxicity of allogeneic transplantation, which causes damage to the skin, gastrointestinal tract, and liver^[27]. Studies have shown that aGVHD frequently occurred when plasma concentrations of cyclosporine decreased to 125-200 ng/mL 12 h after treatment^[25,28]. Depletion of T cells from the graft effectively prevented aGVHD, but it also limited graft-vs-leukemia effects, possibly increasing the rate of graft failure^[29]. Therefore, plasma concentrations of immunosuppressant are currently one of the critical factors to maintain the proper balance between aGVHD and graft-vs-leukemia effects. The lowest plasma cyclosporine concentration (< 200 ng/mL) in the third week after transplantation showed a high risk factor related to aGVHD (grades II-IV) in HSCT patients^[30]. Thus, assessment of cyclosporine levels is a valuable diagnostic tool to predict aGVHD. In the present study, we observed that the incidences of aGVHD (*i.e.*, cytopenia and delayed immune reconstitution) were not much different among the groups examined, which supports the appropriateness of the pharmacotherapy.

Patients currently meet McDonald's VOD-Seattle Criteria by exhibiting two or more of the following criteria: Hyperbilirubinemia > 2 mg/dL, tender hepatomegaly, and either ascites or weight gain (> 2%). A key finding of this study is that VOD occurrences were significantly higher in G#3. Similarly, the incidences of VOD increased in childhood age^[31], whereas VOD was frequently observed day 18 (the median) after intravenous administration of cyclosporine^[32]. When we compared the plasma levels of cyclosporine and other pharmacokinetic parameters, the turnover rate of cyclosporine seemed to vary in different age groups. Our finding showing lower plasma cyclosporine level with higher occurrence of VOD in G#3 differs from the previous report that high plasma concentrations or high doses of drugs in pediatric HSCT patients related to the frequent and severe VOD in different therapy in HSCT patients^[33]. VOD occurrence seems to be associated with clearance of endogenous compounds as well as cyclosporine^[34]. It has also been suggested that the clearance rate of cyclosporine may affect VOD and total bilirubin levels in blood^[34]. This idea is consistent with the finding that the pharmacokinetic profile of cyclosporine was characterized by substantially faster elimination in children compared to adults, which necessitated more frequent dosing intervals and higher doses for younger children^[7,35]. So, low plasma cyclosporine levels in G#3 may reflect its high turnover rate. Overall, our results and others support the contention that the turnover rate of cyclosporine is increased, particularly in HSCT patients of early childhood.

Our finding that HSCT patients of 8 years of age or under were more at risk for the reactions of VOD, which was distinctively characterized by the plasma BILmax

level being ≥ 1.4 mg/dL, indicates that plasma BILmax alone may serve as a valuable marker of VOD in this particular patient population. Since a large fraction of cyclosporine binds with erythrocytes (41%-50%)^[36], cyclosporine-induced hyperbilirubinemia may result from destabilization and/or disruption of red blood cell membranes, with the consequent release of heme for biodegradation and excretion. It has also been shown that the clearance of red blood cells was slower, whereas the maturity and differentiation of red blood cells were lower in children compared to other groups^[37]. Disruption of canaliculi in children has also been shown to increase, even at lower cyclosporine concentrations^[38]. Therefore, the frequency of splenomegaly increases presumably due to the clearance of damaged red blood cells and debris, along with heme disposal, resulting in the subsequent production of bilirubin^[39]. Consistently, red blood cells may be impaired after cyclosporine therapy, especially during radiation therapy^[40].

Since cyclosporine is mainly oxidized *via* cytochrome P450s 3A4 (CYP3A4), followed by glucuronide conjugation *via* UDP-glucuronosyltransferase 1A1 (UGT1A1) and UGT2B7, total bilirubin levels in the blood would increase, enhancing the burden of detoxification^[41]. Cyclosporine is primarily metabolized by CYP3A4 in the liver, 95% of which is excreted *via* the biliary route. The main reason for the low bioavailability of cyclosporine may be due to its extensive intestinal metabolism by CYPs^[42]. The various rate and extent of cyclosporine metabolism, depending on age and drug interactions (60%-90%), may be related with polymorphisms of CYP3A4^[43]. The genetic associations between UGT variations and cyclosporine pharmacokinetics in patients would also affect its efficacy and ADRs (*e.g.*, GVHD, hepatic and/or gastrointestinal disorders) presumably due to unpredictable cyclosporine concentrations^[44]. Our results showed that plasma cyclosporine levels were significantly lower in G#3 despite the highest normalized dose. Clearance of endogenous bilirubin might also be reduced in the patients presumably due to relatively low rate of metabolism. Thus, cyclosporine biotransformation may change depending on the metabolic clearance of bilirubin, which would increase in early childhood compared to adolescents and/or adults^[45]. Alterations in red blood cell turnover and/or interference of biliary excretion of glucuronidated cyclosporine would also contribute to total plasma bilirubin levels^[46].

The value of pharmacist-provided drug-monitoring care to transplant recipients has been recognized as a beneficial service^[47]. Considering the complexity of pharmacotherapy, pharmacists need to implement clinically relevant interventions on the transplant unit^[48]. Although the dangers of ADRs are well recognized by clinicians and pharmacists, the efforts to elucidate the basis of ADRs still exist in clinical fields^[49]. This situation stimulated attempts to validate ways of ADR monitoring by developing new and critical indicators, algorithms and analytical tools^[50,51]. HSCT patients represent a population at high risk for drug-related problems^[52]. Our

results demonstrate that HSCT patients 8 years of age or under are at higher risk for developing the reactions of VOD after cyclosporine therapy, which may be indicated by plasma BILmax levels being ≥ 1.4 mg/dL, suggesting that this new criterion alone may be used as an indicator of VOD during cyclosporine therapy in HSCT patients of young childhood. A guideline for ADR-related problems and interventions may aid staffs working in the HSCT unit to optimize pharmaceutical care of patients, thereby reducing economic costs resulting from inappropriate drug utilization.

COMMENTS

Background

The incidence of veno-occlusive disease (VOD) differs from the ages of childhood, which is an obstacle of the use of cyclosporine, immunosuppressant for organ transplantation. Especially, the VOD incidence was higher in cyclosporine-treated neonates and children who underwent hematopoietic stem cell transplantation (HSCT). Therefore, the authors analyzed the association between plasma bilirubin levels and VOD in childhood patients undergoing HSCT during cyclosporine therapy.

Research frontiers

The sensitive indicator(s) would be of great help to avoid or minimize serious VOD and to accomplish successful cyclosporine therapy, especially in patients of the childhood population with higher VOD incidence. The results of this study contribute to clarifying the associations of bilirubin, VOD and cyclosporine concentrations.

Innovations and breakthroughs

Although age-different effects of cyclosporine therapy on various adverse drug reactions in HSCT patients are existing, the association between plasma bilirubin levels and VOD in non-adult patients undergoing HSCT during cyclosporine therapy was not reported yet. Thus, the authors report that marginally high levels of total plasma bilirubin reliably indicate VOD during cyclosporine therapy in the HSCT patient of early childhood.

Applications

A plasma BILmax levels being ≥ 1.4 mg/dL may be used as an indicator of VOD during cyclosporine therapy in HSCT patients of young childhood. A guideline for adverse drug reaction-related problems and interventions may aid staffs working in the HSCT unit to optimize pharmaceutical care of patients, thereby reducing economic costs resulting from inappropriate drug utilization.

Terminology

A maximal total bilirubin level (BILmax) (-): Lower than 1.4 mg/dL of total bilirubin during cyclosporine therapy; BILmax (+): 1.4 mg/dL of total plasma bilirubin or higher during cyclosporine therapy.

Peer-review

This review is well written, presenting a very significant issue of "an increased risk for developing VOD after cyclosporine treatments in younger (< 8 years old) generations". Authors also claimed that the plasma BILmax levels being ≥ 1.4 mg/dL would provide a useful indicator to recognize the development of VOD in those generations.

Abstract

AIM: To expand the living donor liver transplantation (LT) pool of eligible patients with hepatocellular carcinoma (HCC) using new morphological and biological criteria.

METHODS: Patients with HCC who underwent living donor LT (LDLT) from March 2005 to May 2013 at the National Cancer Center Korea (NCCCK) were enrolled. We performed the ¹⁸F-fluorodeoxyglucose positron emission tomography/computed tomography (PET/CT)

before LDLT. Overall and disease-free survival analysis was done in patients to evaluate the usefulness of new NCCK criteria using PET/CT and total tumor size (10 cm).

RESULTS: We enrolled a total of 280 patients who pathologically confirmed to have HCC and performed the PET/CT before transplantation. Among them, 164 (58.6%) patients fulfilled the NCCK criteria and 132 patients (47.1%) met the Milan criteria. Five-year overall and disease-free survival rates for patients who fulfilled the NCCK criteria showed 85.2% and 84.0%, respectively, and were significantly higher than those beyond the NCCK criteria (60.2% and 44.4%, respectively; $P < 0.001$). The correlation analysis between preoperative imaging tests and pathologic reports using Cohen's Kappa demonstrated the better results in the NCCK criteria than those in the Milan criteria (0.850 *vs* 0.583). The comparison of disease-free analysis among the NCCK, Milan, and University of California, San Francisco (UCSF) criteria using the receiver operating characteristics curves revealed the similar area under the curve value criteria (NCCK *vs* Milan, $P = 0.484$; NCCK *vs* UCSF, $P = 0.189$ at 5-years).

CONCLUSION: The NCCK criteria using hybrid concept of both morphological and biological parameters showed an excellent agreement between preoperative imaging and pathological results, and favorable survival outcomes. These new criteria might select the optimal patients with HCC waiting LDLT and expand the selection pool.

Core tip: National Cancer Center Korea criteria using positron-emission tomography/computed tomography positivity and total tumor size (cutoff 10 cm) expanded the pool of living donor liver transplantation for patients with hepatocellular carcinoma. Patient identification on the bases of the criteria showed an excellent agreement between preoperative imaging and pathological results and favorable survival outcomes.

INTRODUCTION

The application of selection criteria for liver transpl-

antation (LT) in patients with hepatocellular carcinoma (HCC) has changed the HCC treatment algorithm over the past 20 years. The Milan criteria proposed by Mazzaferro *et al*^[1]. helped to increase the number of LTs in patients with HCC and demonstrated remarkably good survival outcomes for these patients. In particular, the Milan criteria, which use both tumor size and number are very useful and have been adopted as selection criteria. Based on these criteria, the patients for whom HCC was identified early had the best chance of being cured of cancer following LT. In Asian countries such as South Korea and Japan, the number of deceased donors is limited and living donor LT (LDLT) has become an important option for treatment in patients with HCC^[2,3]. As the amount of experience and evidence on LDLT for HCC has increased in recent years, the selection criteria for LT have gradually been expanded in large-volume centers. Various expanded criteria based on tumor number and size, such as the University of California, San Francisco (UCSF) criteria, have been proposed^[4-9]. Some Japanese centers have demonstrated that preoperative tumor markers such as the des-gamma-carboxy prothrombin (DCP) level and tumor size were associated with higher recurrence rates^[10,11]. These expanded criteria revealed that selected patients who did not fulfill the Milan criteria showed good overall survival (OS) and disease-free survival (DFS) rates compared with those who fulfilled the Milan criteria. Although the Milan criteria always guarantee the best survival rates in patients with HCC, they are too restrictive and use modalities.

In HCC patients, tumor characteristics, including differentiation grade and microvascular invasion, are well-known independent prognostic factors for OS and DFS following LT^[12]. However, these factors cannot be evaluated by preoperative imaging studies, which reveal the morphological characteristics such as number and size. Recently, several studies using ¹⁸F-fluorodeoxyglucose positron emission tomography/CT (¹⁸F-FDG PET/CT) demonstrated that ¹⁸F-FDG PET/CT findings were a powerful prognostic marker in patients with HCC after LT and showed good correlation with pathological tumor characteristics, such as microvascular invasion and differentiation^[13-15].

In the present study, we performed a retrospective analysis to identify prognostic factors in patients with HCC who underwent ¹⁸F-FDG PET/CT before LDLT. Based on this result, we developed new and simple expanded criteria [the National Cancer Center, Korea (NCCK) criteria], incorporating a hybrid concept of biological and morphological characteristics on PET/CT images, including total tumor size, and compared these criteria with the Milan criteria, which are based on only morphological evaluation.

between March 2005 and May 2013 were collected using prospectively collected database. All patients were diagnosed as HCC by pathologic reports, and underwent ¹⁸F-FDG PET/CT to check biologic status of the primary tumor and the presence of metastasis within 1 mo before LDLT. Routine preoperative imaging tools for clinical staging in patients with HCC before LDLT were ultrasonography, multi-detector CT (MDCT), and/or dual contrast-enhanced magnetic resonance imaging (MRI) including PET/CT without protocol tumor biopsy. We reviewed the medical records for clinicopathological data, including age, sex, serum α -fetoprotein (AFP), viral markers, C-reactive protein, Model for End-Stage Liver Disease (MELD) score, PET/CT reports, tumor maximum standardized uptake value (SUVmax), pre-transplant therapies, and pathologic data such as Edmondson and Steiner grade; vessel, serosa, and duct invasion; capsule formation; cirrhosis; intrahepatic metastasis; and dysplastic nodules. Prognostic factors using clinicopathological data were analyzed for their effect on OS and DFS. This study was approved by the institutional review board of NCKK.

Our policy for selecting recipients with HCC for LDLT was basically based on the Milan criteria by preoperative imaging tools such as MDCT, MRI, or PET/CT. However, considering the specificity of living related donation, we performed LDLT on patients without major vascular invasion and extrahepatic metastasis on preoperative imaging tools even though they do not satisfy the Milan criteria. We do not recommend the downstaging or bridging therapy before LDLT even though the patient had advanced HCC. The operative techniques, immunosuppression, and management for hepatitis virus of donor and recipient have been described in detail in previous our reports^[16,17]. Patients were followed up periodically with interval 3 or 6 mo using imaging studies such as ultrasonography, abdomen, and chest MDCT with AFP and DCP level. As the tumor recurrence was suspected by imaging tools and serologic tests, additional PET/CT was performed to evaluate the

recurrent tumor and distant metastasis. For one or two nodules in the liver, lung, bone, or brain, we performed the resections. However, in case of multiple metastases, we treated tumors with a multimodality approach such as radiofrequency ablation, transarterial chemoembolization (TACE), radiation therapy, or chemotherapy.

¹⁸F-FDG PET/CT

Our protocol of ¹⁸F-FDG PET/CT was described in detail previously^[14]. In brief, ¹⁸F-FDG PET/CT was performed using a PET/CT scanner (Biograph LSO; Siemens Medical Systems and Discovery LS; GE Healthcare, New Jersey, United States). The mean period between PET/CT and LDLT was 14.8 d. All PET/CT images were analyzed by experienced nuclear medicine physicians. SUV was calculated as (decay-corrected activity kBq/mL of tissue volume)/(injected FDG activity kBq/body mass gram). SUVs of the lesions were checked by placing a region of interest (ROI) at the site of the maximum FDG uptake in the PET images. The ROI was drawn to encircle the highest activity of each tumor, by the results of the CT scans that were acquired from PET/CT or MRI scans. PET/CT positivity was defined by experienced nuclear medicine physicians by checking whether the SUVmax of the tumor by CT or MRI scans was higher than that in the surrounding noncancerous hepatic tissue. Mean SUVmax of tumors for PET/CT positivity and negativity in this study was 4.46 and 3.08, respectively ($P < 0.001$).

NCKK criteria

In a multivariable analysis of our data, we identified two significant prognostic factors by evaluating pathological examination results (Table 1). These were positive findings on PET/CT (HR = 2.652, 95%CI: 1.384-50.085, $P = 0.003$ for OS; HR = 2.517, 95%CI: 1.481-4.279, $P = 0.001$ for DFS) and total tumor size of > 10 cm (HR = 2.909, 95%CI: 1.230-6.880, $P = 0.015$ for OS; HR = 3.003, 95%CI: 1.536-5.870, $P = 0.001$ for DFS). Although microvascular invasion was a significant factor only for DFS (HR = 2.148, 95%CI: 1.064-4.336,

$P = 0.033$), it was not included because these data are typically not available before transplantation. We analyzed our data in comparison with the Milan and UCSF criteria using the NCCK criteria (negative findings on PET/CT and total tumor size < 10 cm vs others). The NCCK criteria were assessed both preoperatively and postoperatively.

Statistical analysis

Survival rates were estimated using Kaplan-Meier method, and survival curves were compared with log-rank test. Multivariable Cox proportional hazard regressions were fitted to identify factors that affected post-transplant survival. T -test and χ^2 test analyses were also used in comparing the differences between groups for continuous and categorical variables, respectively. Cohen's Kappa was used to assess classification consistency of each criteria. The prediction model of DFS using each criteria (the NCCK, Milan, and UCSF) adjusted for significant prognostic factors was developed using multivariable Cox proportional hazard regression. The

receiver operating characteristic (ROC) curves and the associated area under the curves (AUC) of these models predicting 1, 3 and 5 years DFS rates were evaluated to compare the discrimination ability of different criteria. Differences in AUCs were tested using Delong's method¹⁸. All statistical analyses were performed using SAS software (9.2 version). P -value less than 0.05 was used to evaluate statistical significance.

RESULTS

Clinicopathological characteristics

During the study period, a total of 280 patients underwent LDLT for HCC. Among them, 116 (41.4%) patients did not fulfil the NCCK criteria. The comparisons of clinicopathological characteristics between patients who did and did not fulfill the NCCK criteria are presented in Table 2. C-reactive protein level, tumor SUVmax, total tumor size (> 10 cm), AFP (> 400 ng/mL), positive findings on PET/CT, differentiation (grade III-IV), microvascular invasion, intrahepatic metastasis, and serosal

Table 3 Comparison between preoperative imaging and explant pathology by the Milan and National Cancer Center Korea criteria

Milan criteria		NCCK criteria		Preoperative imaging	
				Within	Beyond

invasion were significantly greater in patients who did not fulfill the NCCK criteria compared with those who did. The mean C-reactive protein levels in two groups were 0.58 mg/dL and 1.37 mg/dL, and tumor SUVmax were 3.08 and 4.13, in patients who did and did not fulfill the NCCK criteria, respectively. On the other hand, patients who did not fulfill the NCCK criteria had significantly lower MELD scores compared to those within the NCCK criteria (12.5 vs 14.4, respectively, $P = 0.029$). Pre-transplant therapy type, viral hepatitis type, ductal invasion, capsule formation, dysplastic nodules, and cirrhosis were not significantly different between the two groups.

NCCK criteria: Survival rates and comparison between preoperative imaging and explant pathological reports

OS and DFS according to the NCCK criteria are presented in Figure 1. Patients fulfilling the NCCK criteria according to preoperative imaging findings revealed significantly higher OS and DFS than those who did not fulfill the NCCK criteria (five-year OS: 83.6% vs 59.8%, $P < 0.001$; five-year DFS: 80.7% vs 45.1%, $P < 0.001$). In patients who fulfilled the NCCK criteria according to explant pathological reports, five-year OS and DFS were 85.2% and 84.0%, respectively; these values were significantly higher than those among patients who did not fulfill the NCCK criteria (60.2% and 44.7%, respectively, $P < 0.001$).

The number of patients who fulfilled the NCCK criteria according to preoperative imaging and explant pathology reports were 178 (63.6%) and 164 (58.6%). According to the Milan criteria, these were 167 (59.6%) and 132 (47.1%) patients (Table 3). The NCCK criteria exhibited 95.0% accuracy of preoperative imaging and explant pathological reports; in contrast, the Milan criteria demonstrated only 78.9% accuracy. Compared with the Milan criteria, the NCCK criteria exhibited almost perfect agreement between preoperative imaging and explant pathological reports (Cohen's Kappa 0.850 vs 0.583).

Comparative survival analysis among the NCCK, Milan, and UCSF criteria

In a survival analysis including all patients, five-year OS and DFS were 75.2% and 67.7% (Figure 1). The patients who fulfilled the Milan criteria according to

Table 4 Area under the curves and 95%CI for the Milan, University of California, San Francisco, and National Cancer Center Korea criteria for the prediction of 1, 3, and 5 years disease-free survival

Diagnostic approach	Criteria	AUC (95%CI)		
		1 yr	3 yr	5 yr
Preoperative imaging	Milan ¹	0.814 (0.754, 0.873)	0.804 (0.750, 0.858)	0.799 (0.747, 0.851)
	UCSF ²	0.812 (0.754, 0.871)	0.800 (0.747, 0.853)	0.793 (0.741, 0.844)
	NCCK ³	0.810 (0.753, 0.867)	0.806 (0.755, 0.857)	0.802 (0.753, 0.852)
Explant pathology	Milan ⁴	0.824 (0.767, 0.880)	0.815 (0.764, 0.866)	0.807 (0.757, 0.856)
	UCSF ⁵	0.819 (0.761, 0.877)	0.811 (0.759, 0.863)	0.803 (0.752, 0.853)
	NCCK ⁶	0.823 (0.769, 0.878)	0.817 (0.767, 0.866)	0.810 (0.762, 0.857)

¹Adjusted by PET, X, Y and Z; ²By PET, X and Y; ³By maximum tumor size, X, Y, and Z; ⁴By PET, total tumor size, X and Y; ⁵By PET, X, Y, and Z; ⁶By total tumor size, X, Y, and Z. X: Microvascular invasion; Y: Major vessel invasion; Z: Intrahepatic metastasis; AUC: Area under the curves; UCSF: University of California, San Francisco; PET: Positron emission tomography; NCCK: National Cancer Center Korea; 95%CI and P value were calculated by Cox PH regression analyses adjusted by the following covariates for each criteria.

preoperative imaging and explant pathological reports showed good five-year OS and DFS (83.4% and 82.0% according to preoperative imaging; 85.5% and 84.4% by explant pathological reports, Figure 2). These survival results are very similar to those of patients fulfilling the NCCK criteria, particularly with regard to explant pathological reports. There were 34 (12.14%) patients who did not fulfill the NCCK criteria but fulfilled the Milan criteria according to preoperative imaging findings, and 22 (7.9%) according to explant pathological reports. This group showed a trend toward low five-year OS and DFS according to both preoperative imaging and explant pathological reports, compared with those who fulfilled the NCCK criteria; however, the differences between the two groups were not statistically significant ($P = 0.148$ in OS and $P = 0.212$ in DFS according to preoperative imaging findings; $P = 0.658$ in OS and $P = 0.376$ in DFS according to explant pathological reports, Figure 3).

ROC curve and AUC of the Milan, UCSF and NCCK criteria for the prediction of one, three, and five years DFS are presented in Figure 4 and Table 4. The value of AUC by three criteria was similar in both preoperative imaging and explant pathological reports, and there were no significant differences in the area under the ROC curve at one, three, and five years by three groups (five-year DFS, Delong's $P = 0.267$ for Milan vs NCCK, $P = 0.213$ for UCSF vs NCCK in preoperative imaging; $P = 0.484$ for Milan vs NCCK, $P = 0.189$ for UCSF vs NCCK in explant pathological reports).

DISCUSSION

In the present study, the NCCK criteria were associated

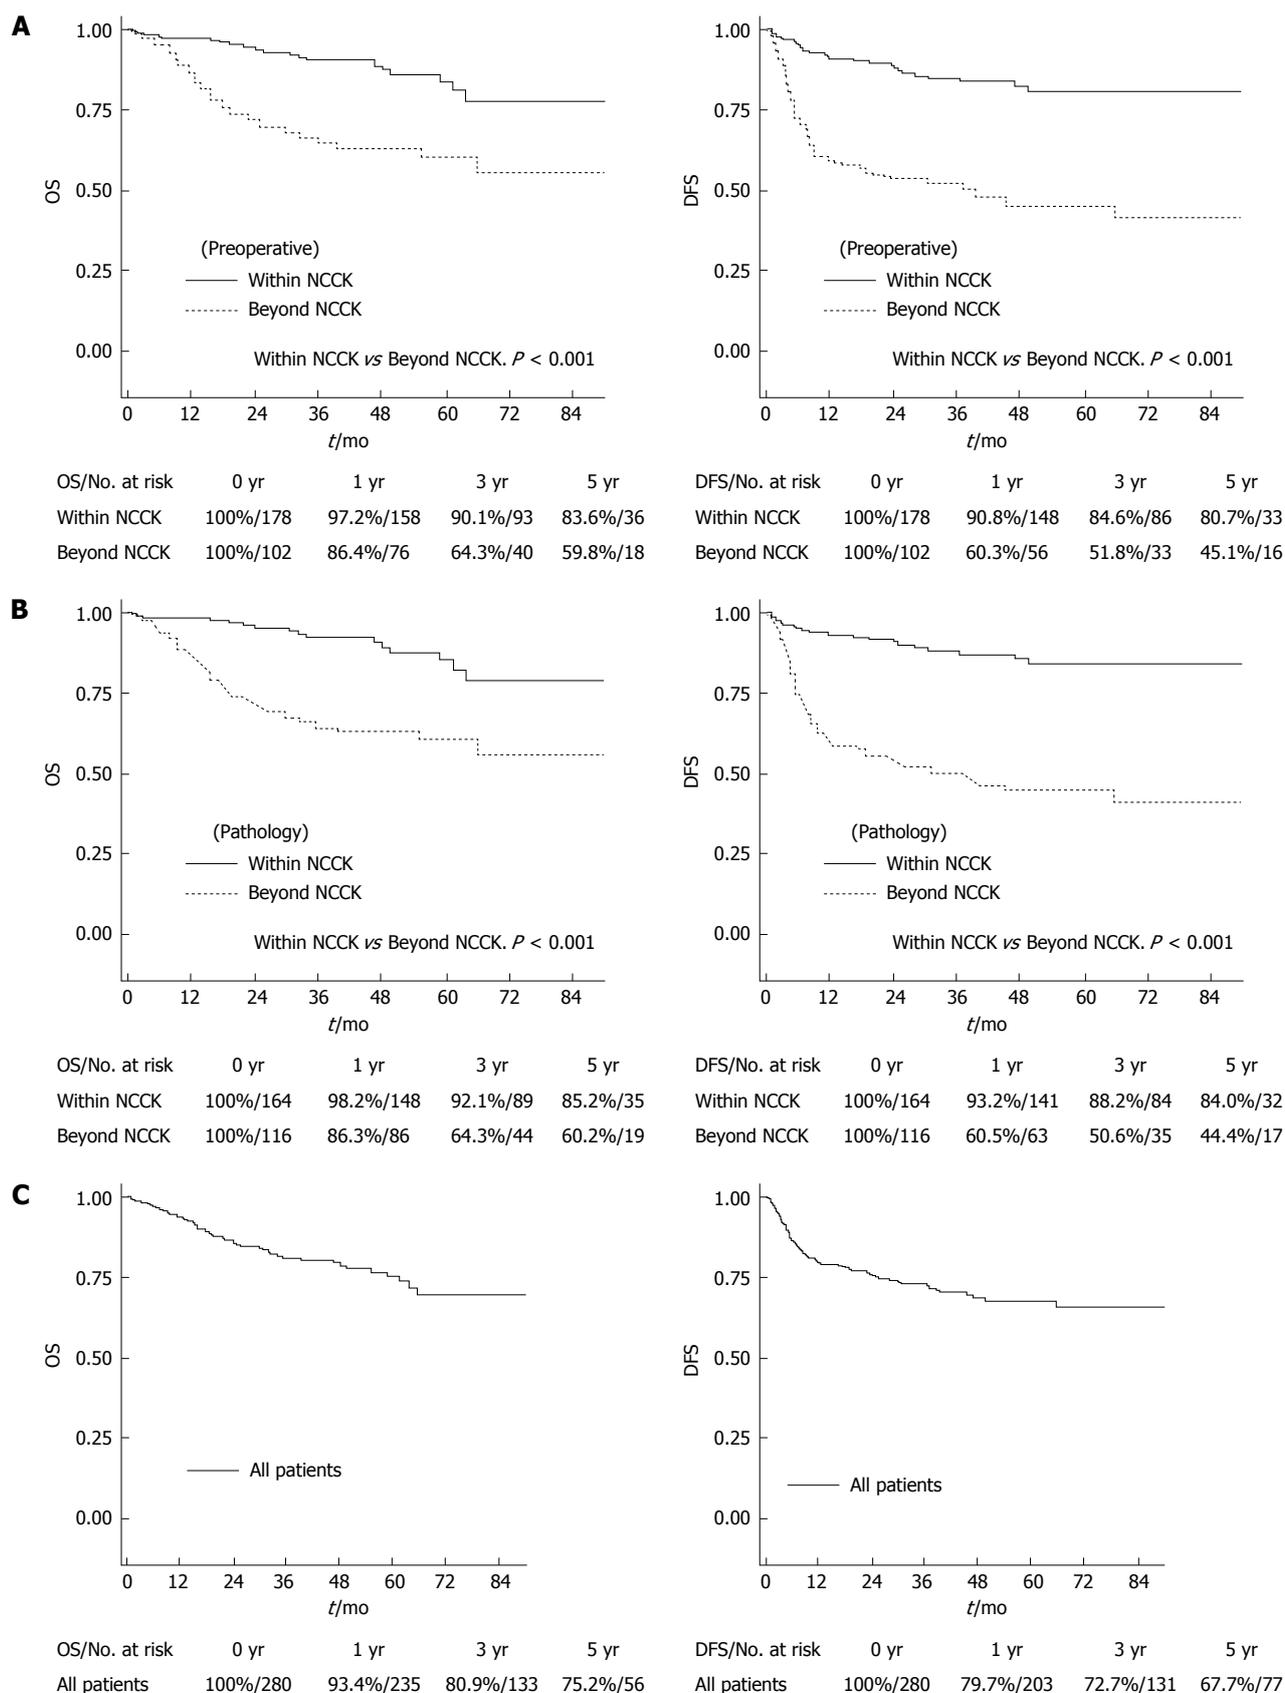

Figure 1 Overall and disease-free survival rates according to the National Cancer Center Korea criteria. A: By preoperative imaging; B: By explant pathology; C: OS and DFS rates for all patients. OS: Overall survival; DFS: Disease-free survival; NCCK: National Cancer Center Korea.

with favorable survival outcomes and expanded the selection pool for LDLT among patients with HCC. Over the past 10 years, the Milan criteria have been regarded as a well-established tool for assessing the prognosis of HCC for LT. However, limited selection and inaccurate assessment using preoperative imaging modalities, such as CT, have been constantly recognized as a limitation of the criteria. Tumor biological characteristics, such as microvascular invasion and differentiation, are strong predictive factors for HCC recurrence. ¹⁸F-FDG PET/CT findings are a useful marker to predict these factors before LT, as well as to detect extrahepatic metastases. Furthermore, total tumor size itself can be simple and relatively accurate measure rather than using both tumor number and size which are used in the Milan and UCSF criteria. The proposed NCKK criteria, therefore, presented with better correlation with preoperative imaging and explant pathological reports than the Milan criteria.

There were several expanded criteria for patients with HCC beyond the Milan criteria. The main factors that were present in these criteria were tumor size and number. The UCSF, Tokyo, and "up-to-seven" criteria are based on tumor morphological characteristics using preoperative imaging or explant pathological reports^[4,8,19]. However, recent studies reported the expanded criteria using markers of tumor aggressiveness as well as tumor morphological characteristics. These included responses to TACE, the degree of differentiation, the gene-expression profile, the presence of microvascular invasion, and the levels of tumor markers, including AFP or DCP^[11,20-24]. In particular, it is well known that microvascular invasion and the degree of differentiation are associated with decreased survival and an increased risk of recurrence following LT. However, these pathological examination results are not routinely available before LT because fine-needle biopsy before surgery has not shown significant correlations with explant

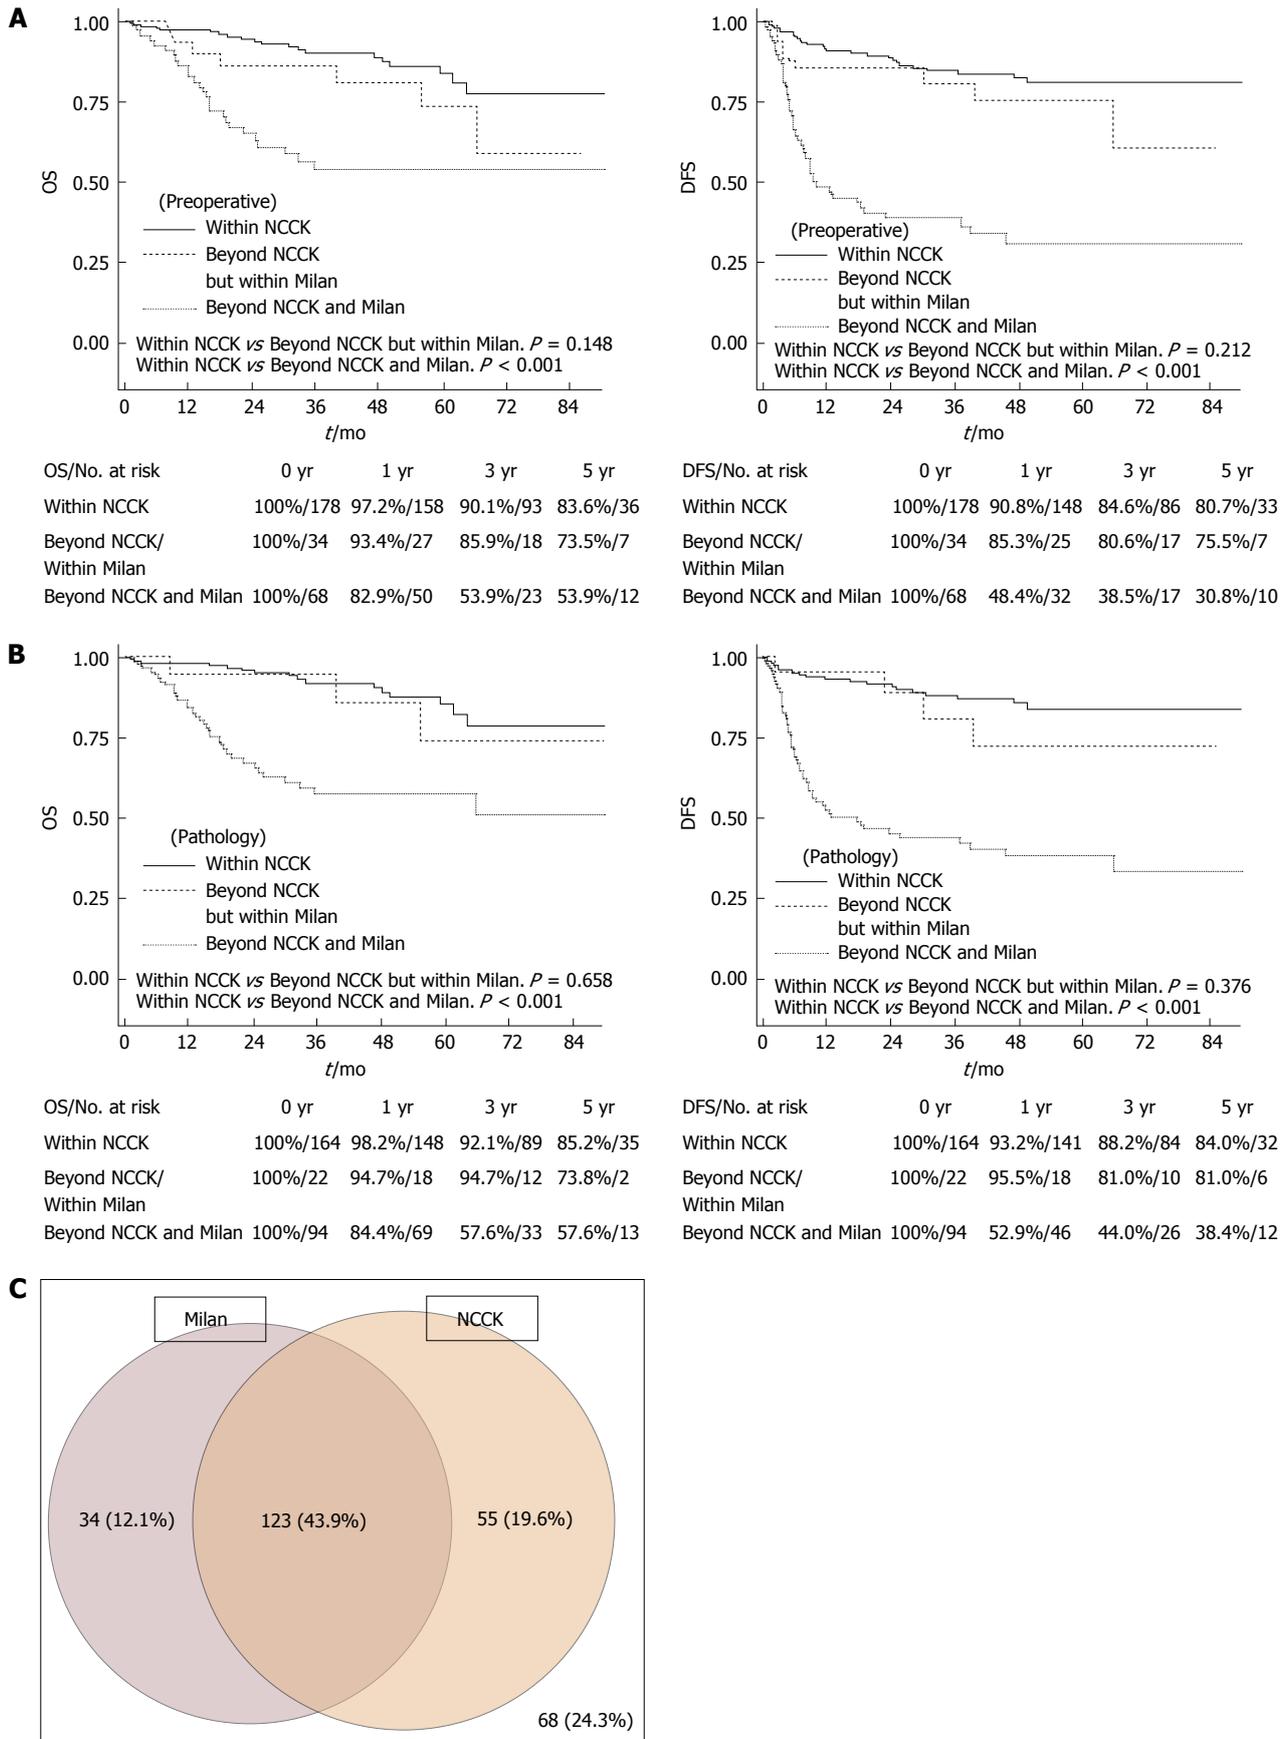

Figure 3 Overall and disease-free survival rates according to three groups (within the National Cancer Center Korea criteria, Beyond the National Cancer Center Korea but within the Milan criteria, Beyond both the National Cancer Center Korea and Milan criteria). pathological reports^[25]. Some promising attempts to identify microvascular invasion before LT through ¹⁸F-FDG PET or PET/CT have been reported^[13,14,26]. Moreover, positive findings on PET/CT in patients with HCC predicted the prognosis and tumor recurrence after LT^[13-15]. In the present study, the patients beyond the NCCK criteria, including positive findings on PET/CT, showed more microvascular invasion (59.5% vs 22.6%, $P < 0.001$) and poor differentiation (52.6% vs 37.8%, $P = 0.02$). One concern regarding the use of PET/CT in patients with HCC is that the sensitivity is low for the primary detection of HCC compared with many other cancers, because glucose metabolism is high in liver tissue^[27,28]. On the other hand, PET/CT has been shown to differentiate between well-differentiated and poorly-differentiated HCC, and is useful in the detection of extrahepatic metastases and recurrence of HCC after transplantation^[29].

The concept of the NCCK criteria began from the observation that good survival rates without recurrence could occur in patients who did not fulfill the Milan criteria. In our data, patients beyond the Milan criteria who also had negative findings on PET/CT showed significantly better survival rates than those who had positive findings on PET/CT (five-year OS, 74.6% vs 51.4%, $P < 0.001$; five-year DFS, 73.3% vs 37.5%, $P < 0.001$). When another significant factor for survival in multivariable analysis (total tumor size < 10 cm) was

considered, patients who did not fulfill the Milan criteria with negative findings on PET/CT and total tumor size < 10 cm showed similar OS and DFS compared with those who met the Milan criteria (OS: mean 90.7 mo vs 83.8 mo, $P = 0.235$; DFS: mean 94.4 mo vs 84.4 mo, $P = 0.076$). Furthermore, positive findings on PET/CT and total tumor size were significant prognostic factors of OS and DFS for all patients (Table 1). Therefore, we applied the NCCK criteria to all patients and analyzed their usefulness and associated survival rates as new expanded criteria that could be used instead of the traditional Milan criteria.

Numerous expanded criteria based on tumor number and size have been reported, but are not used widely due to limited clinical usefulness. The major reason for this is that the risk of underestimating tumor status is considerable regardless the recent developments of new technologies in radiological assessment of liver tumors^[30]. Freeman *et al.*^[31] studied the results from the United Network for Organ Sharing database on 789 LT recipients to analyze the accuracy of imaging findings compared with the explant pathological reports. In that report, radiological imaging underestimated tumor staging in 26.6% of cases, and the risk of overestimation was almost 30%. The overall preoperative accuracy was approximately 50%, regardless of the radiological technique used. In our data, among 167 patients who fulfilled the Milan criteria according to preoperative

imaging modalities, 47 patients (28.1%) were found as not fulfilling the Milan criteria in explant pathological reports. Therefore, some authors proposed that total tumor volume or size was more likely to result in accurate staging before LT^[32-34]. We also used the total tumor size (cutoff 10 cm), which was a significant prognostic factor in multivariable analysis for the NCCK criteria. In our study, among a total of 243 patients with preoperative total tumor size < 10 cm measured with imaging modalities, only 27 patients (11.1%) were confirmed to have a total tumor size of > 10 cm according to pathological reports. Compared with the Milan criteria, the percentage of underestimation in the NCCK criteria using total tumor size (cutoff 10 cm) was lower (9.6%), and Cohen's Kappa was high (0.850), explaining the near-perfect agreement between preoperative imaging and explant pathological reports (Table 3).

In particular, the survival rates of patients who fulfilled the NCCK criteria were quite good and showed similar outcomes compared with the Milan and UCSF criteria (five-year DFS; 80.7% according to preoperative imaging findings, 84.0% in explant pathological reports, Figure 2). Furthermore, the number of patients who fulfilled the NCCK criteria was higher than the Milan criteria [preoperative imaging findings, 178 (63.6%) vs 164 (58.6%) patients; explant pathological reports, 167 (59.6%) vs 132 (47.1%) patients]. The patients who did not fulfill the NCCK, but fulfilled the Milan criteria did not show statistically significant differences compared with those who fulfilled the NCCK criteria; however, a trend toward low five-year OS and DFS according to both preoperative imaging and explant pathological reports was observed (Figure 3). This result was likely because of the fact that the Milan criteria are too restrictive and limited. There was no significant difference observed when the values of AUC and ROC curves for predicting DFS at one, three, and five years were compared among the three criteria (NCCK, Milan, and UCSF) (Figure 4 and Table 4).

There are some limitations to the present study. First, we analyzed LDLT patients without including deceased donor LT patients; therefore, comparison with other studies that included deceased donor LT patients was not possible. However, we included a considerable proportion of patients who were beyond the Milan criteria; thus, the dilution effect on the analysis was less than that in other studies. Second, the present study was retrospective in nature, and selection bias could have influenced the survival analysis. However, we enrolled all consecutive cases and performed routine PET/CT before LDLT in patients with HCC. Therefore, exclusions during the study period were rare.

In conclusion, our data show that the NCCK criteria, utilizing total tumor size and PET/CT findings, successfully expanded the recipient pool and demonstrated better ability of tumor assessment before LT and similar survival rates compared with the well-known criteria, such as the Milan and UCSF. These criteria represent

a new approach to selection for LT that incorporates both tumor biological and morphological characteristics. Therefore, the NCCK criteria are simple and useful expanded criteria for LDLT in HCC, showing excellent agreement between preoperative imaging and explant pathological reports and favorable survival outcomes.

COMMENTS

Background

Several expanded criteria based on morphological features have been proposed to identify appropriate candidates for liver transplantation (LT). However, the definitions are still complex, and the benefit of expanding the pool remains controversial. In this study, the authors evaluated the new criteria using positron-emission tomography/computed tomography (PET/CT) and total tumor size, called as National Cancer Center Korea criteria.

Research frontiers

The expanding criteria for living donor liver transplantation (LDLT) for hepatocellular carcinoma (HCC) is issued recently. The results of this study contribute to clarifying exact criteria using PET/CT and tumor morphologic characteristics.

Innovations and breakthroughs

In this study, they used the PET/CT for all patients underwent LDLT in their institute before transplantation. These results are so unique and included relatively large number of patients. PET/CT is very useful tool for selecting recipients with HCC in LDLT.

Applications

This study suggested that PET/CT is useful for selecting recipient and total tumor size is simple for marker in preoperative imaging tests. If a patient is diagnosed with HCC and waiting the LDLT, PET/CT can be chosen for diagnostic metastasis and prediction of prognosis.

Peer-review

The author this paper evaluated the usefulness of PET/CT and total tumor size for predicting the prognosis after LDLT for HCC, and showed the expanded criteria using these tools. Further trials using these criteria in large population of LDLT will be valuable.

Author contributions: Taber TE, Neidlinger NA and Paramesh AS contributed to the conception and design of the study; Taber TE and Mujtaba MA contributed to the acquisition and analysis of the data; all of the authors contributed to the drafting and critical revisions of the manuscript and gave final approval of the article to be published.

Institutional review board statement: As the study was done on deceased donors, no institutional review board approval was obtained (see body of manuscript).

Informed consent statement: As this was a study looking at deceased donor procurements, there are no patients to consent as the subjects are legally dead per US law. Hence, we are asking for a waiver of informed consent requirements.

Conflict-of-interest statement: The authors have no conflicts of interest to declare.

Data sharing statement: Technical appendix, statistical code, and dataset available from the corresponding author at Dryad repository, who will provide a permanent, citable and open-access home for the dataset. In addition, a copy of the signed statement should be provided to the BPG in PDF format.

Open-Access: This article is an open-access article which was

selected by an in-house editor and fully peer-reviewed by external reviewers. It is distributed in accordance with the Creative Commons Attribution Non Commercial (CC BY-NC 4.0) license, which permits others to distribute, remix, adapt, build upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited and the use is non-commercial. Abstract

AIM: To determine the incidence of surgical injury during deceased donor organ procurements.

METHODS: Organ damage was classified into three tiers, from 1-3, with the latter rendering the organ non-transplantable. For 12 consecutive months starting in January of 2014, 36 of 58 organ procurement organization's (OPO)'s prospectively submitted quality data regarding organ damage (as reported by the transplanting surgeon and confirmed by the OPO medical director) seen on the procured organ.

RESULTS: These 36 OPOs recovered 5401 of the nation's 8504 deceased donors for calendar year 2014.

A total of 19043 organs procured were prospectively analyzed. Of this total, 59 organs sustained damage making them non-transplantable (0 intestines; 4 pancreata; 5 lungs; 6 livers; 43 kidneys). The class 3 damage was spread over 22 (of 36) reporting OPO's.

CONCLUSION: While damage to the procured organ is rare with organ loss being approximately 0.3% of procured organs, loss of potential transplantable organs does occur during procurement.

Key words: Organ procurement; Deceased donations; Organ procurement organization; Organ injury; Organ transplantation

Core tip: This study represents a unique report looking into the incidence of surgical injuries during deceased donor organ procurement. There is no other large scale study reporting this. This represents a multi-organizational study, collecting data prospectively over a period of a year. This study will hopefully help define the problem and contribute to the development of basic standards that organ procurement organizations can follow across the country.

INTRODUCTION

Organ transplantation remains one of the enduring miracles of modern medicine. The ability to replace a dysfunctional organ with a functional allograft that returns the recipient to health is truly an impressive feat. Human organ transplantation essentially started in 1954 with the first successful kidney transplant^[1]. Early transplant successes were limited by the lack of availability of adequate immunosuppression. With the advent of cyclosporine in 1983, the modern era of transplantation began^[2]. Organ transplantation, since that time, has been limited less by the ability to maintain viability of allografts post-transplant than by the supply of transplantable organs^[3]. As most organ transplants are deceased organs, the willingness of potential donor families to agree to organ donation has become paramount. Despite the altruism of these families, over time, there has developed a mismatch of supply and demand with the current waitlist (April 2016) of patients for a solid organ transplant exceeding 121000. Hence, there has been an imperative to ensure that any organ procured should be uninjured during the procedure in

order to maximize utilization. Little data exists in the literature regarding procurement injury. The aim of this study was to determine the incidence of procurement injury in the United States. Organ procurement organization (OPO) system and to further stratify the impact of these injuries by developing a graded scoring system directly linked to the extent of loss.

MATERIALS AND METHODS

There are currently 58 OPOs in this country performing organ procurement. The Association of OPOs (AOPO) serves to unify these individual OPO's and to assist in the sharing of knowledge of best practices in the many tasks performed by the OPOs. Within each OPO, organ procurement is overseen by a medical director to whom each is extended an offer for membership within the AOPO medical council. It is within this medical council that, in 2013, a discussion culminated in the desire to ensure that the "gift of life" of an organ donation should be protected. The medical directors agreed upon a national standard of measurement of organ damage. These levels of damage were agreed upon and range from a level of "0" (no damage); level "1" (minimal damage sustained upon procurement requiring no intervention); level "2" (damage sustained upon procurement requiring some surgical repair but not rendering the allograft non-transplantable); and finally level "3" (damage sustained upon procurement rendering the allograft non-transplantable). These levels of damage would be reported by the transplanting surgeon and reviewed and agreed upon by the medical director of the procuring OPO in consultation with the medical advisory board within that OPO (as deemed necessary by the individual medical director).

After the aforementioned preliminary agreement was reached, this study commenced and included all deceased donors from whom solid organs were procured for transplantation from January 1, 2014 through December 31, 2014. All 58 OPOs were encouraged to prospectively collect data during this period. Data was sent to the AOPO national office where it was transferred to a database and separated by month and OPO. Data was collected for transplantable solid organs: Heart, lung, liver, kidney, pancreas and intestine. Data was subsequently analyzed in an organ-specific fashion. Only data collected for the entire 12 mo of the study was included for evaluation. As noted above, levels of damage were defined as class 1, class 2 or class 3. For each level 3 injury, a written description of the injury was provided to AOPO.

All data for this analysis were collected prospectively in our OPO database. Continuous variables are presented as mean/median. Number and type of organ procured at each OPO and class of injury were reviewed. Class of injury was expressed as 1, 2 or 3 and reported as a frequency at each OPO. Chi square test was used for categorical variables. A two-tailed *P* value of < 0.05 was considered to be significant. The program - graph pad

prism - was used to perform statistical evaluation.

The need for consent in the United States is regulated by local Institutional Review Boards. The consent for brain dead (BD) donors for research is not legally required when no additional tissue, *etc.*, is taken from the donor^[4]. For that reason this study was Institutional Review Board (IRB) exempt and IRB consent was not requested.

RESULTS

A total of 36 OPOs (out of a potential 58) participated in the prospective collection of data (Table 1). An additional 3 OPOs submitted data but were not included in the analysis as this data was not a complete year's collection. By excluding partial year's data, we aimed to minimize selection bias. OPO size (donors/year) varied from 43 to 305 donors/year (mean 147.5; median 141). These 36 OPOs recovered a total of 5401 of the nation's 8594 deceased donors in 2014. From these donors, 19043 procured organs' data was analyzed. Of the donors, 4347 were BD donors and 870 were donation after cardiac death (DCD) donors. Data was reported in terms of both recovered and transplanted organs. The

Table 3 Number of type 3 injuries (one year) by organ procurement organization

OPOs with 1 injury	7
OPOs with 2 injuries	5
OPOs with 3 injuries	6
OPOs with 4 injuries	2
OPOs with 6 injuries	1
OPOs with 10 injuries	1

OPO: Organ procurement organization.

most frequent type of injury was class 1 (Table 2). Class 2 injuries were usually but not always intermediate in number between class 1 and class 3 injuries. In order of increasing incidence of injury, type 3 injuries were compared to recovered organs and occurred in the following frequencies: Intestine: 0/128 (0%); heart 1/1726 (0.05%); liver: 6/4396 (0.14%); lung: 5/2437 (0.21%); kidney: 43/9501 (0.42%); pancreas: 4/855 (0.47%). A total incidence then of class 3 injury in the 19043 organs procured was 0.3%. Among individual OPOs, there were a total of 22 OPOs that reported at least one type 3 injury (Table 3). The median number of class 3 injuries per OPO (in OPOs that had at least 1 injury) was 2.0 with a mean of 2.7 and a mode of 1. One OPO reported 10 class 3 injuries during the year of data collection, one OPO reported 6 and 2 OPOs reported 4 class 3 injuries. The remaining OPOs reporting class 3 injuries fell in the range of 1-3 injuries for the year (#18).

Table 4 Causes of class 3 injury

Organ	# injuries	Cause
Intestine	0	N/A
Pancreas	4	Vascular injury (2) Traction injury to organ (2)
Heart	1	Vascular injury (1)
Lung	5	Vascular injury (2) Inadequate trachea for anastomosis (1) Not specified (1)
Liver	6	Vascular injury (3) Capsular tear (2) Not specified (1)
Kidney	43	Vascular injury (27) Capsular tear (7) Ureteral transection (5) Not specified (3) Failure to flush artery adequately (1)

In looking at OPO size as being predictive of the number of class 3 injuries, 3 of 4 of the OPOs having at least 4 class 3 injuries were larger than the median OPO size in the total cohort (147.5 donors/OPO) but this did not reflect their frequency. The incidence of class 3 injury within this subset of OPO's having at least 4 injuries ranged from 1.3% (of procured organs) to 4.4% with the highest incidence occurring in the OPO with 10 class 3 injuries. Further evaluation of this subgroup of 22 OPOs with class 3 injuries, 7 had only 1 and 5 only had 2. In the subgroup of OPOs with at least 3 class 3 injuries (#10), only 6 of the OPOs had an incidence of over 2.1%. In looking at the highest incidence of injury, 4 OPOs had an incidence of at least 3.9% (range 3.9%-4.7%). In contrast to that noted above in regards to total injuries and OPO size, 3 of these 4 OPOs were smaller OPOs as defined by annual donor numbers (< 147.5 donors/year). Finally, arbitrarily using a 2% injury rate irrespective of number of injuries, there were 7 OPOs that fell within this parameter. Of those OPOs, 5 were in the smaller OPO group (again - as defined as < 147.5 donors/year) and 2 were in the larger group. From a statistical analysis standpoint, using chi square testing, a higher incidence of class 3 injury was observed in the smaller OPOs (grouped together: < 147.5 donors/year) vs larger OPOs (> 147.5 donors/year) with a P value of 0.044.

As class 3 injuries rendered the allograft unable to be transplanted, a summary was received for each lost organ (Table 4). In all allografts (with the exception of pancreas that sustained a "traction" injury) vascular damage was the most common injury rendering the organ non-transplantable. The total BD vs DCD donors were noted but the only data regarding donor type supplied on failed organs was in the narrative. Of note, however, 2 of 6 livers felt to be non-transplantable were noted to be DCDs and 4 of the 43 kidneys. Unfortunately, this data was gleaned from the narrative and not specifically collected so a comparison of DCD vs BD donors reflecting the likelihood of class 3 injuries cannot be made.

DISCUSSION

There have been retrospective reviews regarding surgical damage during procurement but to our knowledge, this is the first prospective look at the surgical outcome of organs procured from deceased donors gathered at the United States OPO level^[5,6]. For that reason, an acceptable degree of surgical damage seen during procurement could not be known. The technique required in procuring organs for donation requires the skills of a vascular surgeon and the insights of a transplant surgeon. Surgical damage may be related to the procurement procedure itself or may be related to the cause of death of the donor (trauma). Damage rendering the organ non-transplantable may be related to parenchymal damage, injury to the vasculature or other parts of the organ (ureter, etc.). The surgeon is required to procure the organ without injury to any of these structures^[7]. In addition, they must obtain enough of the vasculature to allow for anastomosis into the recipient. This desire for adequate vessel length, though, must be balanced with the needs of the other procuring surgeons. Frequently vessel lengths are shared between donor surgeons and a degree of communication and cooperation is required and almost always achieved. Anomalous anatomy also may play a part in organ injury^[8]. This is especially true in the procurement of small organs (pancreas)^[9]. Finally, the insight of the transplanting surgeon should not be overlooked in the determination of transplantability of the organ. If a marginal organ is procured and found to have a significant injury that could potentially impact its function, the transplanting surgeon might be more disinclined to transplant this organ. This could especially be the case in the procurement of a marginal or DCD organ as has been seen previously in DCD kidneys^[10]. Unfortunately, this study was not designed to compare damage seen in BD vs DCD donors. In some cases this information was contained in the narrative describing the injury but as this was not consistent, that information is not reported here.

Despite all the enumerated pitfalls involved in organ procurement, the frequency of organ injury during procurement is rare. The motivation and the skill of the procuring and transplanting surgeon combine to make this outcome predictable. In looking for trends within class 3 injuries, the very scarcity of these injuries made such efforts difficult. What was seen, however, in the OPOs with the highest levels of class 3 injuries was that the injuries tended to cluster within months and then disappear in the months following. In reading the narrative associated with injuries, it was evident that procurement injuries resulted in feedback to the procuring surgeons. It was likely then that such feedback either improved the future focus of the procuring surgeon or resulted in a change or a call for mentorship (in at least one case) in the procuring team. This study would then support the importance of a collegial

discussion with the procurement team in the instance of organ injury.

In looking at class 3 injuries, as noted previously, 14 of the 36 participating OPOs had no such injuries while 3 of 4 of the highest raw number of injuries occurred in larger OPOs (> 147.5 donors/year). However in looking at the frequency of injury of > 2%, smaller OPOs made up the majority of this subset (see above). It does appear then that smaller OPOs by size tend to have a statistically significantly higher likelihood of having a greater frequency of class 3 injury - again arbitrarily defined as a frequency of > 2%. At least one of the reasons for this can be the smaller margin for error when fewer donors are procured. Other potential causes for this would be speculative without further data collection.

Certainly the vast majority of this discussion has been focused on class 3 injuries. The numbers of class 1 and 2 injuries certainly exceed class 3 but, as these do not result in a lost allograft, there is a lessened imperative to examine these events. However, it is likely that these events may be harbingers of class 3 injuries. As no narrative was provided for class 1 and class 2 injuries, it is unknown as to whether OPOs have these discussions after these events. By providing feedback to individual procuring surgeons not just in class 3 but also in the event of a class 1 or 2 injury, there would seem to be potential for improving an individual's procurement surgeon's skills and so avoid future type 3 injuries. These events therefore should continue to be reviewed on an individual OPO level.

Finally, the collection of this data provides OPOs a perspective on their effectiveness in organ procurement. Individual OPOs can, by continuing to follow their surgical injury rate, have an idea as to where their injury rate falls within the national benchmarks. While the goal for surgical damage continues to be the lack of damage, careful review of the frequency of different damage levels will give individual OPOs continuous feedback on at least one aspect of their quality.

The strengths of this study include the prospective data collection, the inclusion of 36 of 58 OPOs as well as the use of the entire 12 mo of data during the collection period. The inclusion and review of the narrative also gave insight into the individual OPOs efforts in enhancing quality. The weaknesses of this study include the lack of participating would have shown a higher level of surgical injury but that outcome again would not be a *fait accompli*. Additionally, expanding data collection to include determination of BD vs DCD donors, names of procurement teams and levels of experience of these teams would have been helpful in interpreting the data. Finally, as the degree of damage was first quantitated by the transplanting surgeon, there is a potential for under-reporting type 1 and 2 injuries if the procuring team were from the transplanting center. This degree of underreporting should not be seen, however with type 3 injuries as the loss of an organ would be evident to the on-site OPO coordinators. Taking all of these concerns

into account, the goal of this study was to establish a standard in the description of procurement surgical damage and a baseline of injury rate. Examined in this light, this study achieved its goals.

A 12 mo collection of surgical damage data from 36 of 58 OPOs in the United States was reviewed. In the entire group, surgical damage was a rare event with the loss of allograft seen in less than 0.5% of procured organs. The majority of the surgical damage seen was related to vascular injuries. Incidence of class 3 injury appears to be higher in OPOs with smaller donor volumes.

COMMENTS

Background

There is a paucity of information about organ injuries during deceased donor procurements. This has significant importance into the numbers of organs that are transplanted every year. This study set out to document and report, for the first time, the incidence and grades of surgical injury to organs during their procurement across the United States. This has the potential to set national standards for quality and offer future ideas for research.

Research frontiers

As the waiting list for organ transplants gets bigger, there has been recent impetus for research to look at more ways to obtain such organs. One such important way would be to identify the numbers of organs that are lost to injury during procurement.

Innovations and breakthroughs

There have been no previous large scale reports of this kind, hence the novelty of this study.

Applications

This study offers for the first time, a national perspective on procurement organ injuries. It helps define a national problem, which the authors know little about. This offers the potential to establish national standards for organ procurement organizations, training of transplant surgeons, and even insurance and regulatory purposes.

Terminology

OPO: Organ procurement organizations. These are independent organizations, contracted with the United Network of Organ Sharing in the United States. Their purpose is the responsibility of procurement and distribution of organs from deceased donors in their assigned geographic area; AOPO: Association of OPOs. A national organization representing all of the 58 OPOs across the United States.

Peer-review

This study is a large scale multi-organizational report looking into the incidence of surgical injuries during deceased donor organ procurement, collecting data prospectively over a period of a year. Organ damage was classified into three tiers, with the latter rendering the organ non-transplantable.

Abstract

AIM: To increase inspiratory muscle strength and improve the quality of life of candidates for liver transplantation.

METHODS: Twenty-three candidates for liver transplantation participated in the control group and 14 made up the intervention group. The control group consisted of 18 men and 5 women, body mass index (BMI) 27.3 ± 4.5 kg/m² and Model for End-Stage Liver Disease (MELD) 18.2 ± 6.1 . The intervention group consisted of 11 men and 3 women, BMI 28.6 ± 5.4 kg/m² and MELD 18 ± 4.5 . The presence or absence of ascites was identified in the first patient evaluation and after three months. We evaluated maximal inspiratory pressure (MIP) and maximal expiratory pressure, spirometry, root mean square (RMS) of diaphragm and rectus abdominis, and the quality of life. The exercises were performed daily by patients at home for three months and were supervised at distance monthly. The manual consisted of diaphragmatic breathing exercises, diaphragmatic isometric exercise, Threshold IMT[®], lifting upper limbs with a bat and strengthening the abdomen.

RESULTS: There was significant difference ($P = 0.01$) between the first (initial) and the third month (final) MIP in the control group and in the intervention group, but there was no difference ($P = 0.45$) between the groups.

The RMS of the diaphragm was lower ($P = 0.001$) and the functional capacity was higher ($P = 0.006$) in the intervention group compared to the control. The general health and mental health domains received higher scores after three months in the control group ($P = 0.01$) and the intervention group ($P = 0.004$), but there was no significant difference between them. The comparison between the presence of initial ascites with the presence of ascites was performed after three months in the control group ($P = 0.083$) and intervention group ($P = 0.31$). There was no significant difference, in relation to the presence of ascites after three months between groups ($P = 0.21$). In the intervention group, patients with ascites at the end of the time period had decreased scores on the social aspects SF-36 domain ($P = 0.023$) compared to those who had no ascites.

CONCLUSION: The proposed exercises provide an increase in the inspiratory muscle strength and improve functional capacity, consequently bettering the quality of life of liver disease patients.

Key words: Respiratory muscles; Pre-operative period; Electromyography; Muscle strength; Breathing exercises

Core tip: Studies on the effects of exercises, mainly those on breathing for liver transplant patients on the waiting list, are rare in the literature. This study proposes a manual of exercises for this group in order to increase muscle strength and improve their quality of life, as sarcopenia found in these patients contributes to a worsening of quality of life and is associated with mortality. The results are encouraging and may represent the beginning of further studies in the area and the establishment of exercise protocols for liver diseases.

INTRODUCTION

Liver transplantation means a chance of survival for individuals with advanced chronic liver diseases or acute liver failure when there are no clinical treatments available^[1-3]. However, there is a disproportion between the supply of organs^[4] and those in need of transplantation, increasing the time on the waiting list and the chance of complications^[5] such as fatigue, decreased aerobic capacity, malnutrition, sarcopenia^[6] and impaired ventilator mechanics due to ascites^[7].

Sarcopenia may be associated with mortality in cirrhotic patients^[8,9] and contributes to an impaired of

quality of life in these patients^[10-13].

Probably also due to loss of muscle mass, according to the authors Oliveira da Silva *et al*^[7], and da Silva *et al*^[14], the liver disease patients showed on average higher RMS of the diaphragm when compared to healthy subjects. This means that the respiratory muscles of patients with liver disease should try harder to gain the best resistance in the basal ventilation profile, in order for the electrical activity of the diaphragm to be higher.

Studies of Dharancy *et al*^[15], Pieber *et al*^[16] and Wiesinger *et al*^[17], suggest that a change from the predominance of aerobic metabolism to anaerobic metabolism occurs early during exercise in individuals with cirrhosis compared to healthy subjects^[8].

The findings in cardiopulmonary exercise testing, early termination of exercise with low peak VO_2 (oxygen consumption), hyperventilation precocious and reduced or unattainable ventilatory threshold^[15,18] may correspond to a fatigue at the beginning of exercise or indicate deconditioning thus hampering the exercise. This reflects the difficulty that cirrhotic patients have to performing everyday activities, as well as feeling fatigue^[17] even when they are hospitalized.

All these complications in the preoperative period, which also influence the recovery after transplantation, can be mitigated with well-defined and specific intervention programs for this group.

Therefore, the aim of the study was to increase inspiratory muscle strength and improve quality of life for liver disease patients with the proposed manual of breathing exercises.

MATERIALS AND METHODS

In this prospective, randomized and controlled trial, data collection was performed at the Unit of Liver Transplantation, Hospital de Clinicas, State University Campinas (Unicamp). The study protocol followed the Ethics Committee of the Medical Sciences Faculty, Unicamp, CEP: 922/2009. Each study participant signs the Informed consent statement.

Liver disease patients were included, men and women, aged over 18 years, with or without a diagnosis of cardiorespiratory disease and those with any Model for End-Stage Liver Disease (MELD) score obtained. All patients filled out a form for identification, age, gender and diagnosis of liver disease. The MELD and body mass index (BMI) were calculated. The presence or absence of ascites was identified in the first patient evaluation and after three months.

Exclusion criteria were: The inability to understand verbal commands, patients with poor general condition (for example, bed reset condition), the failure to perform the evaluations and acute liver failure diagnosis.

The study population was selected from the liver transplant waiting list from August 2012 to February 2014. From the 49 patients evaluated, 27 individuals were chosen through a random draw for participation in the control group. However, four patients were

excluded; three died and one was submitted to a liver transplantation. Thus, 23 patients made up the control group. Twenty-two patients were randomly picked to take part in the intervention group, through a random draw. However, eight patients were excluded as three died, two had liver transplant operations and three individuals declined to perform the exercises. Thus, 14 patients constituted the intervention group. Software for randomization and allocation was not used; the names of the patients were placed in identical envelopes and drawn by the researcher, one by one, to make up the control group and intervention.

The control group was composed of 18 men (78.3%) and five women (21.7%) and the intervention group consisted of 11 men (78.6%) and three women (21.4%). Table 1 shows the demographic and baseline characteristics of the patients.

The respiratory pressures, maximal inspiratory pressure (MIP) and maximal expiratory pressure (MEP) were measured using an analog manometer Gerarmed® (SP, Brazil), with unit scale in cmH₂O, coupled to a mouth-piece and nose clip, always with the patient seated. The data were always collected by the same researcher.

To measure the MIP was requested a maximum exhalation until residual volume and after, a maximal inspiratory effort. To measure the MEP a maximal inspiratory effort was asked for in order to achieve the level of total lung capacity, and then a maximum expiratory effort. The maneuvers were repeated three to five times at intervals of 30 s and it was considered the highest value obtained^[19].

The surface electromyography EMG System of Brazil Ltda®, Series 00405, Model 210C (SP, Brazil) was used to obtain the electrical activity of the diaphragm and rectus abdominis, represented by the root mean square (RMS). Electrodes 3M Brazil® (Sumare, SP, Brazil) were used for the study of electrical activity in these muscles.

The electronic circuit acquisition captures and processes the signals, making them available to the EMG

System of Brasil® software, it was installed on a computer Intelbras I21® (SP, Brazil).

The participants were positioned at 45° in order to study the electrical activity of the diaphragm. A passive electrode was adapted in the paraxiphoid position about 5 cm from the xiphoid process and another 16 cm from the right costal margin. To measure the rectus abdominis an electrode was adapted in the rectus abdominis muscle 5 cm away from the umbilicus and another about 15 cm along the involved muscle^[7]. On the left hand side was positioned a ground electrode. Participants breathe normally while the electrical activity was recorded for ten seconds. A heavy breathing was requested every three seconds. For rectus abdominis was used 500 Hz of frequency and 500 μV of the sensitivity of signal amplitude^[7]. For the diaphragm was used 300 Hz frequency and 300 μV of the sensitivity of signal amplitude^[7].

Through EasyOne Diagnostic Espirometer World® (Zurich, Switzerland), it was possible to perform spirometry, following the Guidelines for Pulmonary Function Tests^[20]. Forced vital capacity (FVC), forced expiratory volume in one second (FEV₁) and forced expiratory flow rate at 25%-75% of FVC curve (FEF_{25%-75%}) were measured.

The "short form 36" (SF-36)^[21] was used to evaluate the quality of life of the participants. The questionnaire consisted of 36 items related to eight domains covering different concepts of health, functional capacity, physical role, pain, general health, vitality, social aspects, emotional role and mental health.

Participants in the intervention group received a manual with illustrations and explanations to be held at home for three months and they received orientation from the therapist at the time of the delivery of the material. The first evaluation was made at this time; the second was made after three months. Figure 1 shows the prepared manual.

The therapist remained available for any questions

and followed up these patients monthly by phone.

Patients were aware regarding diaphragmatic breathing and instructed to perform this breathing in all the exercises.

In addition to the diaphragmatic breathing, the

exercises described in the manual were: Diaphragmatic isometric exercise with the patient in the supine position and 1kg of weight placed on the diaphragm muscle, exercise with Threshold inspiratory muscular training (IMT)[®] (Philips Respironics[®]), elevation of upper limbs

¹Difference between groups; ²Difference in the intervention group after three months. MIP (cmH₂O): Maximal inspiratory pressure; MEP (cmH₂O): Maximal expiratory pressure; EMG: Electromyography; FVC: Forced vital capacity; FEV₁: Forced expiratory volume in one second; FEF_{25%-75%}: Forced expiratory flow rate at 25%-75%.

with the help of a bat and strengthening the abdominal muscles.

The manual contained information of the possible complications during the postoperative period. It was highlighted the importance of bronchial hygiene and the proper way to cough in the postoperative period. Patients were instructed to perform the exercises in three sets of fifteen repetitions.

The control group did not perform the exercises; the second evaluation was done three months after the first.

The patients' tolerance was a parameter for the choice of load for training with the Threshold IMT[®], since it is already established in the literature that liver disease patients have fatigue^[17,22,23] and interrupt the exercise early with low peak VO₂^[15,18].

The manual also contained orientation for patients regarding the avoidance of alcohol, cigarettes, sweets and fried foods and had information about the importance of exercises during postoperative recovery from liver transplantation, especially concerning bronchial hygiene and effective cough.

Statistical analysis

The Statistical Analysis System (SAS) System for Windows (SAS Institute Inc, Cary, NC, United States), version 9.2 was used for statistical analysis.

Position and dispersion measures were used for numerical variables and frequency tables for categorical variables, for descriptive analysis.

For comparison of proportions, the χ^2 test or Fisher's exact test were used when necessary. For comparison of numerical measurements between two groups the exact Mann-Whitney test was used. For comparison of measurements between groups and times, ANOVA for repeated measurements was employed or post hoc transformation. To compare changes in proportions, the

McNemar test was used. The significance level used was $P < 0.05$.

RESULTS

There was significant difference ($P = 0.01$) between the first (initial) and the third month (final) MIP in the control group and in the intervention group, but there was no difference ($P = 0.45$) between the groups.

After three months, the electromyography of the diaphragm represented by RMS decreased in the intervention group ($P = 0.001$) compared to that of the control group.

The score of the domain functional capacity (SF-36) was not statistically different between the groups; however, in the intervention group there was a significant increase in the score ($P = 0.006$) after three months.

The general health and mental health domains received higher scores after three months in the control group ($P = 0.01$) and the intervention group ($P = 0.004$), but there was no significant difference between them.

The descriptive analysis and comparison between groups are detailed in Table 2.

In the first evaluation, 10 patients had ascites in the control group and 3 had ascites in the intervention group. After three months, 13 patients had ascites in the control group and 5 patients had ascites in the intervention group.

The comparison between the presence of initial ascites with the presence of ascites was performed after three months in the control group ($P = 0.083$) and intervention group ($P = 0.31$). There was no significant difference in relation to the presence of ascites after three months between groups ($P = 0.21$).

The presence or absence of ascites three months after the first assessment was compared with age, BMI, MIP, MEP, RMS of the diaphragm and rectus abdominis,

FVC, FEV₁, FEF_{25%-75%} and the SF-36 domains.

There was no significant difference between the variables in the control group. In the intervention group, patients with ascites at the end of the time period had decrease of scores on the social aspects domain ($P = 0.023$) compared to those who had no ascites.

DISCUSSION

Patients on the waiting list for liver transplantation waiting a long time for the new organ and consequently, there may be complications in this period, such as sarcopenia. Therefore, rehabilitation becomes an important alternative in order to reduce inactivity, increase muscle performance, as well as exercise tolerance, and to avoid complications in the post-operative period^[24].

The results of this study showed that most patients were men, aged above 50 years and BMI revealing overweight. These findings are consistent with other studies^[9,25].

Several authors^[26,27] have recommended IMT in order to minimize respiratory muscle dysfunction in the postoperative period of cardiac, thoracic and abdominal surgery. Despite the literature employing a 40%^[28] initial MIP load for IMT and increasing it over time training, patients' tolerance has been responsible for the choice of load for training with the Threshold IMT[®], since it is already established in the literature that liver disease patients have fatigue^[20-23].

In the current study, there was a significant increase of MIP in the intervention group after the final evaluation.

In the study of Gosselink *et al.*^[29], a meta-analysis was performed on the effects of IMT in patients with chronic obstructive pulmonary disease. The study revealed better results in the inspiratory muscle strength, functional capacity and dyspnea after strength training.

In the study by Serón *et al.*^[28], the Threshold IMT[®] was effective for strengthening inspiratory muscles.

One possible explanation for the non-significant increase in MEP in the present study is that the main focus of the prepared manual was to strengthen the inspiratory muscles. Unlike what was expected, the control group also showed a significant increase in MIP after three months. One possible explanation is that the patients were not discouraged from performing physical activities or were advised to stop exercising because they were participating in the research.

The intervention proved to be effective in this study; after three months there was a reduction of the RMS of the diaphragm in the intervention group, and due to the increase of the inspiratory muscle strength, the diaphragm needed to perform less force in order to overcome the same resistance. In other words, the action's potential decreased since only a small amount of fibers were needed to be recruited during normal breathing. No articles on the effects of inspiratory muscle training on electromyography of the diaphragm have been found; therefore, further studies are required for a

broader discussion on the issue.

The exercise program also provided relevant improvement in functional capacity domain. This means that the difficulty in performing daily life activities decreased, and individuals became more active and willing. Regarding liver transplant, two authors^[30,31] proved that the quality of life can be improved with physical exercises.

The general and mental health areas received higher scores after three months in the intervention and control groups, demonstrating that the patients' perception of their health improved. The control group may have presented positive changes in the mentioned aspects for the same reasons already explained above.

Also, one must consider, on average, an increase of some values of variables (FVC, FEV₁, FEF 25%-75%, vitality, social aspects and emotional role) at the end time, in the intervention group, showing the positive effects of the intervention performed.

The two groups were not ideally matched, because the incidence of ascites was lower in the intervention group in the first evaluation and after three months. However, the presence of ascites did not affect the respiratory variables evaluated. In the intervention group, patients with ascites had worse scores on the social aspects domain. In the final stage of cirrhosis, ascites causes the appearance of symptoms that can impair the performance of activities of daily living^[32]. All these factors contribute to social isolation being away from work and low self-esteem. According to Saab *et al.*^[33], the ascites, associated or not with encephalopathy, was associated with poorer quality of life.

Certainly, new studies on the benefits of breathing exercises will be necessary after liver transplantation. However, the results of the present study are satisfactory regarding the improvement of quality of life as well as the electrical diaphragm activity result using the exercises learnt in the preoperative manual. This study is the beginning of exercise protocols developed specifically for this group, and it may prompt new research with a larger population sample.

ACKNOWLEDGMENTS

The authors also thank Philips Respironics[®] who kindly provided the Threshold IMT[®] for the study. Our acknowledgments to Stephen A Shaw for the English revision.

COMMENTS

Background

Some changes usually affect the quality of life of patients with chronic liver disease, such as fatigue, malnutrition and predominance of anaerobic metabolism. In order to improve the functionality, muscle strength and physical conditioning of the liver disease patients and physically prepare them for transplantation, minimizing possible postoperative complications, specific preoperative rehabilitation programs for this population become necessary.

Research frontiers

The liver transplant waiting list patients belong to the Unit of Liver Trans-

plantation at the Hospital de Clinicas/Unicamp, and are from several cities in the state of Sao Paulo, and other regions of Brazil. Therefore, it was difficult to weekly or even monthly require patients to participate in evaluations or in the respiratory intervention group at the Unit of Liver Transplantation. In addition, these patients are constantly doing exams, have difficult schedules, and often need help for locomotion. As a result, these patients were followed up by phone each month. Despite these hardships, in the current study, only three participants were excluded from the trial, since they declined to perform the exercises. The other patients satisfactorily agreed to the exercises. Due to lack of financial resources, the authors used the analog manometer and some Thresholds inspiratory muscular training (IMT)[®] were donated by Philips Respiration[®]. Each participant remained with the Threshold IMT[®] for three months. This contributed to the reduced sample in the intervention group, in addition to other factors, such as death, abandonment or the transplant itself.

Innovations and breakthroughs

An illustrative and explanatory manual was prepared with breathing exercises to be performed by patients at home, for a period of three months. Monthly, they were accompanied by the same researcher by telephone, and doubts were resolved.

Applications

The results found in the group that performed the exercises were encouraging; there was a decrease in the electrical activity of the diaphragm and increase some scores of the short form 36 domains. These results represent a start for new rehabilitation programs which are developed preoperatively. Still, the proposed manual in this article may be used in other studies, with extended samples, and further positive results may be found.

Terminology

The manual of the exercises was prepared by the researchers and consisted of breathing exercises, including the Threshold IMT[®]. The Threshold is a device designed for respiratory muscle training in which the load is independent of the air flow. It consists of a chamber where at the distal end there is a valve which is held closed by the positive pressure (graduated in cmH₂O) of a spring. If a negative pressure with an absolute value greater than the spring pressure is generated, the valve will open and allow the air passage.

Peer-review

Studies on the effects of exercises, mainly those on breathing, in liver disease awaiting transplantation are rare in the literature. This issue can spark interest in other researchers who want to study the manual exercises in an enlarged sample of liver disease patients and who also want to follow up these patients postoperatively, evaluating the effects of exercises in this period. Another possibility is to use this study as a basis for development of new specific exercise programs before surgery for this population.

Abstract

Total pancreatectomy and islet auto transplantation is a good option for chronic pancreatitis patients who suffer from significant pain, poor quality of life, and the potential of type 3C diabetes and pancreatic cancer. Portal vein thrombosis is the most feared complication of the surgery and chances are increased if the patient has a hypercoagulable disorder. We present a challenging case of islet auto transplantation from our institution. A 29-year-old woman with plasminogen activator inhibitor-4G/4G variant and a clinical history of venous thrombosis was successfully managed with a precise peri- and post-operative anticoagulation protocol. In this paper we discuss the anti-coagulation protocol for safely and successfully caring out islet transplantation and associated risks and benefits.

Key words: Islet transplantation; Autoislet transplant; Pancreatectomy; Chronic pancreatitis; Hypercoagulable disorder; Heparin

INTRODUCTION

Patients with chronic pancreatitis suffer from significant pain and associated decrease in the quality of life and also a potential of forming type 3C diabetes and the pancreatic cancers^[1-4]. It is an inflammatory disease, which is characterized by irreversible, morphological changes that cause permanent loss of function, and fibrosis and development of severe pain and complications. Over time, fibrosis in the pancreas, results in destruction of the islet cells, and patients are at risk of diabetes^[1,3,4]. The risk of pancreatic cancer is 10 to 15 fold higher in chronic pancreatitis patients and if it is associated with hereditary pancreatitis with genetic mutations, then the lifetime risk is 75%^[2,5]. Many surgical, medical, endoscopic and intervention radiological treatments are applied to these patients, despite which many still suffer from continuous dependence on narcotics and bad quality of life.

Removal of the pancreas followed by autologous islet cell transplantation is a great option for selected patients with chronic pancreatitis^[6-14]. Islet auto transplantation helps to take care of 3 Ps that are necessary for this disorder: (1) Pain relief; (2) Prevention of the brittle diabetes mellitus; and (3) Prevention of pancreatic cancer^[15]. At times, the results of the autologous islet cell transplantation are criticized because the variable insulin independence rate reported^[16,17]. We have previously argued that the insulin independence is not the only marker of the success, the wide marker of the success would be euglycemia, preventing cancer and having better quality of life^[15].

Good outcomes of islet auto transplantation are based on various factors from selection of the case to performing safe surgery, good isolation and safe injection of the cells followed by good engraftment of the islet cells. Once the islets are isolated and brought back to the patient, a small angiocatheter is introduced in one of the vessels either the splenic vein stump or any vessels draining into the superior mesenteric vein to infuse these cells into the portal vein so that they can flow to the liver. Safety is important in terms of decreasing the risk of thrombogenesis in these vessels by paying attention to the details of the procedure, the physiology of the patient, and the liver pathology^[18]. Surgical complications are most dreaded compared to the long-term outcome and insulin dependency because they can add to significant morbidity and therefore poor quality of life to the patient. Porto-venous thrombosis would arguably be the most important complication. It can vary in magnitude from a segmental vein to thrombosis of the main portal vein and potentially complete thrombosis of the superior mesenteric access requiring a bowel resection and consequent problems^[19,20]. The risk of portal vein thrombosis will be increased if the patient has a hypercoagulable disorder.

We report a case from our new program with physiological challenge in the context of issues described. These include a case of islet autotransplantation per-

formed in a patient with a hypercoagulable disorder. To our knowledge, it is the first such case in the literature.

CASE REPORT

The patient was a 29-year-old lady (body weight 83 kg, body mass index 29.3 kg/m²) with a history of chronic abdominal pain related to chronic pancreatitis. At the time of her initial visit she was in the emergency room or hospitalized on a weekly basis. Her history dated back 13 years and she had been on narcotics for 6 years. She had undergone 7 endoscopic retrograde cholangiopancreatographies over the years and magnetic resonance imaging (MRI) had shown pancreas divisum. Our own MRI scoring system^[21] indicated minimal pancreatic damage (atrophy, 1/6). The pre-operative C-peptide was 1.75 ng/mL and hemoglobin A1c was 5.5%. We also considered gall stone disease, alcohol and completed a genetic analysis for common hereditary gene mutations that are causally associated with chronic pancreatitis. She had also reported having developed thrombosis related to PICC line placement on multiple occasions at an outside institution. During her evaluation we obtained hypercoagulability studies, which included factor V Leiden mutation, prothrombin gene mutation, plasminogen activator inhibitor-1 (*PAI-1*) gene mutation and level, clotting factor VII, protein C, protein S levels, methylenetetrahydrofolate reductase (*MTHFR*) gene mutations and an autoimmune thrombophilia screen. She was found to be homozygous for the 4G variant of the *PAI-1* gene and heterozygote for the *MTHFR* A1298C.

Her surgery was performed using the technique described earlier^[22] and islet infusion was also done through splenic vein stump. Islet preparation was performed at the current good manufacturing practice facility in the Islet Cell Laboratory at the Georgetown University Hospital.

The pancreas was explanted post 1 and half min of warm ischemia time and placed immediately into an ice-cold Viaspan solution in a sterile container and delivered to the lab on ice. On arrival of the lab, the pancreatic duct was cannulated after trimming. The pancreas was then divided into two portions at the neck. On the cut surface both openings of the pancreatic duct were cannulated with a 14-gauge cannula. An enzyme solution containing collagenase HA and Thermolysin (Vitacyte, Indiana, United States) was infused into the pancreas through the cannula and connected with a 60 cc syringe through an extension tube. In addition, the parenchyma was then repeatedly injected with the enzyme solution using a 60 cc syringe. The thoroughly distended pancreas was then digested using the semi-automated method of Ricordi^[23]. The pancreas weighed 65.9 g. The total cold ischemia time from removal of the pancreas to completion of trimming was 51 min. The digestion rate was 92.2% post 18 min of digestion. After purification using a modified continuous density gradient method with cell processor COBE2991^[24], the

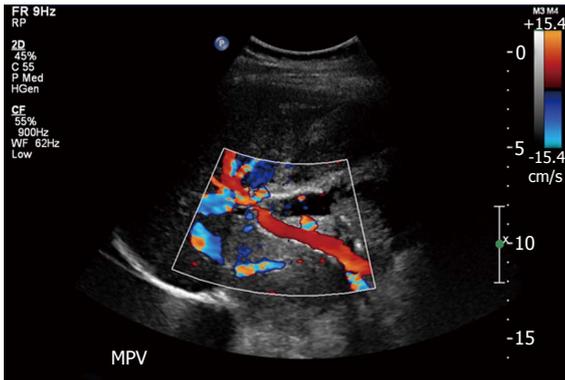

Figure 1 Post-operative Doppler ultrasound of the liver demonstrating widely patent portal vein with normal direction of blood flow. MPV: Main portal vein.

final pellet was reduced from 36 to 12 mL^[25]. The total islet yield was 459164 islet equivalents (IEQ) which was quantified as IEQ by normalizing the islet mass to an islet size of 150 μ m diameter. The islet recovery was 7552 IEQ/g of pancreas tissue. The final pellet was suspended in the transplantation media (5% human serum albumin) containing 35 units of Heparin per kilogram of patient body weight. In total, 5532 IEQ per kilogram recipient body weight (IEQ/kg) of islets were available.

The islet infusion in to the liver involved a venous catheter placed in a splenic vein stump and advanced intravenously towards the portal vein. In order to reduce complication rates of acute portal hypertension and thrombosis in this case at the most, low-volume (12 mL pellet) prepared through purification procedure, was infused. We gave the patient 35 U/kg intravenously in addition to the 35 U/kg of Heparin along with islet infusion; the patient therefore received a total dose of 70 U/kg of heparin. Portal pressures were closely monitored during infusion, because of an established tenfold (1.52%-15.2%) increase in the risk of thrombosis with portal pressure changes above 25 cm H₂O^[25]. The pre infusion portal pressure was 4.5 cm/saline and the post infusion pressure was 15 cm/saline.

Heparin was started intra-operatively. Fifty IU/kg of body weight bolus before the infusion of islet cells followed by 25000 IU mixed with 500 mL of D5 1/2 normal saline at the rate of 10 IU/kg per hour. Postoperatively, the patient was continued on a heparin drip according to our protocol and activated thromboplastin time was maintained in the range of 50 to 60 s. At the end of three days when she started on clear liquid diet, we continued the patient on low molecular weight heparin and monitored with anti-Xa activity factors maintained between 0.6 to 1 international units/mL. Postoperative Doppler ultrasound of the liver was performed on day 1, 2 and 5 and once weekly for one month and biweekly for another two months. Specifically, the doppler studies during the first week demonstrated patency and normal flow in the portal veins, hepatic arteries and veins; the main portal vein peak velocities

ranged between 25-38 cm/s, left and right portal vein velocities ranged from 11-27 cm/s (Figure 1). The patient was discharge home after 14 d. At three months the patient was off insulin with a C-peptide of 1.95 ng/mL. At the end of three months, the dose of low molecular weight heparin was reduced to maintain anti-Xa level between 0.3 to 0.6 international units/mL. Six months after the surgery, the low molecular weight heparin was discontinued after consultation with hematology. The patient did not develop venous thrombosis of any form during follow-up and was able to resume a normal life.

DISCUSSION

Total pancreatectomy and islet auto transplantation has been described by some as a radical option though it has a clear role for patients with chronic pancreatitis. Patients undergo multiple endoscopic procedures and fail to get a satisfactory outcome and all the time their narcotic requirement keeps escalating. This definitive procedure is feared because of surgical complications like portal vein thrombosis and also the failure of the islets to prevent diabetes.

Hypercoagulability is a significant risk factor for portal vein thrombosis. In one study 28% of patients with portal vein thrombosis had an inherited thrombophilic disorder^[26]. Of this factor V Leiden mutation was the most common (11%) followed by anti-thrombin III deficiency (11%) and protein c deficiency (8%). Prothrombin gene mutations are also commonly implicated in venous thrombosis^[27]. The PAI 4G variant and MTHFR mutations are considered less severe though do have an increased risk for venous thrombosis after major surgery including transplantation. Such situations are challenging because of the post-operative risk of thrombosis leading to graft failure or bleeding from anticoagulation. However, many such transplants are carried out in a safe manner. Our patient had a *PAI-1* gene mutation, which was only diagnosed after diligent history taking helped us to obtain the risk in this case. The authors have previously worked at different auto islet cell transplantation centers and as with other surgeries it was not routine to do a hypercoagulable workup since obtaining this panel in every patient is very expensive and may not be cost effective^[15,18,22].

Portal vein thrombosis after islet auto-transplant though uncommon, can be risky and life threatening. There are few previous individual reports of portal vein thrombosis after islet auto-transplantation^[20] and one series that indicated a prevalence of 3.7% after clinical islet transplantation^[28]. There is however no systematic study of the cause of thrombosis in such cases. In a previous publication we have noted that there may be unrecognized mild fibrosis and or steatosis^[18]. We were however unable to show that any specific histologic pattern was more susceptible to venous thrombus formation. To prevent portal venous thrombosis in patients such as ours above with pre-existing risk factors it is imperative to identify at risk patients and manage these

patients with therapeutic anticoagulation with heparin. Heparin also has advantage in the islet engraftment process and hence it has dual advantage, but has a significant risk of post-operative bleeding and hence it is very important that the surgery is performed with good hemostasis. Heparin is given by almost all the centers performing auto-islet cell transplant to their patients. However, there are no consensus guidelines on the amount and duration it needs to given. We adapted an approach in which we start a heparin drip in operating room at the time of starting islet infusion after giving bolus. It is continued for the next three days maintaining the activated thromboplastin time in the range of 50 to 60 s. At the end of three days when the patient starts taking clears, we continue with low molecular weight heparin two times a day dose based on patient's weight with anti-Xa activity factors maintained between 0.6 to 1 international units/mL. Patient's postoperative Doppler ultrasound on the liver is done on postoperative day 1, 2 and 5 and subsequently was done once weekly for one month and then twice weekly for another two months if they are at high risk. High risk is defined by three main factor: (1) hypercoagulable disorder; (2) previous history of deep venous thrombosis other than segmental splenic vein thrombosis related to chronic pancreatitis (even if the hypercoagulable panel is normal); and (3) high portal pressure after infusion (more than 25 cm of saline). If the patient is high risk then at the end of three months, low molecular weight heparin dose is reduced to maintain anti-Xa level to be between 0.3 to 0.6 international units/mL. Six months after the surgery, the low molecular weight heparin is discontinued after consultation with hematology. If the patient is not at high risk then after two weeks dose is reduced and then stopped after another two weeks.

In summary, islet auto transplantation in itself is a challenging procedure and even more challenges can arise medically if there are physiological challenges like a hypercoagulable disorder. Despite all these challenges with careful teamwork and experience, these patients can be safely managed.

Islet auto transplantation is a challenging procedure and even more challenges can arise medically; if there are physiological challenges like a hypercoagulable disorder. Despite all these challenges with careful teamwork and experience, these patients can be safely managed.

COMMENTS

Case characteristics

Total pancreatectomy and islet autotransplantation complicated by primary hypercoagulability that presented as repeated thrombosis of indwelling venous lines.

Clinical diagnosis

The presentation was characterized by symptoms of chronic pancreatitis and a history of deep venous thrombosis.

Differential diagnosis

An alternative explanation to a primary hypercoagulability to account for thrombosis if intravenous lines would be that the presence of intravenous lines themselves was the cause of catheter thrombosis.

Laboratory findings

Screening for hypercoagulability included plasma proteins, genetic defects and autoimmunity as potential causes of thrombosis with the patient having a plasminogen activator inhibitor-1 variant.

Imaging diagnosis

Serial ultrasounds were used to monitor for portal vein thrombosis after islet infusion in to the portal vein after total pancreatectomy.

Pathological diagnosis

Confirmation of chronic pancreatitis as the cause for abdominal pain.

Treatment

Heparin infusion followed by low molecular weight heparin and aspirin as prophylaxis for a prothrombotic state.

Related reports

There are previous cases of a hypercoagulability giving rise to deep venous thrombosis, most notably with factor V Leiden mutation.

Term explanation

Hypercoagulability refers to a pathological increase in the tendency to form intravascular clots. Patients undergoing major intraabdominal operations should be screened for a hypercoagulable state if there is any history of abnormal venous clot formation.

Peer-review

This a successful case of islet autotransplantation performed in a chronic pancreatitis patient suffered from significant pain with a hypercoagulable disorder. It is imperative to identify at risk patients and manage these patients with therapeutic anticoagulation with heparin to prevent portal venous thrombosis in patients with pre-existing risk factors. The author's careful teamwork and experience is helpful for safely managing these patients.

Abstract

Kidney transplantation is the treatment of choice for a significant number of patients with end-stage renal disease. Although immunosuppression therapy improves graft and patient's survival, it is a major risk factor for infection following kidney transplantation altering clinical manifestations of the infectious diseases and complicating both the diagnosis and management of renal transplant recipients (RTRs). Existing literature is very limited regarding osteomyelitis in RTRs. Sternoclavicular osteomyelitis is rare and has been mainly reported after contiguous spread of infection or direct traumatic seeding of the bacteria. We present an interesting case of acute, bacterial sternoclavicular osteomyelitis in a long-term RTR. Blood cultures were positive for *Streptococcus mitis*, while the portal entry site was not identified. Magnetic resonance imaging of the sternoclavicular region and a three-phase bone scan were positive for sternoclavicular osteomyelitis. Eventually, the patient was successfully treated with Daptomycin as monotherapy. In the presence of immunosuppression, the transplant physician should always remain alert for opportunistic pathogens or unusual location of osteomyelitis.

Core tip: Although immunosuppression therapy improves kidney allograft and patient's survival, it is a major risk factor for infection following kidney transplantation, altering the clinical manifestations of the infectious diseases and complicating both the diagnosis and management of renal transplant recipients (RTRs). Existing literature regarding osteomyelitis in RTRs is very limited while sternoclavicular osteomyelitis is a rare entity presenting with its own unique set of risk factors and complications. Infections caused by unconventional

pathogens with unconventional infection sites are being increasingly diagnosed in RTRs and the physician should always remain alert when dealing with these patients.

INTRODUCTION

Kidney transplantation is the treatment of choice for a significant number of patients with end-stage renal disease. Renal transplant recipients (RTRs) benefit from a longer life expectancy and a better quality of life. Despite, recent accomplishments in the field of kidney transplantation, both short- and long-term medical complications still exist. Infectious diseases constitute one of the most common complications after kidney transplantation and the second most common cause of death among RTRs with a functioning graft^[1]. Even though immunosuppressive therapy improves graft and patient survival, it has been reported that the increasing load of maintenance immunosuppression predisposes RTRs to clinically important infectious sequelae. The plethora, diversity and consequences of infectious complications in kidney transplantation have led to the accumulation of a growing amount of evidence describing the problem and trying at the same time to establish guidance for optimal management and support of these patients^[1].

Existing literature comprises of a very small number of cases reporting osteomyelitis in RTRs. Traditional risk factors for osteomyelitis include trauma to the bone and trauma near a site of infection, the presence of sickle-cell disease, rheumatoid arthritis, diabetes mellitus, dialysis and related procedures, as well as immunosuppression. Most cases of osteomyelitis in adults are of hematogenous origin and primarily affect the spine^[2]. The sternoclavicular joint is less commonly associated with osteomyelitis but presents its own unique set of risk factors and complications. We present a rare case of an adult long-term RTR who was diagnosed with acute, hematogenous sternoclavicular osteomyelitis due to streptococcus bacteremia whereas remarkably a portal entry site was not identified.

CASE REPORT

A 50-year-old male RTR, presented at the emergency department of our Tertiary University Hospital complaining about fever, chills and pain over the left sternoclavicular area, radiating to the shoulder and neck for the last two days. He denied any recent history of trauma, intravenous drug administration or dental procedure. Physical examination revealed pyrexia and

marked tenderness over the left sternoclavicular area which appeared warm, red and swollen. Laboratory exams showed an elevated white blood cell count and C-reactive protein (Table 1), while the cervical spine and chest X-rays were unremarkable. The patient was directly admitted to the Renal Unit Ward and serial blood cultures were taken.

The patient was a long-term RTR regularly followed up at the renal transplant outpatient clinic (OC) of our Hospital during the last year. On his last visit a month ago, he was asymptomatic with unremarkable clinical findings and stable renal function, with an estimated glomerular filtration rate (eGFR) of 41 mL/min per 1.73 m² (Modification of Diet in Renal Disease equation). Maintenance immunosuppression therapy included cyclosporine (75 mg bid, C2 levels of 436 ng/mL), mycophenolate mofetil (1 g bid) as well as prednisolone (5 mg qd). The patient was diagnosed with chronic kidney disease of unknown etiology more than twenty years ago, was treated with hemodialysis for approximately 7 years and subsequently received a renal allograft from a cadaveric donor 14 years ago. Three months after the transplantation, the patient had suffered an acute rejection episode, which was successfully treated with intravenous pulses of steroids. The rest current medical history included well controlled arterial hypertension (antihypertensive treatment: Amlodipine 10 mg qd) and hip osteopenia diagnosed by a Dual-energy X-ray absorptiometry scan (DEXA) (Alfacalcidol 0.25 µg qd).

Immediately after admission, imaging of the sternoclavicular area excluded the presence of a fluid collection that could be aspirated. Considering the patient's clinical findings and his long-term immunocompromised status, empirical treatment for septic arthritis with Vancomycin (dose adjusted to eGFR) and Ciprofloxacin was commenced. Further diagnostic workup included a dental examination which did not reveal a possible portal entry site for the bacteria. Abdominal ultrasound findings were unremarkable while ultrasound of the renal allograft was within normal. Urine cultures were negative. Transthoracic echocardiography revealed mild mitral regurgitation and calcifications of the aortic cusps and mitral annulus. A transesophageal ultrasound was subsequently performed, ruling out concomitant endocarditis.

All blood cultures became positive within 48 h for *Streptococcus mitis* (Viridans group streptococcus) with a good sensitivity profile, including Glycopeptides (Vancomycin minimum inhibitory concentration < 1 mg/L) and Daptomycin. Vancomycin treatment, targeting trough blood levels of 15-20 mg/L, was continued whereas Ciprofloxacin was stopped. In order to further evaluate the sternoclavicular joint and differentiate between septic arthritis and osteomyelitis, magnetic resonance imaging (MRI) (no gadolinium administration) of the region was performed. The MRI showed bone edema of the left intraarticular surface of the sternum and the clavicle together with soft tissue

Table 1 Patient's laboratory findings at admission and on discharge

	At admission	On discharge
Hemoglobin (g/dL)	13.3	11.3
WBC (/ μ L)	11760	11900
Neutro-Lympho-Mono (%)	83-6-10	83-7-7
PLT (/ μ L)	163000	290000
ESR (mm/h)	41	15
CRP (mg/L)	130	17
eGFR (mL/min per 1.73 m ²)	36	40
Urea (mg/dL)	86	76
Sodium (mEq/L)	136	139
Potassium (mEq/L)	4.2	4.3
PTH (pg/mL)	75	80
Phosphate (mg/dL)	3.9	2.7
Albumin (g/L)	3.4	3.4

WBC: White blood count; PLT: Platelets; ESR: Erythrocyte sedimentation rate; CRP: C-reactive protein; eGFR: Estimate glomerular filtration rate (calculated by CKD-EPI formula); PTH: Parathyroid hormone.

edema, findings suggestive of acute sternoclavicular osteomyelitis (Figure 1). No intraarticular fluid collection was observed. A three-phase whole body bone scan (technetium-99m methylene diphosphonate) was subsequently performed, which showed focally intense, increased activity over the left sternoclavicular area, a finding positive for osteomyelitis (Figure 2).

A week from admission the patient continued to have low grade fever and was dependent on analgesics for pain control, despite achieving adequate Vancomycin trough levels. Considering the diagnosis of acute bacterial osteomyelitis with an unconventional location, the patient's clinical course, the need of long-term intravenous antibiotic treatment, the difficulties of Vancomycin treatment (monitoring levels and possible related nephrotoxicity) and practical issues (patient's residence was far from the hospital), the decision of switching antimicrobial treatment to Daptomycin as monotherapy (dose 4 mg/kg per 24 h) was taken. The patient became afebrile within a few days, inflammatory markers gradually declined and his physical status progressively improved (Table 1). No surgical debridement was performed as there was no evidence of a soft tissue abscess or subperiosteal collection, and no concomitant joint infection was diagnosed. The patient was discharged from the hospital a fortnight after admission, with recommendations for continuation of antimicrobial treatment for a total period of 6 wk and close medical follow-up at the renal transplant OC.

The patient remains asymptomatic and with preserved renal function six months after the completion of the antimicrobial treatment.

DISCUSSION

In the modern era of renal transplantation infectious diseases remain a major cause of morbidity and mortality in RTRs^[1]. The introduction of new immunosuppressant agents in renal transplantation along with the increasing

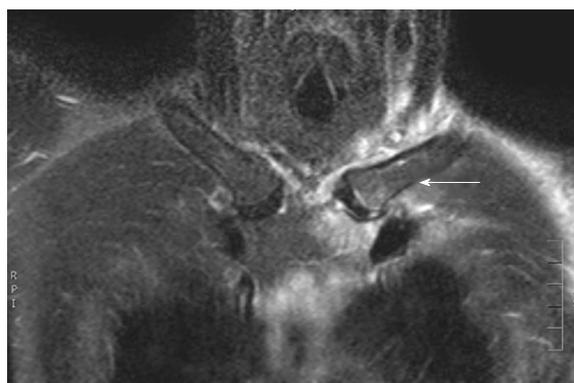

Figure 1 Magnetic resonance imaging of the sternoclavicular area showing edema on the left intraarticular surface of the sternum and the clavicle together with edema of the surrounding soft tissues (arrow).

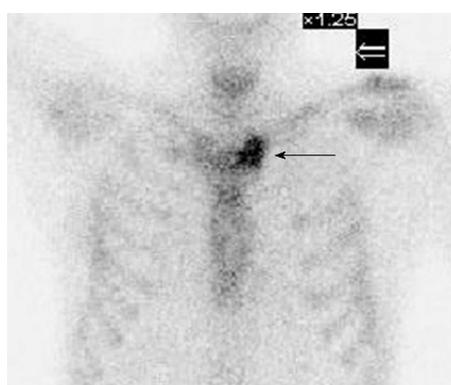

Figure 2 Three-phase bone scan (technetium-99m methylene diphosphonate) showing intense increased focal activity uptake over the left sternoclavicular area (arrow).

resistance of pathogens to antimicrobial agents worldwide are partially responsible for the emergence of rare infectious clinical cases which constitute a major challenge for the transplant clinicians. Here, we report an interesting, noteworthy case of acute bacterial sternoclavicular osteomyelitis in a long-term adult RTR, with no portal entry site for the bacteria which was successfully treated with Daptomycin as monotherapy.

In general, traditional risk factors for osteomyelitis include trauma to the bone and trauma near a site of infection, the presence of sickle-cell disease, rheumatoid arthritis, diabetes mellitus, dialysis and related procedures, as well as immunosuppression. Most cases of osteomyelitis in adults are of hematogenous origin and primarily affect the spine^[2]. The clavicle contains scanty red marrow and sparse vascular supply. It is an exceedingly rare site for osteomyelitis, especially of hematogenous origin^[3]. Clavicular osteomyelitis is rare and has been mainly reported after contiguous spread of infection or direct traumatic seeding of the bacteria^[4]. Thus, there are reports in the literature of sternoclavicular osteomyelitis following central line placement^[5], major head and neck surgery and radiation therapy to head and neck tumors^[6]. Intravenous drug abusers are an especially high risk group for clavicular

osteomyelitis and septic arthritis^[7].

With regard to the responsible pathogens, *S. aureus* is the most commonly isolated organism in most types of osteomyelitis, affecting 50%-70% of cases, while other gram positive cocci and gram negative bacilli are identified less often, accounting for approximately 20%-25% of acute osteomyelitis cases respectively^[8,9]. Treatment of osteomyelitis requires prolonged antimicrobial therapy and frequently adjunctive surgical therapy for the debridement of necrotic material in order to eradicate the infection. Antibiotic therapy should be adjusted to culture and susceptibility results. If culture results are not obtainable, broad spectrum empiric therapy, including Vancomycin together with an agent with activity against gram negative organisms, should be administered^[10-12].

Regarding selection of antimicrobial treatment in our patient, Daptomycin was finally chosen as it has exhibited activity in the treatment of gram positive bone and joint infections^[13]. It is rapidly bactericidal and appears effective against multidrug-resistant gram positive pathogens, commonly found in osteomyelitis and joint infections, even when other first-line antibacterial treatments have failed^[14-16]. Daptomycin is well tolerated; it has a relatively safe side effect profile, no interactions with calcineurin inhibitors, and a low risk of spontaneous resistance. The mode of action, rapid *in vitro* bactericidal activity against growing and stationary-phase bacteria, a once-daily dosing regimen, and no requirement for drug monitoring contribute to its potential therapeutic utility^[17].

Existing literature comprises of a very small number of cases reporting osteomyelitis in RTRs, which involve locations such as the ankle, the symphysis pubis or the vertebral column^[13,18-21], whereas there are no reports in the literature regarding sternoclavicular osteomyelitis in RTRs. The additive effect of long-term immunosuppression treatment and possibly osteopenia (although previous routine DEXA scans revealed only hip localized osteopenia) rendered our patient among patients' subgroups with increased risk for osteomyelitis. Remarkably, a portal entry site for the bacteremia was not identified. Finally, the sternoclavicular bone was the solitary site of infection as demonstrated from the imaging studies.

Considering the immune suppressed status as a predisposing factor for infections as well as the growing number of RTRs, we might come across more cases of unconventional pathogens and sites of infection in the future^[22]. Prevention, vigilance and deep knowledge of the diagnostic and therapeutic management of infections could potentially mitigate the consequences for RTRs.

COMMENTS

Case characteristics

A 50-year-old male renal transplant recipient complained about fever, chills and pain over the left sternoclavicular area, radiating to the shoulder and neck for

the last two days.

Clinical diagnosis

Physical examination revealed pyrexia and marked tenderness over the left sternoclavicular area which appeared warm, red and swollen.

Differential diagnosis

Differential diagnosis was between septic arthritis and osteomyelitis.

Laboratory diagnosis

Laboratory exams showed an elevated white blood cell count and C-reactive protein and all blood cultures became positive within 48 h for *Streptococcus mitis*.

Imaging diagnosis

Magnetic resonance imaging (no gadolinium administration) of the region showed bone edema of the left intraarticular surface of the sternum and the clavicle together with soft tissue edema, without intraarticular fluid collection and a three-phase whole body bone scan [technetium-99m methylene diphosphonate (⁹⁹Tc-MDP)] showed focally intense, increased activity over the left sternoclavicular area, findings positive for osteomyelitis.

Treatment

Empirical treatment for septic arthritis with Vancomycin and Ciprofloxacin was commenced and subsequently switched to treatment with Daptomycin as monotherapy.

Related reports

Clavicular osteomyelitis is rare and has been mainly reported after contiguous spread of infection or direct traumatic seeding of the bacteria as occurs following central line placement, major head and neck surgery and radiation therapy to head and neck tumors.

Term explanation

A three-phase whole body bone scan is a ⁹⁹Tc-MDP based diagnostic test is used in nuclear medicine in order to detect different types of pathology in the bones. The three phases are the flow phase, the blood pool image and the delayed phase. Differential diagnosis is based on differential image processing from the three phases; Calcineurin inhibitors: Cyclosporine and Tacrolimus - are a class of immunosuppressive drugs which are used as first line agents for maintenance therapy after kidney transplantation.

Experiences and lessons

Considering the immune suppressed status as a predisposing factor for infections as well as the growing number of renal transplant recipients, the authors might come across more cases of unconventional pathogens and sites of infection in the future.

Peer-review

The authors describe a very unusual complication occurring late after renal transplantation. The case report is well written and useful for the reader just because of the unusual complication.

Abstract

The differential diagnoses of a cavitary lung lesion in renal transplant recipients would include infection, malignancy and less commonly inflammatory diseases. Bacterial infection, Tuberculosis, Nocardiosis, fungal infections like Aspergillosis and Cryptococcosis need to be considered in these patients. Pulmonary cryptococcosis usually presents 16-21 mo after transplantation, more frequently in patients who have a high level of cumulative immunosuppression. Here we discuss an interesting patient who never received any induction/anti-rejection therapy but developed both BK virus nephropathy as well as severe pulmonary Cryptococcal infection after remaining stable for 6 years after transplantation. This case highlights the risk of serious opportunistic infections even in apparently low immunologic risk transplant recipients many years after transplantation.

Key words: Lung cavity; Immunosuppression; Renal transplantation

INTRODUCTION

Fungal infections causing cavitory lung lesions usually manifest in transplant recipients who have received a high level of cumulative immunosuppression. We describe an unusual case, where a low risk transplant recipient who had been stable for 6 years developed severe pulmonary Cryptococcal disease and BK virus nephropathy.

CASE REPORT

A 40-year-old Indian man was admitted with low grade fever and dry cough for one month. He had end stage renal disease due to unclassified primary disease and had a live related renal transplantation with his sister as the donor in 2009. He was detected hepatitis B surface antigen (HBsAg) positive before transplantation and has been on Tenofovir since then. He received no induction and was initially maintained on Tacrolimus, Mycophenolate Mofetil (MMF) and Steroids. After a year, MMF was changed to Azathioprine due to financial constraints. He received Trimethoprim-Sulfamethoxazole for 6 mo after transplantation but no primary prophylaxis for Cytomegalovirus (CMV), Tuberculosis (TB) or fungal infection. His postoperative course was uneventful and he maintained serum creatinine of 1.1-1.2 mg/dL. He is a non smoker.

Clinically, the patient was febrile, hemodynamically stable and hypoxemic (SPO₂ 92% on room air) requiring oxygen by mask. Investigations revealed pancytopenia (Hb 7.4 g/dL, total leucocyte count -3400/cu mm, platelet count -87000/cu mm) and high serum creatinine (2.5 mg%). Azathioprine was stopped. Tacrolimus trough level was 3.7 ng/mL. Urinalysis was unremarkable. Graft biopsy showed BK virus (BKV) nephropathy and serum BKV plasma load was more than 10⁴ copies/mL.

He was started empirically on broad spectrum antibiotics. Blood and urine cultures and quantitative CMV PCR assay were non-contributory. A non-contrast CT thorax showed bilateral, multiple, diffuse centrilobular and peribronchovascular cavitating nodules coalescing to form areas of consolidation with a larger cavity in apico posterior segment of upper lobe of left lung (Figure 1). Bronchoscopy with bronchoalveolar lavage (BAL) fluid cultures was unrevealing. Serum Cryptococcal antigen was negative. Serum and BAL fluid galactomannan were negative.

Since patient continued to be febrile, computed

tomography guided biopsy of the cavitory lesion in the left lung was done and the histopathology (Figure 2) showed Cryptococcal infection. He was treated with liposomal Amphotericin for 6 wk and given Fluconazole prophylaxis. Flucytosine was not available at that time. Patient showed clinical as well as radiologic improvement and was discharged on oral fluconazole. His pulmonary infection has subsequently recurred and now he is being treated with a combination of Amphotericin and Flucytosine.

DISCUSSION

A renal transplant recipient may present with a cavitory lung lesion due to infection, malignancy (post-transplant lymphoproliferative disorder) or inflammatory disease, though infections are the predominant causative factor^[1-3]. TB is the commonest cause of cavitory lung lesions in endemic areas like India and patients may receive empiric anti-TB therapy if the index of suspicion for rarer infections is not high and investigations are non-contributory. Aspergillosis (either angioinvasive or chronic necrotizing form) is the most common fungal infection associated with cavitation. Other causes are Nocardiosis, Cryptococcosis, Actinomycosis and rarely Legionella pneumophila. In a sick patient, the possibility of septic emboli has to be kept in mind^[1,2].

Cryptococcosis is the third most common fungal infection seen in transplant recipients^[4,5]. It typically occurs late with median time to onset being 16 to 21 mo after renal transplantation. However our patient presented very late - 6 years after transplantation. So besides TB and fungal infection, post-transplant lymphoproliferative disease was an important differential diagnosis considered. All factors which increased the cumulative immunosuppression in patients increase the risk of disseminated Cryptococcal disease. Presence of chronic liver disease and use of steroids, T cell depleting antibodies and Alemtuzumab are specifically associated with increased risk of Cryptococcosis. Calcineurin inhibitor based regimens are believed to be protective, being associated more commonly with Cryptococcosis limited to lungs with less likelihood of dissemination^[5,6].

Our patient is HBsAg positive. But he had not received induction, had no history of rejection requiring pulse steroid therapy and has not been on MMF for 5 years. Though the apparent dose of immunosuppressive drugs given seems to be low, his cumulative immunosuppression level is definitely high as is suggested by the onset of late BKV associated nephropathy.

Cryptococcal infection commonly presents with neurologic disease (meningitis) or pneumonia. But it may also involve the skin and soft tissue, bones, joints and other organs like the liver and the kidney. Isolated pulmonary disease is uncommon seen in only 33% of the patients. Serum Cryptococcal antigen has 90% sensitivity in disseminated disease but may be

and dry cough for one month.

Clinical diagnosis

A febrile patient with respiratory symptoms.

Differential diagnosis

Chest infection-bacterial/Tuberculosis/fungal.

Laboratory diagnosis

Pancytopenia with high serum creatinine.

Imaging diagnosis

Non contrast computed tomography scan of chest showed bilateral, multiple, diffuse centrilobular and peribronchovascular cavitating nodules coalescing to form areas of consolidation with a larger cavity in apico posterior segment of upper lobe of left lung.

Pathological diagnosis

Biopsy from the lung lesion showed Cryptococcal infection and graft kidney biopsy showed BK virus associated nephropathy.

Treatment

He was treated with liposomal Amphotericin and Flucytosine.

Related reports

A renal transplant recipient may present with a cavitory lung lesion due to infection, malignancy (post-transplant lymphoproliferative disorder) or inflammatory disease, though infections are the predominant causative factor.

Term explanation

Cryptococcal infection is the third most common fungal infection seen in transplant recipients. It commonly presents with neurologic disease (meningitis) or pneumonia, but may also involve the skin and soft tissue, bones, joints and

other organs like the liver and the kidney.

Experiences and lessons

Tissue biopsy or culture is required to diagnose isolated pulmonary cryptococcosis. Early diagnosis and initiation of treatment is essential for survival.

Peer-review

The case discusses an important issue in patients with kidney transplantation.

AIM AND SCOPE

World Journal of Transplantation (*World J Transplant*, *WJT*, online ISSN 2220-3230, DOI: 10.5500) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJT covers topics concerning organ and tissue donation and preservation; tissue injury, repair, inflammation, and aging; immune recognition, regulation, effector mechanisms, and opportunities for induction of tolerance, thoracic transplantation (heart, lung), abdominal transplantation (kidney, liver, pancreas, islets), transplantation of tissues, cell therapy and islet transplantation, clinical transplantation, experimental transplantation, immunobiology and genomics, and xenotransplantation. The current columns of *WJT* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography.

AIM AND SCOPE

World Journal of Transplantation is now indexed in PubMed, PubMed Central.

Abstract

Organ transplantation saves thousands of lives every

year but the shortage of donors is a major limiting factor to increase transplantation rates. To allow more patients to be transplanted before they die on the wait-list an increase in the number of donors is necessary. Patients with devastating irreversible brain injury, if medically suitable, are potential deceased donors and strategies are needed to successfully convert them into actual donors. Multiple steps in the process of deceased organ donation can be targeted to increase the number of organs suitable for transplant. In this review, after describing this process, we discuss current challenges and potential strategies to expand the pool of deceased donors.

Key words: Consent; Eligible death; Imminent brain death; Organ procurement; Potential organ donor

Core tip: An increase in the number of donors is necessary to allow more patients to be transplanted before they die on the wait-list. Multiple steps in the process of deceased organ donation can be targeted to increase the number of organs suitable for transplant.

Girlanda R. Deceased organ donation for transplantation: Challenges and opportunities. *World J Transplant* 2016; 6(3): 451-459 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i3/451.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i3.451>

INTRODUCTION

Several obstacles have been overcome over the last few decades to make organ transplantation an effective life-saving treatment for many patients. Among them, the refinement of surgical techniques and the availability of effective immunosuppressive regimens against rejection

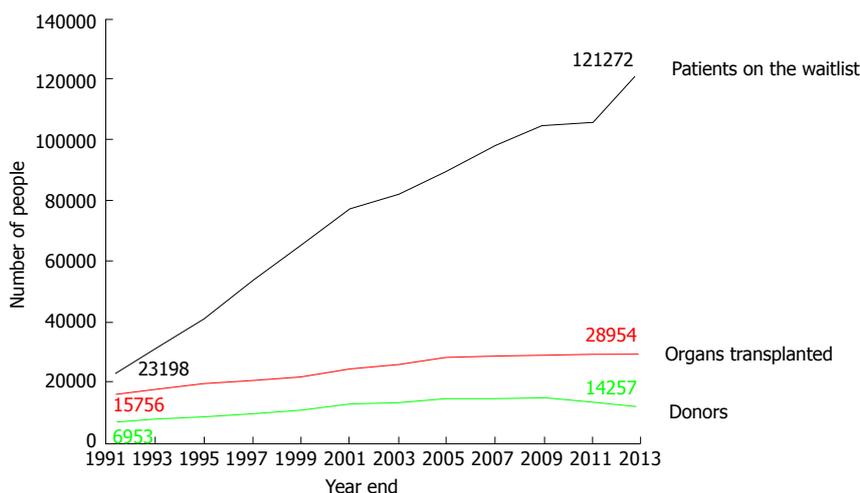

Figure 1 The gap between organs needed and organs available continues to grow. Available from: URL: <http://www.organdonor.gov/about/data.html>.

have played a major role. However, only the availability of donated organs from deceased persons (DD) has made it possible for organ transplantation to become an established, worldwide treatment for patients with organ failure. Without the “gift of life” from deceased donors, it is difficult to imagine how so many lives could have been saved. Currently, the shortage of organs is a major obstacle to making organ transplantation more accessible to a larger number of candidates. Only 30973 transplants from 15064 donors have been performed in the United States in the year 2015, while more than 121000 candidates were waiting for a transplant^[1]. Furthermore, the gap between the number of patients on the wait list and the limited number of available organs continues to widen. As a consequence, more than 6000 patients die every year while waiting for a transplant. In the ideal situation of an unlimited organ supply, virtually no patient would die on the wait list. Instead, due to the persistent scarcity of organs, a candidate for transplant has a 10%-30% chance of dying, depending on the organ, while on the wait list to receive an organ.

The common parameter adopted in different countries to measure the activity of organ donation has been traditionally the number of donors/million population. Although this metric is prone to the flaws of regional variations in health status, it is still used worldwide^[2]. In this review, because our observations are limited to the United States, we will refer instead to the total number of donors/year.

The shortage of organs has been recognized worldwide as a major limiting factor to organ transplantation. The World Health Organization and several international agencies have addressed organ shortage at different levels^[3-7]. Over the past decade, several initiatives have been put into place in the United States to address the shortage of organs. Among them, The Organ Donation Breakthrough Collaborative, funded by the Division of Transplantation in the Health Resources and Services Administration of the Department of Health and Human Services, was launched in September 2003 with the

intent of increasing the number of organs available for transplant. The goal of this initiative was to achieve a donor conversion rate (*i.e.*, from eligible to actual donor, see below) of 75% or higher across the country. Since its inception, more than 180 hospitals have met or exceeded this goal. Another goal proposed in this initiative was to increase the number of organs transplanted per donor. Subsequently, the Institute of Medicine (IoM) published the document “Organ Donation: Opportunities for Action”^[8]. This report emphasized that the current system of organ donation could be greatly improved and offered a number of specific recommendations to help increase the supply of transplantable organs. Given the wide variation in consent rate, ranging between 30% and 70%, across Organ Procurement Organizations (OPO), the IoM recommended the identification of best practices and their dissemination among institutions in the organ-procurement and transplantation system. In addition, the IoM report suggested to devote research efforts to identify new ways to improve the system and increase donation rates. Importantly, among them, it was recommended to integrate organ donation in the process of end-of-life care, recognizing that patients and their families should be offered the opportunity to donate as part of the standard care at the end of life. Still, after those and other efforts, over the last decade the donation rate from deceased donors has remained stagnant in the United States (Figure 1).

Brain dead donors

The vast majority (80%-90%) of organs from DD are procured after declaration of death by neurologic criteria (or “brain death”, BD). Brain death is determined after irreversible cessation of brain stem activity documented by bedside neurologic tests (reflexes, Table 1).

The oxygenation of a comatose person who suffered a devastating irreversible brain injury fulfilling the criteria for brain death is maintained by mechanical ventilation, while cardio-circulatory activity and organ perfusion is supported, if needed, by inotropic medications.

Table 1 Brain stem reflexes

Corneal reflex
Cough reflex
Facial motor response to painful stimuli
Gag reflex
Oculocephalic reflex ("Doll's eyes")
Ocuvestibular reflex (caloric response)
Pupillary response to light

Donation after cardiac death

Unlike BD donors, a proportion of DD, currently 16% of the organs procured nationally, are recovered after declaration of death by circulatory criteria [donation after cardiac death (DCD)]^[9]. In this scenario, patients who have suffered severe brain injury but do not fulfill the criteria for brain death, may still be organ donors if the patient, by advance directive, or the patient's family decides to withdraw life support. In these circumstances, after consent for organ donation has been obtained, the patient is brought to the operating room where ventilation is disconnected and life-sustaining medications are withdrawn. After the cessation of cardio-circulatory activity for 2-5 min, depending on the local protocol, the patient is pronounced dead by a member of the primary team. After declaration of death the organ procurement team arrives to the operating room and begins organ recovery. The different dynamics involved in BD and DCD pathways and their implications on organ allocation and function are beyond the scope of this review. For historical purposes, it is interesting to note that at the beginning of organ transplantation in the 1960s all organs were procured from DCD donors, since the concept and legislation of brain death had not been developed. Only in 1968, an *ad hoc* committee at Harvard Medical School defined brain death as the state of irreversible coma with unresponsiveness and lack of reactivity, absence of movement and breathing and absence of brain-stem reflexes^[10]. Since then, the vast majority of DD have been BD. Only over the past decade there has been an increase in the proportion of DCD from 7% in 2005 to the current 16% of all deceased donors, with wide regional variation ranging between 7%-30%. The recent increase in the proportion of DCD donors has paired with only a small increase in the total number of DD. This has raised the legitimate concern whether the BD pool is curtailed as a result of more DCD donors being pursued. Specifically, the question is raised whether some of the DCD donors could/would have progressed to BD had life support been continued for a sufficient time to allow BD to occur. In a multicenter report from 27 European countries participating in a survey on organ donation, including 10 countries with established DCD programs, the number of both DBD and DCD overall increased during the interval 2000-2009. However, DBD decreased of about 20% in three countries with a predominant DCD activity, implying that DCD might have negatively impacted on DBD activity^[11]. Ideally, in order to increase the overall

donation rate, the expansion of the DCD pathway should have an additive rather than detrimental effect on DBD, so that, in aggregate, more potential donors become actual donors compared to the DBD pathway alone. Indeed, a recent study from the New England Organ Bank, one of the top ranking OPOs in the United States by percentage of DCD (> 30%), reports a 5-year experience with 331 DCD donors without a concomitant reduction of DBD, suggesting that a DCD program may actually expand the donor pool rather than curtailing it. The results of this study also show that overall more potential donors had been identified that would have not been realized without the DCD program^[12]. Regardless, DCD alone and/or in combination with current DBD practices are unlikely to bridge the gap between current organ availability and need. In addition to DCD, other strategies to optimize the current limited organ pool are needed, including the use of less-than-ideal organs ("marginal organs") and split techniques (in case of the liver). While these strategies partially mitigate the donor shortage, still do not resolve the problem of organ shortage and call for additional initiatives. Among them, a considerable attention has been given lately in several countries to the pool of potential donors.

"Potential" deceased donors

Multiple recent studies from different countries, including the United States, have documented the potential for increasing the number of deceased donors. The Iberoamerican Network/Council on Donation and Transplantation has reported a 52% increase in deceased donation in less than 10 years in Central and South America^[3], indirectly demonstrating that the pool of potential donors was previously incompletely exploited. According to a report from Spain, 2.3% of hospital deaths and 12.4% of deaths in the intensive care unit could yield potential donors, making the number of actual donors up to 21% higher if all potentials were to be identified and followed^[13]. The Spanish donation system, among the top performing worldwide, has been widely recognized as a valid model in both BD and DCD pathways and includes an internal hospital chart review of patients who died in ICU performed by transplant coordinators followed by an external periodic audit. Although the plain application of the Spanish model to other national donation systems would not necessarily lead to increased donation rates due to several socio-economic and cultural differences between countries, nonetheless the Spanish experience in recent decades and published studies from other countries indicate that the donor potential is probably not fully exploited. A few definitions currently used in the organ donation literature and protocols are reported in Table 2.

Although with different definitions, the number of potential donors has been estimated in previous studies. According to the IoM report, the number of donor-eligible deaths has been estimated in the range between 10500 and 16800 per year, significantly higher than the actual 8500-9000 deceased donors/year over

Table 2 Definitions^[14]

Donor	A person from whom at least one organ was procured for the purpose of transplant, regardless of whether the organ was transplanted
Eligible death	Death of a person aged 70 yr or younger, legally declared brain dead according to hospital policy and without exclusions listed in OPTN policy
Imminent neurological death	70 yr or younger, ventilated, with severe brain injury and without exclusion criteria, lacking 3 brain stem reflexes but not fulfilling BD criteria
Potential donor	Patient with devastating irreversible brain injury apparently medically suitable for organ donation and suspected to fulfill BD criteria

BD: Brain death; OPTN: Organ Procurement Transplantation Network.

the last two years^[8,15]. In other reports, the potential for brain dead donors has been estimated between 10000 and 26000 per year, depending on the study modality based on either mortality records or hospital chart review^[16-20]. In 2010 the Health Resources and Service Administration of the Department of Health and Human Services commissioned UNOS to conduct the Deceased Donor Potential Study to estimate the number of potential donors in the United States. According to the results of this study, the pool of potential donors is larger than previously estimated with as many as 35000 to 40000 potential donors each year meeting basic criteria for donation^[21]. Although the true potential could have been over-estimated due to the lack of more detailed medical information, nevertheless this study confirms that there is an untapped pool of potential donors. Another interesting finding in this study was that, among people who met basic medical criteria for deceased donation, the actual donation rate was considerably lower (10%) in the age group 50 to 75 years compared to those age 18 to 34 (50%), implying that more donors could be potentially obtained in the age group 50-75 years.

The potential for donation varies across geographic areas of the United States with a four-fold difference in eligible death/million population reported to OPTN by OPOs (national mean 31 eligible death/million population, ranging from 15 to 61) based on the existing geographical variability in mortality (91-229 deaths/million population from cerebro-vascular accident and trauma)^[2]. Importantly, this study highlighted that the number of eligible deaths is correlated to the number of deaths from cerebro-vascular accidents and trauma in that specific area (r square = 0.79).

Outside the United States, studies from Europe, Canada and other countries have documented similar findings regarding potential donors. In Belgium, Roels *et al*^[22] found that 57% of deceased potential donors were missed along the process due to non-identification or missed referral or lack of consent. Likewise, a study from Canada based on discharge data submitted to the Hospital Morbidity Database reported that only 1 in 6 potential donors (17%) became actual donor^[23]. Even assuming that the study methodology overestimated the number of potential donors due to the limitations of analyzing abstract data rather than actual patient chart review, nevertheless this study confirms that the potential to increase the number of deceased donors exists. Regardless of the definition of potential donor,

it is evident from several studies that the number of actual donors represents only a small proportion of the pool of potential donors (Figure 2).

Therefore, a major challenge to increase donation rates would consist of expanding the pool of actual donors to include potential donors. The process of organ donation and potential strategies to expand the pool of actual donors will be discussed below.

THE PROCESS OF ORGAN DONATION (DECEASED DONORS)

Currently, organs for transplant are recovered after determination of the donor's death. This standard practice, commonly known as the "dead donor rule", requires that the intended donor be declared dead before the removal of any life-sustaining organs^[24]. This rule was introduced to protect the person's life before death and to prevent that lives were ended for the purpose of procuring organs. This rule is important to maintain the public trust in organ donation and transplantation and to avoid the misconception that care is withdrawn from potential donors in order to expedite death for the purpose of organ recovery. Recently, however, the dead donor rule has been reconsidered^[25]. In the opinion of some ethicists, while the "dead donor rule" assures patients, families and health professionals that a patient is dead before removing organs, therefore making organ transplantation legally and ethically acceptable, on the other hand it may jeopardize donation in selected cases. As an example, it is quoted the case of a DCD potential donor with prolonged agonal phase (the interval between withdrawal of support and cardiac arrest) that prevented organ recovery and transplantation due to prolonged ischemia. It is argued by some that, after the decision of withdrawing support has been reached, organs be procured without waiting for the declaration of death by circulatory criteria (*i.e.*, cardiac arrest). The advantage of this pathway would be to give patients the opportunity to donate even before death is declared, when death is imminent ("near death") and donation is desirable, in order not to jeopardize the viability of donated organs for transplant. It is argued that, when death is very near, some patients may want to die in the process of helping others to live, even if that means altering the timing or manner of their death. Regardless of this debate about the dead donor rule, it is important that ICU physicians, transplant professionals and organ

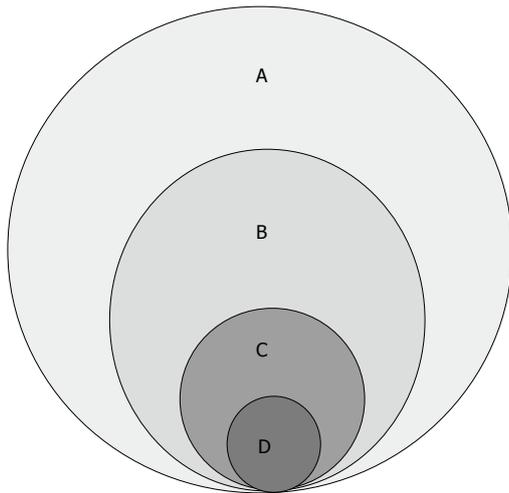

Figure 2 The number of actual organ donors is only a small proportion of the pool of deaths. A: Total deaths; B: Imminent deaths; C: Eligible deaths; D: Actual donors.

procurement organizations make every effort towards maintaining public trust. Mistrust from the general public regarding the procurement of organs will likely result in reduced consent rates for donation based on the perceived fear by the donor's family that treatment is withdrawn from their loved one in order to obtain organs. In other words, fearful people will assume that physicians care more about obtaining organs than saving the patient's life. In addition, this debate on the dead donor rule emphasizes the importance of a previous recommendation by the IoM about the integration of organ donation with end-of-life care. By this integration, the donation process starts before the occurrence of the donor's death, at the time when the potential donor with irreversible devastating brain injury is referred but is not yet declared dead. Since every actual donor has been a potential donor sometime before in the process, it is likely that the coordination of end-of-life care and organ donation would allow to identify and manage potential donors early in the process, increasing the chances of donation. The process leading from donation to transplantation can be described in the following 6 steps: Brain injury, referral, brain death, consent, organ recovery and organ transplantation (Figure 3).

The process of organ donation for transplantation has been described before^[11]. In this review we will limit our considerations to deceased organ donation in the United States.

Brain injury

Organ donors are patients with extensive brain injury resulting, most commonly, from cerebro-vascular accident or trauma or anoxia. Only a small proportion of those patients who suffered extensive and irreversible brain injury become actual organ donors because of the variable impact, in terms of intensity and timing, of brain injury on neurological functions and on brain stem activity. As a result, the occurrence of brain death

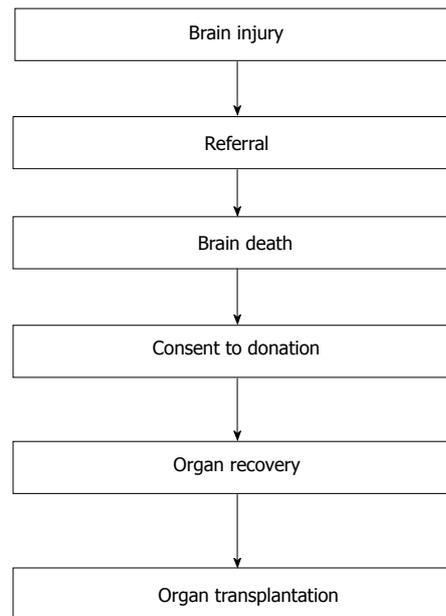

Figure 3 The process of deceased organ donation.

is more or less likely and more or less rapid in different patients. As an example, a patient with large intracerebral hemorrhage or a bilateral pontine hemorrhage is more likely to progress to brain death within a relatively short timeframe than a patient with diffuse anoxic injury without intracranial hypertension^[26]. Consequently, the time interval between brain injury and brain death varies, impacting on the management of the potential donor and costs. In addition, during the time interval between brain injury and brain death the patient is exposed to the systemic adverse effects of brain injury, including hemodynamic instability, diabetes insipidus, and others. In this context, the management of the potential donor while in ICU is paramount and has been described elsewhere^[27].

Referral

Among all patients with brain injury as described above, the medical suitability for organ donation is determined according to established criteria and represents the second step of the process leading to the referral of the potential donor. Federal rules require hospitals to notify the OPO of an individual whose death is imminent or who has died in the hospital^[28]. A network of 58 OPOs constitutes the liaison system designated by the United States federal government to coordinate the organ donation process. The criteria (or triggers) for referral from the hospital to the local OPO are reported in Table 3.

The referral of a potential donor to the OPO can occur as early as on patient presentation to the Emergency department^[29]. After referral, the OPO is involved with the management of the potential donor by coordinating the logistic, medical and regulatory aspects of donation. Importantly, an OPO representative approaches the family of the donor providing support from the time of referral through donation and after

Table 3 Criteria for referral of a potential donor

Every ventilated patient with
Glasgow coma scale of 5 or less without sedation
Brain death testing being considered/pursued
Do-not-resuscitate or comfort care being considered
Withdrawal of support being considered
Family initiates conversation about donation
Every cardiac death within 1 h

donation. The potential donor is considered medically suitable for donation based on established criteria of transplantability of the organs except in cases with potentially transmittable diseases, such as infections or cancer, as indicated in the UNOS policy^[30].

Brain death

Once exclusion criteria have been ruled out, the potential donor becomes eligible for donation after declaration of brain death, which is the third step of the process. Established neurologic tests allow the determination of death by neurologic criteria (brain death tests) and therefore determine eligibility for donation. According to UNOS definition (see above), an eligible death for organ donation is defined as the death of a patient 70 years old or younger, without any exclusion criteria for donation, legally declared brain dead according to hospital policy independent of family decision regarding donation or availability of next-of-kin, independent of medical examiner or coroner involvement in the case, and independent of local acceptance criteria or transplant hospital practice.

The concept of brain death has been introduced in 1968 following the proposal by an *Ad Hoc* Committee that a person could be declared dead after irreversible cessation of the function of the entire brain^[10]. Before the introduction of this concept, the death of a person was declared after irreversible cessation of circulatory and respiratory function. After the introduction of brain death, it became accepted that a person requiring mechanical ventilation can be declared dead even while maintaining heart beating. This is an important aspect to discuss with the donor's family given that the concept of death in the public opinion is mainly associated with arrest of cardio-circulatory activity.

Consent to donation

After brain death, in observance of the principles of autonomy and non-maleficence, the consent to donation is sought from the patient, the family or the next of kin before proceeding with organ recovery. This represents the fourth step in the process and an important focus for future strategies to increase donation (see below). Several aspects of the step of obtaining consent to donation are crucial, including the timing, the method and the approach. Usually, the donor's family is approached after declaration of brain death. However, in selected cases it may be indicated to approach the family before brain death, as in the case of an unstable

donor where rapid deterioration of organ function may occur. This critical step of communicating with the family highlights the importance of effective coordination of end of life care between ICU providers and OPO personnel. In some countries outside the United States, regulations allow the procurement of organs based on the presumed consent of the donor in absence of documented objection to donation. In the United States system, which is based on explicit rather than presumed consent, it is important that the approach to the family and the process of obtaining consent for donation is conducted in a culturally-sensitive way. It is becoming increasingly clear that a better understanding of the donor's family language, culture, faith, and values is critically important to increase consent rates^[31]. The current consent rate is on average 76% ranging between 62% and 93% across OPOs^[32]. Little is known about the factors associated with such variability across regions. In addition, the reasons for denied consent to donation by the donor's family are still poorly understood and represent an opportunity for action in order to increase deceased donation (see below).

Organ recovery

After consent is obtained, the OPO, in collaboration with the donor hospital, allocates suitable organs and arranges for the operation of organ recovery, which represents the fifth step of the process. Typically, multiple organs are procured in different combinations including heart, lungs, liver, kidneys, pancreas and intestine from the same deceased donor during a multi-team operation lasting several hours. Each team carries the burden of recovering the respective organ in the best possible condition for their intended recipient. Therefore excellent communication and coordination between teams is essential during procurement. Typically the teams recovering the thoracic organs and the abdominal organs proceed simultaneously. The intra-operative management of the donor during organ recovery has been reviewed elsewhere^[33]. It is critical to assess and correct, when necessary, the hemodynamic, metabolic, hormonal and pro-inflammatory alterations occurring in the setting of brain death. Studies have documented that the quality of donor management impacts on the quality of the procured grafts and on graft function^[34]. The different techniques of multi-organ procurement have been described extensively and vary among countries.

Organ transplantation

The allocation and transplantation of the procured organs represents the final step of the process. In the United States organ allocation is regulated by organ-specific policies following the criteria of urgency as indicated by the degree of disease severity of transplant candidates. Although the vast majority of recovered organs are subsequently transplanted, not all recovered organs are always transplanted. The reasons for failure to transplant procured organs are multiple and include

damage to the organ during procurement, organ unsuitability discovered during or after procurement, sudden unsuitability of the intended recipient to receive the allocated organ and others. Regardless, to maximize the use of this scarce resource it is important to prevent organ "discard" after recovery. The conversion rate, which reflects the proportion of eligible donors that becomes actual donors and is one of the parameters monitored by the OPO, is an indirect way to assess discard rate of procured organs. Accordingly, actual donors are considered those in which at least one organ has been successfully transplanted. Multiple factors impact on conversion rates and are beyond the scope of this review. Each step of the process of organ donation from deceased donors as outlined above can potentially be the target of strategies to increase donation rates, as discussed below.

CHALLENGES AND OPPORTUNITIES TO INCREASE DECEASED ORGAN DONATION

The "imminent" death

The number of deceased organ donors per year has remained relatively stable over the last decade with only a small annual increase over the years from 8016 deceased organ donors in the year 2006 to 8143 in 2012 and 8596 in 2014^[35]. At the same time, the number of patients added to the wait list has increased at a faster pace every year, making the gap between need and supply of organs wider every year (Figure 1). One of the strategies to narrow this gap is to increase the number of donors for transplant, especially deceased donors. Being the pool of potential donors larger than the number of actual donors, as outlined above, and considering that all donors were "potential" at some point during the process, it is reasonable to focus efforts on identifying and managing potential donors in order to increase donation rates. This would require a novel and broader approach to deceased donation to include not only those fulfilling brain death criteria (eligible deaths) but also those closed to it ("near brain death" or "imminent death"). According to OPTN, imminent donor is a potential donor who is imminent to fulfill the criteria for the determination of death by neurologic criteria (BD). Currently, imminent deaths are being monitored by OPOs, although their definition varies among regions and hospitals. It would be important to have a uniform characterization of imminent deaths and, more importantly, to have a better understanding of their evolution in terms of progression to BD.

Several challenges have been identified at each step of the process of deceased organ donation that could potentially be the target of action to improve donation rates. These include: Missed clinical triggers for referral, premature withdrawal of support before BD testing, cardiac death during evaluation, lack of consent, donor instability and death during organ recovery, organ

damage at procurement or organ unsuitability discovered after recovery and others. At the very beginning of the process of organ donation from deceased donors it is crucial that the potential donor is recognized early after presentation to hospital and referred promptly to the local OPO. The determination of the suitability for donation based on initial demographic (age) or clinical parameters and co-morbidities of patients with devastating brain injury should be deferred to the OPO representative rather than to the primary ICU team. An early referral allows the OPO sufficient time to evaluate the potential donor for medical suitability and to approach the family^[36].

The donor's family

The donor's family plays a key role in the donation process. Within the OPO, a dedicated team of trained personnel approaches the family in a sensitive way. Even in case of registered donors, the family is always consulted before organ procurement. Although legally the donor's consent is sufficient to allow organ recovery, nevertheless the wishes of the family are always taken in consideration and usually organ recovery is not pursued in case of opposition from the donor's family. Respect for the donor's family is important to maintain the public trust: It would be deleterious to pursue organ donation against the family wishes, even in presence of donor's consent. In addition, it is important to understand the motivations behind the declined consent by the donor's family. Factors associated with declined consent include donor age (older), ethnic minority, time interval between certification of brain death and approach to the family and the amount of time spent by the coordinator with the family^[37,38]. The education of families from ethnical minorities using a culturally-sensitive approach seems particularly important, since minority groups are disproportionately represented on the transplant waiting list and unfortunately also suffer from disparities in deceased and living donation. Barriers to donation in minority groups include decreased awareness of transplantation, religious or cultural distrust of the medical community, fear of medical abandonment and fear of racism^[39]. Culturally sensitive communication and interventions are needed to overcome these barriers^[40].

"CPR" for organs

After referral, the ideal management of the potential donor involves both ICU team and OPO personnel. This combined approach provides the best chances to effectively integrate organ donation as part of end of life care, as recommended by the Institute of Medicine. Although prognostic factors have been studied and identified^[41], still the likelihood and timing of progression to BD in patient with brain injury remains incompletely understood. Further studies are needed to better identify early predictors of brain death.

BD is associated with a plethora of systemic manifestations including hemodynamic, metabolic and endo-

crine disturbances. Guidelines have been developed to assist the donor management before organ recovery. Occasionally, eligible donors are lost due to intercurrent hemodynamic instability and cardiac arrest. As part of the integration of end-of-life care with organ donation, it would be important to identify risk factors for cardiac arrest, treat disimbalances and discuss with the donor's family the code status of the donor, including the possibility of hemodynamic support and, if necessary, cardio-pulmonary resuscitation in order to maintain organ perfusion until organ recovery occurs.

CONCLUSION

An increase in deceased organ donation is necessary to make organ transplantation accessible to more candidates. Among others, new strategies to manage the pool of potential donors are needed in order to increase donation rates.

ACKNOWLEDGMENTS

I am indebted to the Washington Regional Transplant Community staff, especially Lori Brigham, Emily Johnson and Carlos Fernandez-Bueno, MD, for fruitful collaboration.

Abstract

Diarrhea is a common complication in solid organ transplant (SOT) recipients and may be attributed to immunosuppressive drugs or infectious organisms such as bacteria, viruses or parasites. *Cryptosporidium* usually causes self-limited diarrhea in immunocompetent hosts. Although it is estimated that cryptosporidium is involved in about 12% of cases of infectious diarrhea in developing countries and causes approximately 748000 cases each year in the United States, it is still an under recognized and important cause of infectious diarrhea in SOT recipients. It may run a protracted course with severe diarrhea, fluid and electrolyte depletion and potential for organ failure. Although diagnostic methodologies have improved significantly, allowing for fast and accurate identification of the parasite, treatment of the disease is difficult because antiparasitic drugs have modest activity at best. Current management includes fluid and electrolyte replacement, reduction of immunosuppression and single therapy with Nitazoxanide or combination therapy with Nitazoxanide and other drugs. Future drug and vaccine development may add to the currently poor armamentarium to manage the disease. The current review highlights key epidemiological, diagnostic and management issues in the SOT population.

Core tip: Diarrhea caused by *Cryptosporidium* is a serious and underrecognized cause of diarrhea in solid organ transplant recipients. The most important diagnostic challenge is low index of suspicion, since many new diagnostic methods have improved detection of the parasite. Treatment can be challenging as the disease may cause severe dehydration and antiparasitic drugs have modest activity. Electrolyte and fluid replacement, reduction of immunosuppression and antiparasitic

therapy are the cornerstones of management. Newer antiparasitic drugs and vaccines may help manage the disease in the future.

INTRODUCTION

Cryptosporidium is a parasitic protozoan causing a gastroenteritis syndrome^[1]. It is a common intestinal pathogen, not detected by routine ova and parasite evaluation. Because testing for *Cryptosporidium* is not routinely sought, the infection is often underdiagnosed, posing important epidemiological problems. In immunocompetent persons, cryptosporidiosis is usually a self-limited disease lasting between just a few days up to 10-14 d^[1,2]. In immunocompromised patients, clinical presentation can vary from asymptomatic to acute gastroenteritis, chronic diarrhea or even extra-intestinal manifestations^[1,3-24]. The parasite binds on the apical surface of the intestinal epithelium fostering its own reproduction and causing direct injury of the epithelial cells and a local inflammatory response, leading to impairment of the absorption and secretory function of the intestine^[1,25]. Several *Cryptosporidium* spp. have been associated with human disease, of which *Cryptosporidium parvum* (*C. parvum*) and *Cryptosporidium hominis* (*C. hominis*) account for > 90% of the cases^[26-28]. In this review, we examine the current epidemiology of *Cryptosporidium* in solid organ transplant (SOT) recipients, review its pathogenesis and clinical manifestations, diagnostic approach, discussion-available treatment options and possible future approaches.

EPIDEMIOLOGY

The incidence and prevalence of cryptosporidiosis varies according to socioeconomic status in both developed and developing countries. In the United States, it is estimated that 748000 cases occur every year^[29], but prevalence in patients with diarrhea can be as high as 12% in developing countries. In SOT recipients are largely unknown (Table 1). Cryptosporidiosis is most likely underreported in SOT, with most of the data being confined to case reports and case series, many of them from endemic areas such as Brazil, India and Middle East^[3,10,30,31]. In a study from Brazil, *Cryptosporidium* infections were more common in renal transplant recipients (35%) and hemodialysis patients (25%) compared to the control group (17.4%)^[30]. Similarly, in a study from Turkey, the prevalence of cryptosporidiosis in kidney transplant recipients was found to be significantly higher than in healthy immunocompetent

patients (21.2% vs 3.0%, $P = 0.01$)^[10]. A recent study from India, shows that cryptosporidiosis accounts for the majority of infectious diarrhea (28.5%) in adult transplant recipients^[3]. Children and immunocompromised patients are disproportionately affected, especially in developing countries^[32]. Between 1.8% and 3.8% of immunocompetent children in child-care settings in the United States, United Kingdom, Spain, and France have been found to be asymptomatic carriers for *C. hominis*^[31,33,34]. This proportion may be underestimated as up to 70% seroprevalence was found in children living in the United States-Mexican border^[35]. Bandin *et al*^[8] reported that *Cryptosporidium* infections were diagnosed in 3.5% of the new pediatric kidney recipients, and was responsible for 18% of the cases of infectious diarrhea over a period of 3 years. This marked heterogeneity in the prevalence of cryptosporidiosis in SOT from different studies (Table 1) is probably the result of different inclusion criteria used in each study, the geographical distribution, the sensitivity and specificity of the diagnostic tests used, type of induction and maintenance immunosuppression regimen^[3,11].

Epidemiological studies, animal models and human case reports show that *Cryptosporidium* is transmitted from person to person spread *via* fecal-oral route, including sexual transmission and possibly *via* respiratory secretions^[28,35-40]. Infectivity depends on the number of oocysts and *Cryptosporidium* species and subtypes^[41,42]. Outbreaks of cryptosporidiosis in developed countries have been described in daycare centers^[43,44] in association with animal petting farms^[45,46] and recreational water use^[47,48]. During the last few decades, several waterborne outbreaks have been reported after ingestion of contaminated recreational water or drinking water, one of these was thought to affect more than 400000 people^[49-58]. Risk factors in SOT recipients reported in the literature are described in Table 2. *Cryptosporidium* oocysts are resistant to chlorine disinfection and can survive for days in treated recreational water despite adequate chlorination^[36,59]. *Cryptosporidium* can be eliminated by boiling the water or just heating it to 62 °C for few seconds and by filtration through < 1 µm filters^[40]. Transmission of cryptosporidiosis *via* respiratory secretions is less common; isolation of *Cryptosporidium* DNA in the sputum of children with intestinal cryptosporidiosis and cough supports the respiratory route of transmission of this organisms^[60]. Even more, all of the life stages of *Cryptosporidium* have been described in the microvillus border of epithelial cells and within the bronchial mucus glands^[61]. Cryptosporidiosis has also been reported as a donor-derived infection after intestinal transplantation^[14].

depends on the infecting species, virulence of the parasite and the host immune response (the degree of the immunodeficiency that impacts mainly T cell function), and the incubation period can range from 2 d up to 2 wk^[1,2].

Cryptosporidium significantly affects intestinal cells with consequent alterations in absorptive and secretory functions. This may be either caused by direct cell injury or alternatively by activation of the immune system with release of pro-inflammatory cytokines^[1]. Toll-like receptors (TLR2 and TLR4) play an important part in initiating immune activation following mucosal injury by the parasite^[62-64] and inducing cytokine release

(IL-12, IL-15, IL-18, TNF- α and IFN- α/β) followed by activation of the NF- κ B cells with IFN- γ production, mononuclear cell infiltration in the lamina propria, crypt cell hyperplasia, villous atrophy and blunting^[65-67]. Toll-like receptors also have a role in establishing immunity to infection^[62]. Innate immunity controls infection, but elimination of the parasite seems to require adaptive immunity^[62]. IFN- γ is an important cytokine determining CD4⁺ T cell response to infection, including memory response against *Cryptosporidium* infection in the intestine^[62,68,69] (remove 63, add Pantenburg Infection and immunity). The role of the T cell function is supported by severe and prolonged cryptosporidiosis in

patients with AIDS and CD₄ count < 50 cells/mm³, and improvement of the symptoms after introduction of highly active antiretroviral therapy^[70] (Change reference for more recent one) or after decreasing immunosuppression in transplant recipients that allows recovery of the immune system. Antibodies have a minor role in elimination of the infection, being more an indirect marker of the cellular immune response^[68]. All these changes at the level of the epithelium lead to malabsorption and secretory diarrhea^[12,65].

In SOT the type of immunosuppression might play an important role in development of cryptosporidiosis. A recent study showed that patients on a tacrolimus-based immunosuppressive regimen had a significantly higher risk of *Cryptosporidium* infection compared to the patients on a cyclosporine-based regimen. Being on

cyclosporine seemed to protect against infection (OR = 0.35; 95%CI: 0.17-0.72). Those on tacrolimus who developed cryptosporidium also had graft dysfunction, likely due to dehydration and increased tacrolimus levels^[3].

CLINICAL PRESENTATION

Most of the *Cryptosporidium* infections in the SOT population have been reported in renal transplant recipients (Table 1). *Cryptosporidium* can cause asymptomatic infection in transplant recipients and because of that, many cases may be missed^[30,71]. A relatively high prevalence of oocyst excretion in asymptomatic transplant population might be detected in the stool with random stool screening^[71]. When clinically evident,

SOT recipients typically present with profuse and prolonged watery diarrhea, sometimes associated with nausea, vomiting, abdominal pain and fever^[1,4-10,12-24]. Other nonspecific symptoms have been described in immunocompetent and immunocompromised patients such as malaise, generalized weakness, myalgia, anorexia and headache^[1,5,17]. Persistent vomiting and diarrhea can lead to dehydration and wasting and have been associated with increased morbidity^[4,7,8,17]. Several study described acute renal failure, most likely secondary to dehydration, hypotension and sometimes tacrolimus toxicity^[3-5,7-9,16,23]. Atypical manifestations such as respiratory tract disease, pancreatitis, cholangitis and urinary tract infection, have been reported in patients with immune deficiencies, mainly AIDS^[72-75]. Biliary involvement with *Cryptosporidium* inducing sclerosing cholangitis has been reported in few SOT recipients^[12,15,18]. However, elevated liver enzymes should not be equivalent to the diagnosis of sclerosing cholangitis as they can be abnormal in the settings of hypotension or high tacrolimus levels^[11]. Radiologic findings in support of the diagnosis of sclerosing cholangitis: Abdominal ultrasound can show dilation of the biliary duct; Technetium 99m iminodiacetic scan might show biliary stasis, irregularity of the biliary ducts, focal strictures^[18]; endoscopic retrograde cholangiography or magnetic resonance cholangiopancreatography could demonstrate dilation and/or irregularity of the biliary ducts^[15,76].

Infection of the biliary tree in immunocompromised patients could represent an extra-intestinal reservoir that would allow the organism to avoid certain antiparasitic agents (paromomycin) and would lead to relapses. Drugs with biliary excretion such as nitazoxanide should be preferred in these patients^[2,77]. Relapse rates in cryptosporidiosis are high (up to 40%-60%) due to incomplete eradication of the oocysts, especially from the biliary tree and possibly due to inadequate intestinal drug levels in patients with severe diarrhea^[12,14]. Respiratory cryptosporidiosis can present as an upper or lower respiratory tract infection manifested by nasal discharge, voice change, cough, dyspnea and hypoxemia^[78-81].

DIAGNOSIS

Stool microscopy is the main and cheapest method for diagnosis, however all microscopic methods are labor intensive and have low sensitivity unless a high concentration of oocysts are being released in stool. The size of the oocysts is also important (between 3-7 μm) as they can be confounded with yeast, so modified staining with Ziehl-Neelsen or fluorescent techniques such as auramine-rhodamine can be employed to improve detection. The sensitivity of these stains still remains low^[82,83], requiring about 500000 oocysts/mL in formed stools for detection^[35]. The most commonly used test by microbiology laboratories is currently direct immunofluorescence which may be either a standalone test or a combined *Cryptosporidium*/*Giardia* diagnostic kit^[35]. There are several enzyme linked immunosorbent

assay (ELISA) kits available with sensitivities ranging from 66%-100% but excellent specificity and have the advantage of being more automated when compared to conventional staining methods^[41,84-89]. Immunochromatographic tests have lower sensitivity compared to other molecular or other antigen tests and are not as sensitive to detect species other than *C. parvum* or *C. hominis* but are easy to perform, correlate well with EIA/ELISA tests and provide results in a matter of minutes^[89,90]. Molecular methods provide the highest diagnostic sensitivity and are the preferred methods for diagnosis given their superior sensitivity and specificity. There are several multiplex polymerase chain reaction (PCR) test that can detect different gastrointestinal pathogens including viruses, parasites and bacteria however, these may not available in all laboratories^[91]. These tests usually have high sensitivity to detect *Cryptosporidium*, although speciation may require further testing and carry a higher cost^[26,41,42,92-94].

Tissue histopathology is a useful method for diagnosis, especially when intestinal biopsies are obtained. Parasites may appear lining epithelial surfaces or in the lumen. When hematoxylin is used to stain the tissue, intracellular parasites appear blue or purple^[2,16,17,20]. Intestinal transplant recipients may have negative stool examinations but the parasite may be readily seen on graft biopsies, highlighting the importance of endoscopic examination even in cases where diarrhea persists and routine stool examinations are negative^[11,16,17].

Detection of *Cryptosporidium* in respiratory sample specimens is usually achieved with acid-fast, modified acid-fast staining or and indirect immunofluorescence^[28,74] although PCR testing may also be possible^[28]. Histopathology may show parasites lining the mucosal epithelium of trachea, bronchi or lung; tissue biopsies may also show intra or extracellular organisms^[28].

TREATMENT

The main treatment approach is oral rehydration whenever possible, however intravenous fluids that include sodium, potassium, glucose and bicarbonate may be required in severe cases. A lactose free diet is recommended since *Cryptosporidium* destroys mature epithelial cells that are located in the villi resulting in loss of enzymes such as lactase. The disease is associated with high intestinal transit that may interfere with fluid, electrolyte, and drug absorption. Antimotility agents may be used once other causes of diarrhea such as *Clostridium difficile* or dysentery are ruled-out.

The first step in SOT patients is an attempt to restore immune function by adjusting or switching immunosuppressive therapy, because severity of disease is likely related to the degree of immunosuppression and CD4 cell counts^[3,10,13,19,37,74,82,95]. This example was illustrated in a renal transplant recipient with enteritis and sclerosing cholangitis, where an accidental reduction of immunosuppression resulted in clearance of the disease^[15]. Mycophenolate, a commonly used

immunosuppressive agent may have some antiparasitic activity against *Cryptosporidium* by inhibiting folate metabolism^[4]. *Cryptosporidium* induced diarrhea may also result in increased tacrolimus levels^[37] as evidenced in two recently published case series^[4,5]. The pathophysiology is not entirely clear but it is likely a combination of factors including reduced cytochrome 3A activity during inflammation^[96], interaction with other drugs, and reduced renal function due to fluid depletion^[4]. Increased tacrolimus may in turn worsen renal function, and prolong immunosuppression^[3]. Cholecystectomy may be indicated for cases with acalculous cholecystitis and sclerosing cholangitis usually needs endoscopic retrograde pancreatography with possible papillotomy and stenting^[97]. To date, there has not been a highly effective agent to treat cryptosporidiosis in immunocompromised individuals^[98]. A meta-analysis of seven trials including 130 patients with AIDS found no evidence for effective agents against cryptosporidiosis, although significant heterogeneity and flaws of individual trials may have influenced the negative results^[95]. Moreover, whether any drug may have partial effect or the use of combination therapy were not investigated in this meta-analysis. To date, no randomized clinical trial with antiparasitic drugs has been conducted in SOT recipients with cryptosporidiosis and most experience is extrapolated either from data in immunocompetent hosts, patients with human immunodeficiency virus (HIV) infection^[37] or case series and case reports (Table 3)^[3-19,21,23,24,30,99,100]. Several antiparasitic drugs such as paromomycin, nitazoxanide or azithromycin have been used with variable success. Nitazoxanide is the only FDA approved drug for treatment of cryptosporidiosis, it is available in tablets and suspension, it has no significant drug-drug interactions or dosing requirements in renal or hepatic failure^[98]. Its activity, including the one of its metabolites has previously been shown *in vitro*^[101] and it is believed to interfere with the pyruvate: Ferredoxin oxidoreductase enzyme-dependent electron transfer reaction, which is essential to anaerobic energy metabolism^[102]. Nitazoxanide has been effective in 3 randomized clinical trials among immunocompetent adults and children, showing reduction in duration of diarrhea and eradication of cysts from stool^[103,104]. Its effectiveness in immunocompromised patients has been variable with some clinical trials showing positive results whereas in other trials the drug was no better than placebo. In a randomized study of nitazoxanide in HIV infected patients with cryptosporidiosis treated with either 500 mg twice a day or 1 g twice a day vs placebo, good responses to nitazoxanide were seen in those with CD4 cell counts > 50/mm³ although no difference to placebo was seen in the subgroup with CD4 < 50/mm³^[105]. Nitazoxanide effectiveness was also questioned in a randomized double-blind trial in children with HIV infection who received the drug for 28 d and there was no difference with placebo for clinical and parasitological cure or mortality^[106]. One difference with patients with HIV infection when compared to SOT recipients is in

many cases the ability to more readily manage and adjust immunosuppression, whereas in HIV infection restoration of the immune system with antiretroviral therapy is key and may take longer time^[98]. The recommended nitazoxanide dose in SOT recipients is 500 mg twice daily for 14 d^[37], however data from randomized trials in SOT recipients is lacking and longer courses of therapy are sometimes employed^[3,4,8].

Paromomycin, a non-absorbable aminoglycoside has limited activity against the parasite, probably the doses used in clinical practice are not enough to achieve the high concentrations needed to inhibit parasitic activity^[97]. It was useful reducing oocyst excretion in a small clinical trial^[107]. Because paromomycin has not been shown to be useful as a standalone agent, combination therapy with other antiparasitic agents such as azithromycin and Nitazoxanide may be an attractive option^[5,7,9,11,14,16,23,108].

Macrolide antibiotics such as azithromycin, clarithromycin or spiramycin also have activity against cryptosporidium^[98], and were shown to reduce duration of symptoms and oocyst shedding in a clinical trial of treatment of children with cryptosporidiosis^[109], but these findings were not replicated on a subsequent randomized trial^[110]. Several clinical trials and case series evaluating the use of azithromycin in immunocompetent and immunocompromised patients with cancer and also HIV infection have shown mixed results in clinical response including duration of symptoms, and oocyst shedding^[110-114]. Several case reports and case series have described successful use of spiramycin and azithromycin either alone, or in combination therapy with paromomycin or Nitazoxanide in SOT patients^[5,7,9,11,13,14,16-18,23]. Drug-drug interactions between macrolides and immunosuppressive agents such as tacrolimus or cyclosporine should be considered before treatment is initiated and may further limit prolonged use of these antibiotics^[99].

Rifamycins also have antiparasitic activity. Rifabutin was shown to decrease cell infection by *Cryptosporidium*^[115] and rifaximin has also been shown to be active *in vitro*^[98]. Interestingly, the incidence of cryptosporidiosis was dramatically decreased in patients with advanced HIV infection who used rifabutin as part of *Mycobacterium avium* chemoprophylaxis^[116,117]. To date, there have been no randomized clinical trials to evaluate its efficacy in SOT recipients or other immunocompromised hosts. Drug-drug interactions with rifabutin may also be an important issue in those who take tacrolimus or cyclosporine^[15,99]. Tacrolimus levels are not affected by rifaximin, however an elevation of rifaximin levels may be seen as a result of P-glycoprotein inhibition.

Because individual drugs lack full activity against the parasite, use of combination therapy may be a more attractive option. Current guidelines recommend starting with nitazoxanide alone as preferred therapy, although combination therapy is listed as an alternative option^[37]. Our review of the literature showed some authors have used nitazoxanide as standard therapy, while others have used this approach in relapsed or refractory cases,

¹The number of patients; TAC: Tactolimus; MMF: Mycophenolate mofetil; AZT: Azathioprine; S: Steroids; AZM: Azithromycin; NTZ: Nitazoxanide; PAR: Paromomycin; N/A: Not available; TMP/SMX: Trimethoprim/sulphamethoxazole.

usually with long courses advocated^[3-5,8,9,23]. Azithromycin has been combined with either nitazoxanide or paromomycin also with reported success^[5,82,115,118]. Caution should be exercised though, because large studies using combination therapy including nitazoxanide have not been carried out to date. Current data on combination therapy is derived from case reports and case series, which may only reflect positive outcomes, while negative results may not be necessarily reported.

PREVENTION

Transplant recipients should be cautious about swimming in streams or lakes and if possible avoid untreated well or lake water. Drinking water should either be treated municipal, filtered by < 1 µm filters or bottled water. Contact with anyone who has diarrhea should be limited,

(food and water may be contaminated by those infected) and hand-washing for everyone, especially all household members is strongly encouraged. Moreover, all surfaces should be cleaned with running water and soap^[37,119]. Safe sexual practice using condoms is also encouraged for anal intercourse, since it increases the risk of transmission as well^[119].

PERSPECTIVE

Oral bovine immunoglobulin (hyperimmune colostrum) seemed an attractive alternative for treatment although it has not been effective at conventional doses and at higher doses oocyst excretion was decreased but diarrhea increased and clinical symptoms were not reduced^[120]. More recently, monoclonal or polyclonal antibodies have shown to reduce oocyst shedding

and improve clinical symptoms^[121]. Thus, although still controversial, using oral bovine immunoglobulin or monoclonal antibodies along with antiparasitic agents may be a strategy to consider in immunocompromised individuals with recurrent or recalcitrant disease^[121].

The genome of both *C. parvum* and *C. hominis* has been decoded and this should also help develop antiparasitic drugs against specific targets such as calcium-dependent protein kinases, microtubule formation inhibitors, hexokinase, lactate dehydrogenase, inosine-5-monophosphate dehydrogenase, and fatty acylCoA binding inhibitors among others^[82,122].

Despite this, the full understanding of *Cryptosporidium* immunopathogenesis remains unclear^[35,68].

Declines in infection rates with increasing age among children in developing countries points to possible acquisition of immunity against the parasite, although immune responses that may lead to protective immunity are not well understood^[35,82]. A study conducted in healthy volunteers who were challenged with *Cryptosporidium*, showed that after second re-challenge episodes of diarrhea were similar but clinical severity was milder and fewer subjects were shedding oocysts^[123]. Both IgG and IgA antibodies increased after exposure, however there was no correlation with infection^[123]. Vaccination may be a viable alternative and vaccine has been evaluated in a mouse model^[124]. The two most common species causing human disease, *C. parvum* and *C. hominis* share > 95% of their genome so it may be possible to have one vaccine for both species (Mead 2015). Several parasitic antigens such as gp15 and gp40 have been evaluated in vaccine development. Both elicit an immune response and production of interferon gamma by mononuclear cells in patients previously infected with cryptosporidium. A vaccine trial in Bangladesh using IgA against gp15 showed the antibody was not species specific and resulted in shorter duration of illness^[82]. There are other targets being investigated including a recombinant DNA vaccine using Vaccinia, Salmonella or Lactobacillus as DNA vectors^[82]. A successful vaccine would first have to be proven effective in immunocompetent hosts before moving on to immunocompromised patients, although the latter are the ones who would most likely benefit from vaccination.

CONCLUSION

Diarrhea caused by *Cryptosporidium* is a serious clinical syndrome in SOT recipients and diagnosis may be delayed if the infection is not routinely suspected or investigated. Advances in diagnostic methodologies has improved the sensitivity of detection, however, treatment remains problematic, especially in immunocompromised patients. Aggressive fluid and electrolyte replacement, reduction in immunosuppression along with antiparasitic therapy are the mainstay of therapy, but few partially active drugs are available and the infection may follow a protracted course with many relapses. Combination therapy with nitaxoxanide and paromomycin or macro-

lides may be the best approach, especially in SOT recipients. New therapies in the horizon such as hyperimmune colostrum, monoclonal antibodies, and vaccination may help increase the armamentarium to manage the disease.

Abstract

Nephropathy secondary to BK virus, a member of the *Papoviridae* family of viruses, has been recognized for some time as an important cause of allograft dysfunction in renal transplant recipients. In recent times, BK nephropathy (BKN) of the native kidneys has been increasingly recognized as a cause of chronic kidney disease in patients with solid organ transplants, bone marrow transplants and in patients with other clinical entities associated with immunosuppression. In such patients renal dysfunction is often attributed to other factors including nephrotoxicity of medications used to prevent rejection of the transplanted organs. Renal biopsy is required for the diagnosis of BKN. Quantitation of the BK viral load in blood and urine are surrogate diagnostic methods. The treatment of BKN is based on reduction of the immunosuppressive medications. Several compounds have shown antiviral activity, but have not consistently

shown to have beneficial effects in BKN. In addition to BKN, BK viral infection can cause severe urinary bladder cystitis, ureteritis and urinary tract obstruction as well as manifestations in other organ systems including the central nervous system, the respiratory system, the gastrointestinal system and the hematopoietic system. BK viral infection has also been implicated in tumorigenesis. The spectrum of clinical manifestations from BK infection and infection from other members of the Papoviridae family is widening. Prevention and treatment of BK infection and infections from other Papovaviruses are subjects of intense research.

Key words: BK viral infection; BK nephropathy; Cardiac transplant; Bone marrow transplant; Liver transplant; Pancreatic transplant; Lung transplant

Core tip: BK virus (BKV) is a member of a family of viruses that cause various diseases in animals and humans. Severe disease in transplanted kidneys was the first recognized human disease caused by BKV. In more recent times, BKV was also recognized as a cause of disease in the native kidneys of patients who had received bone marrow, heart, lung, liver and pancreas transplants, as well as in the kidneys of patients with loss of resistance to infection, such as patients with acquired immune deficiency syndrome or patients treated for malignant tumors. In addition to disease of the kidneys, BKV has also caused severe disease of the urinary bladder, the brain, the lungs, the gut and the blood. The diagnosis and particularly the management of infection by BKV present difficulties. Research for new medications specific for treating this infection is imperative.

BK nephropathy in the native kidneys of patients with organ transplants: Clinical spectrum of BK infection. *World J Transplant* 2016; 6(3): 472-504 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i3/472.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i3.472>

INTRODUCTION

BK virus (BKV) is a human polyomavirus identified in 1971 when it was isolated from the urine of a Sudanese kidney transplant recipient with renal failure secondary to distal ureteral stenosis^[1]. It belongs to the *Papovaviridae* family of viruses^[2]. BKV along with other papovaviruses, *e.g.*, JC virus (JCV), can cause disease in humans^[3,4]. BKV is ubiquitous in the general population and serologic studies suggest that primary infection occurs in early childhood at a median age of 4-5 years^[5,6]. BKV primary infection usually results in upper respiratory symptoms with rare reports of acute

cystitis^[5,6]. The route of transmission is not conclusively known. It is believed that transmission occurs *via* the respiratory pathway^[5,6].

Latent infection with BKV typically causes clinical disease in the genitourinary tract since the virus has a tropism for renal tubular and transitional epithelial cells. In these cells BKV establishes a life-long latency^[3,4,7]. Viral reactivation usually occurs in patients with immunosuppressed states resulting in viruria. A small percentage of patients with viruria develop an invasive infection of the kidney^[3]. BKV infections involving the urinary tract were the first to be reported in kidney transplant recipients and are the most frequent manifestations of BKV. BKV infection in other organs is less frequent^[2,3,8].

BK nephropathy (BKN) was recognized as an emerging problem in renal transplant recipients with the introduction of improved immunosuppressive treatments such as tacrolimus, mycophenolate, and antilymphocyte globulins^[6,7,9]. Renal transplant failure rates, due to BKN, especially if diagnosed late, can reach as high as 50%-80% within 24 mo^[7]. Therefore screening for BKV in renal transplant recipients has become routine^[2,9]. Costa *et al*^[10] reviewed the clinical and histologic features, diagnosis, monitoring of the virology and immunological picture and treatment of BKN. Their review was based primarily on reports of BKN involving renal allografts^[10].

In recent years, reports of BKN in native kidneys and of BKV infection in other organ systems have emerged with increasing frequency in non-renal solid organ and bone marrow transplant patients^[2,5,7,8,11] as well as in other immunosuppressed patients. The main purpose of this review is to summarize the clinical characteristics, diagnosis, pathophysiology and treatment of BKV infection in patients with solid organ and bone marrow transplantation. The spectra of manifestations of BKV infection and of patient groups developing BKV infection are enlarging. In addition to BKN in native kidneys of transplant recipients, this report will also address manifestations of BKV infection outside the urologic system and in patients without organ transplants. Several aspects of BKV infection, particularly the diagnosis, pathogenesis, and treatment of BKN have been studied extensively in kidney transplant recipients. This review will therefore include relevant studies of renal transplant recipients in these three areas.

The review has three major parts: (1) clinical manifestations of BKV infection; (2) diagnosis of BKN and pathogenesis of BKV infection; and (3) treatment of BKV infection and human diseases secondary to other members of the Papovavirus family. Key points of each major part will be presented at its end.

PART A CLINICAL MANIFESTATIONS OF BKV INFECTION

Two cases will illustrate the clinical features and histology of BKN in native kidneys of transplant recipients.

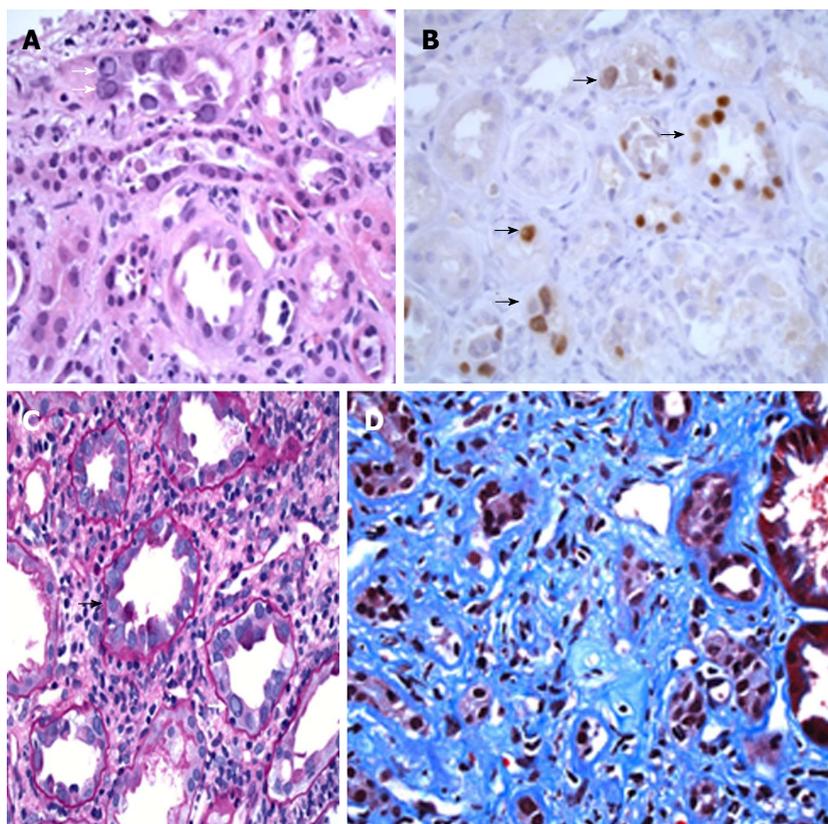

Figure 1 BK nephropathy in the native kidneys of a lung transplant recipient (Patient 2 in this report, A and B) and in the native kidneys of a bone marrow recipient (patient 1 in this report, C and D). Kidney biopsy showing BK nephropathy (BKN), taken from a 70-year-old male with a history of lung transplantation for pulmonary fibrosis. A renal biopsy was performed because of significant worsening in renal function over a one-month period. A: Kidney biopsy showing active BK virus infection of renal tubules, with multiple homogeneous-appearing viral nuclear inclusions (white arrows), and features of associated acute tubular injury, including sloughing of tubular cells (H and E stain, 400 × magnification); B: Multiple renal tubules show positive nuclear staining for the SV40 large T antigen by immunoperoxidase staining (black arrows), confirming infection of tubular cells by polyomavirus (400 × magnification); Kidney biopsy from a 30-year-old male with a history of an allogeneic bone-marrow transplantation for aplastic anemia, who developed sequentially post-transplant Epstein-Barr virus associated large B-cell lymphoma, graft vs host disease and progressive elevation of his serum creatinine. This patient died from pneumococcal pneumonia and invasive aspergillosis two months after the diagnosis of BKN; C: Biopsy of renal cortex showing mononuclear tubulitis (black arrow), intranuclear BK virus inclusions (white arrow), and a prominent interstitial chronic inflammatory infiltrate (PAS stain, 400 × magnification); D: Another area of the biopsy shows extensive interstitial fibrosis and tubular atrophy, consistent with late changes secondary to infection (Trichrome stain, 400 × magnification).

Patient 1

A 30-year-old Hispanic man received a matched allogeneic bone marrow transplant from an unrelated donor approximately two years after the diagnosis of aplastic anemia. Six months after the transplant he developed post-transplant lymphoproliferative disorder (Epstein Barr Virus associated diffuse large B cell lymphoma of the right tonsil). He underwent tonsillectomy, localized radiation, and one cycle of CHOP (cyclophosphamide, adriamycin, vincristine, prednisone) followed by two treatments with rituximab.

Two years after transplantation he developed graft vs host disease of his esophagus and small intestine which required initiation of immunosuppressive therapy. He was placed on tacrolimus. After ten months, tacrolimus was tapered and sirolimus was started because of concern for calcineurin inhibitor toxicity. After three months sirolimus was replaced by mycophenolate mofetil because his graft vs host disease was not improving.

The patient's serum creatinine was 0.7-0.9 mg/dL

pre-transplant and 1.2 mg/dL prior to the initiation of tacrolimus. Renal function worsened while he was on tacrolimus, which was discontinued when the serum creatinine reached 2.0 mg/dL. All blood tacrolimus trough levels were between 2 and 3 ng/mL. Despite discontinuation of tacrolimus, the patient's renal function continued to decline. Approximately four years following the bone marrow transplant, his serum creatinine was 3.15 mg/dL (estimated glomerular filtration rate by CKD-EPI equation of 25 mL/min per 1.73 m²). Urine microscopy was bland and urine protein to creatinine ratio was 0.6 g/g. Renal ultrasound was unremarkable. Serum antinuclear antibodies, antineutrophil cytoplasmic antibodies (ANCA), hepatitis panel, and human immunodeficiency virus (HIV) test were negative. Serum complement levels (C₃, C₄) were normal. Serum BK viral load was 700000 copies/mL.

Percutaneous renal biopsy demonstrated morphologic features consistent with BKN. Light microscopy was notable for lymphocytic tubulitis and viral nuclear inclusions (Figure 1C and D). Immunohistochemical

staining for SV 40 large T antigen showed positivity in tubular nuclei. There were no specific findings on immunofluorescence or electron microscopy.

The patient's BKN was treated with ciprofloxacin only because immunosuppression could not be lowered given his graft vs host disease and leflunomide could not be used due to preexisting leukopenia. During treatment with ciprofloxacin renal function and BKV titer continued to worsen. One month after the start of ciprofloxacin treatment, the patient was hospitalized with pneumococcal pneumonia and invasive aspergillosis. He became progressively septic and died one month later.

Patient 2

A 70-year-old Caucasian male with history of pulmonary fibrosis due to usual interstitial pneumonitis underwent a left sided lung transplant. His immunosuppressive regimen included tacrolimus, mycophenolic acid and prednisone. One year following the lung transplant, he suffered unprovoked pulmonary embolism and has remained on anticoagulation with warfarin since then. Serum creatinine levels were stable at 1.0-1.1 mg/dL until two years following the lung transplant when they began to rise. BK viremia was detected and mycophenolic acid was discontinued. However, renal function continued to decline and serum creatinine reached 3.0 mg/dL. His blood tacrolimus levels were between 5 and 8 ng/mL.

Urine microscopy was bland. Renal ultrasonogram demonstrated normal sized kidneys with multiple bilateral simple cysts. Serum BKV level was 10 million copies/mL. Renal biopsy showed active BKN, with visible viral inclusions, positive tubular nuclear staining for SV-40 large T antigen, and associated tubular cell injury/necrosis and mainly mononuclear tubulitis (Figure 1A and B). There was moderately severe interstitial fibrosis and tubular atrophy (about 40%-45%) and global glomerulosclerosis (13%). There were no specific findings on immunofluorescence microscopy.

Following the renal biopsy, administration of tacrolimus and prednisone was continued and Leflunomide was started at a dose of 10 mg daily and was slowly titrated up to 20 mg daily two months later. He also received three monthly doses of intravenous immunoglobulin (IVIG) at a dose of 1 g/kg. However, despite improved BK viral titers (from 10 million to 3.5 million copies/mL), his serum creatinine continues to range between 2.8 and 3.0 mg/dL.

GENERAL CONCEPTS OF BKV INFECTION IN PATIENTS WITH ORGAN TRANSPLANTS

Evolution of BKN in kidney transplant recipients^[12-22]

An early study by Hogan *et al.*^[12] detected polyomavirus excretion in the urine in 20% of renal transplant recipients. Approximately equal numbers of patients

with viremia excreted JCV and BKV. The same study reported a tendency to more frequent complications related to the renal graft in patients with documented viral replication^[12]. Subsequently, Rosen *et al.*^[13] described the development of tubulointerstitial nephritis secondary to BKV in a 6-year-old boy with a renal transplant. A few years later Randhawa *et al.*^[14] calculated that the incidence of BKN in renal transplant recipients was as high as 5%. Shinohara *et al.*^[15], using a BKV-specific antibody, found that the virus was localized in renal calyces, renal pelvis, ureter and the urinary bladder. These findings are consistent with the clinical manifestations of BKV infection in the urinary tract.

Hirsch *et al.*^[16] reported associations of BKN with high BK viral loads in the plasma of renal transplant recipients and with treatment for rejection, particularly with corticosteroids. Additionally, Hariharan^[17] computed a high incidence (between 30% and 60%) of irreversible renal transplant failure in patients with BKN. Bohl *et al.*^[18] stressed the association between potent immunosuppression and BKN in renal transplant recipients and the need for screening for early detection and prevention of BKN.

In an analysis of a large cohort of renal transplant recipients reported to the Organ Procurement Transplant Network national registry of the United States, Dharnidharka *et al.*^[19] found an increasing Kaplan-Maier incidence of BKN with time and a higher risk of BKN with immunosuppressive regimens that included rabbit antithymocyte globulin and tacrolimus/mycophenolate combinations. Subsequently, the same group^[20] stressed the risks of over-immunosuppression in respect to BKV infection and the lack of optimal methods for treating BKN. Nicleleit *et al.*^[21] reviewed recent developments in the diagnosis of BKN, including noninvasive diagnostic procedures, and the expanding role of polyomaviruses in oncogenesis in patients with organ transplants. Sawinski *et al.*^[22] identified male gender, advanced age of the recipient, previous rejection episodes, severity of leukocyte antigen mismatching, long cold ischemia time, serology for BKV and ureteral stent placement as additional risk factors for BKN.

Evolution of the concepts of BKN in native kidneys and of other manifestations of BKV infection^[2,23-37]

The manifestations of BKV infection from the urinary tract may differ between transplanted organ recipients. BKN and ureteral stenosis were identified as the cardinal manifestations of BKV infection in kidney transplant recipients and hemorrhagic cystitis was recognized as a cardinal manifestation of BKV infection in recipients of bone marrow transplants^[23-25]. The documented sites of BKV-associated disease include the urinary system, the lungs, the eyes, the brain, the retinae and the blood vessels^[24].

Rates of BK viremia and viremia in recipients of organ transplants were reported from several geographical sites. In a study from Madrid^[26], viremia was detected in

26.5% of kidney transplant recipients, 25.5% of heart recipients and 7.8% of liver recipients, while viremia was found in 12.2% of kidney recipients and 7.0% of heart transplant recipients. In Pittsburgh, BK viruria was detected in 8.7% of non-immunosuppressed controls, 34.9% of renal transplant recipients and 15.9% of liver transplant recipients, while BK viremia was detected only in renal transplant recipients (7.7%)^[27]. In the same study, the BK viral load in urine was higher in the kidney transplant patients than in the liver transplant recipients or control patients; interestingly, JC viruria was observed in 34.7% of controls, 22.3% of renal transplant patients and 22.7% of liver transplant recipients. JC viremia was not detected in any group.

In a study from Mayo Clinic, Rochester, Minnesota and University of Toronto, Ontario^[28], combined BK and JC viremia was found in 26% of kidney transplant patients, 7% of heart transplant patients and 4% of liver transplant recipients. In the same study, BK viremia was associated in certain instances with renal transplant rejection. A study combining findings from Philadelphia, Pennsylvania, and Seattle, Washington^[29], found a 15% incidence of BK viruria in 34 recipients of lung, liver, heart, and heart-lung transplants with chronic renal dysfunction. In contrast, a study from Alberta, Edmonton^[32], which also found an incidence of BK viruria in recipients of heart, liver or lung transplants, reported no association between renal dysfunction and BK viruria.

Sharma *et al.*^[34] presented the histological features of BKN, combined in one case with focal medullary JC viral co-infection, in patients with hematologic malignancies, with and without bone marrow transplants, or lung transplants. Several reviews^[2,7,30,31,33,35,36] addressed the manifestations and pathogenesis of BKV infection. Finally, a recent systematic review^[37] analyzed a large number of studies of BKV infection in non-renal solid organ transplant recipients. This study concluded that BK viremia was lower in non-renal than in renal transplant recipients and that BKN is rare in non-renal transplant recipients. In non-renal organ transplant recipients, overall incidence of BK viruria was 20% and incidence of BK viremia was 3%, with the highest incidence of BK viremia and BKN found in heart transplant recipients^[37].

URINARY MANIFESTATIONS OF BKV INFECTION IN PATIENTS WITH BONE MARROW OR STEM CELL TRANSPLANTS AND SOLID TRANSPLANTS OTHER THAN KIDNEY

Table 1 shows the reported organ transplants, other than solitary kidney transplants, in which clinical manifestations of BKV infection have been described. An extensive list of references is attached to each transplanted organ with BKV infection indicating the

rising interest in this topic.

BK viral infections in the urinary system of recipients with bone marrow or stem cell transplants^[2,5,8,38-81]

Hemorrhagic cystitis has been a frequent and serious complication of bone marrow transplantation. This condition had been attributed to the use of cyclophosphamide. Arthur *et al.*^[38] reported a substantially higher frequency of BK viruria in patients who developed hemorrhagic cystitis compared to those who did not develop hemorrhagic cystitis after bone marrow transplantation. They also identified a temporal association between the development of BK viruria and the onset of hemorrhagic cystitis. Bedi *et al.*^[41] concluded that prophylactic treatment with MESNA and forced diuresis directed at cyclophosphamide toxicity failed to prevent hemorrhagic cystitis in patients with BK viruria.

Subsequently, a large number of publications^[5,39,41,43-45,47-50,52,53,55-57,59,61,62,66-68,71,75] provided firm evidence linking BKV infection and hemorrhagic cystitis in bone marrow or stem cell recipients and addressed various aspects of this syndrome.

Peinemann *et al.*^[45] reported that hemorrhagic cystitis in pediatric bone marrow transplant recipients is characterized by delayed onset, prolonged duration, viral reactivation and use of high doses of the alkylating agent busulfan. Bielora *et al.*^[46] described patients with BKV-induced hemorrhagic cystitis triggered by cytomegalovirus (CMV) reactivation. Giraud *et al.*^[57] reported that the frequency of BK viruria and hemorrhagic cystitis was reduced in bone marrow recipients with related donors and in those receiving reduced intensity conditioning for the bone marrow transplant. The data analyzed by Koskevu *et al.*^[71] suggest that BKV hemorrhagic cystitis may result from nosocomial transmission in pediatric bone marrow transplant recipients with very low or undetectable BKV antibodies. These authors raised the issues of infection control and prophylactic use of cidofovir.

Various malignancies and aplastic anemia were frequent underlying diseases leading to bone marrow transplantation in the reports of BKV hemorrhagic cystitis. Hereditary hematological diseases, including thalassemia and sickle cell anemia were reported in a few instances^[66]. The severity of BKV hemorrhagic cystitis varies. Patients with life-threatening blood loss from hemorrhagic cystitis require drastic surgical interventions. Sébe *et al.*^[48] reported successful treatment of life-threatening blood loss by subtotal cystectomy in

BK nephropathy was manifested at various times post-heart transplantation. Ages reported in this Table are the calculated ages at the time of diagnosis of BK nephropathy. ESRD: End-stage renal disease; ARF: Acute renal failure; SCr: Serum creatinine; GFR: Glomerular filtration rate; GVHD: Graft vs host disease; NR: Not reported.

patients with BKV hemorrhagic cystitis.

The level of BK viruria^[40,54,65,72,74,80] and plasma loads of BKV DNA^[76] predict clinical manifestations of BKV infections, including hemorrhagic cystitis. However, BKV infection is not the only, or even the more common, cause of hemorrhagic cystitis^[43]. Use of busulfan^[44] and adenovirus infection^[46] were also identified as other

important causes of this entity.

Other manifestations from the urinary system of BKV infection in bone marrow or stem cell recipients include ureteritis with ureteral stenosis^[78,80] and BKN^[8,11,49,50,51,58,60,63,64,70,75,77,79]. One report^[69] reviewed the features of BKN in bone marrow transplant recipients. Table 2 summarizes reported cases of BKN in recipients of bone marrow or stem cell transplant recipients. The majority of subjects developed end-stage renal disease (ESRD) and were placed on dialysis. Mortality was high in this patient sample. De laCruz *et al*^[73] reviewed the clinical manifestations of BKV infection in hematopoietic stem cell transplantation.

BK viral infections in the urinary system of recipients of heart transplants^[11,82-96]

Table 3 summarizes reported cases of BKN in cardiac transplant recipients^[11,84,85,86,89,90,91,93,94,96]. Rejection episodes of varying severity and frequency requiring increased immunosuppressive medications were reported in nine patients and ESRD in eight. Six patients underwent dialysis and three patients died. Lorica *et al*^[94] describe two additional pediatric heart transplant recipients with BKN. A three-month-old girl was on peritoneal dialysis at the time of the report while a 3-year-old girl on peritoneal dialysis died from BK encephalomyelitis^[94]. Thus, BKN has severe adverse effects on both renal function and overall state of health in cardiac transplant recipients. Persistent detection of the characteristic decoy cells in the urine indicating persistent BKV infection without any evidence of clinical manifestations was reported in one heart transplant recipient^[83].

Puliyanda *et al*^[88] compared the incidence of BK viremia and the risk of BKN in patients with isolated kidney, heart, liver, and combined kidney-heart, kidney-liver, kidney-pancreas and kidney-heart-liver transplant recipients. These authors concluded that the risk of BKN is lower in patients with isolated heart or liver transplants than in those with kidney transplants. High levels of BK viremia were associated with BKN in this study. However, none of the patients with heart transplants exhibited BK viruria and the plasma levels of BKV were low in liver transplant recipients.

Ducharme-Smith *et al*^[95] found BK viruria in approximately one third and BK viremia in only 7% of pediatric heart transplant recipients. One of the viremic patients developed BKN. Multivariate analysis identified history of Epstein-Barr infection as the only predictor of BK viruria in the same study^[95]. In another study, Pendse *et al*^[87] found definitive evidence of BK viruria in 13% of the heart transplant recipients but no signs of BKN. These authors proposed that a second organ-specific insult to the kidneys is needed for patients with BK viruria to develop BKN.

BK viral infections in the urinary system of recipients of lung transplants^[97-102]

A small number of cases of BKN in lung transplant

Table 3 BK Nephropathy in heart transplant recipients

Ref.	Gender age	Renal function	Clinical associations
[11]	Male, 65 yr	ESRD Refused dialysis	No rejection episodes Urothelial transitional cell carcinoma causing bilateral hydronephrosis Death following perforated gastric ulcer

BK nephropathy was usually manifested several years post-heart transplantation. Ages reported in this Table are the calculated ages at the time of diagnosis of BK nephropathy. ESRD: End-stage renal disease; SCr: Serum creatinine; eGFR: Estimated glomerular filtration rate.

recipients has been reported^[98,101,102]. Pertinent features of these patients are summarized in Table 4. Two of the three patients developed ESRD and were started on dialysis. One of these two patients died. One case of nephropathy secondary to a different polyomavirus (simian virus 40 or SV40) in a 32-year-old man with cystic fibrosis who had received a lung transplant was also reported^[97]. This case progressed to ESRD. Another publication reported a case of BK hemorrhagic cystitis in a lung transplant recipient^[99].

Thomas *et al*^[100] studied longitudinally the frequency of viruria from three different polyomavirus species (BKV, JCV, SV40) in lung transplant recipients. Viruria, at least in one instance, was found for BKV in 42% of the patients, for JCV in 28% and for SV40 in 7%. Although no definitive evidence of clinical polyomavirus infection was detected in this study, patients with viruria had shorter survival.

BK viral infections in the urinary system of recipients of liver transplants^[32,88,103-113]

We found only one reported case of BKN in a liver transplant recipient^[112]. This case is summarized in Table 4. One man with combined liver-kidney transplants developed IgA nephropathy in his native kidneys and BKN in the transplanted kidney^[110].

Several reports analyzed the frequency of BK viruria and viremia and its relationship with renal disease in liver transplant recipients^[32,88,103-109,111,113]. Low frequencies of BK viruria and viremia and low risk of BKN were commonly reported^[32,88,103,108]. Salama *et al*^[104] concluded that BKV infection is not associated with a decline in renal function in liver transplant recipients. Rauschenfels *et al*^[105] concluded that hepatotropic viruses, including BKV, do not have a major role in the pathogenesis of biliary atresia, which is the major condition leading to liver transplantation in pediatric populations.

Higher frequencies of BK viruria and viremia and a risk of kidney disease from BKV infection were reported in a few studies of liver transplant patients. Loeches *et al*^[106] reported BK viruria in 21% and BK viremia in 18% of the liver recipients, the last one early after transplant, and concluded that persistent BK viremia may be associated with renal dysfunction. Demir-Onder *et al*^[111] reported similar results. Higher frequency of BK viruria in pediatric than adult liver transplant recipients was described by Brinker *et al*^[107]. Finally, Mitterhoffer *et al*^[109] reported a higher frequency of BK viremia (56%) in prospective liver transplant recipients with preexisting chronic kidney disease than in those with normal kidney function (14%).

BK viral infections in the urinary system of recipients of pancreas and kidney-pancreas transplants^[114-135]

We found only one confirmed case of BKN in a recipient of an isolated pancreatic transplant recipient^[114]. This case is summarized in Table 4. BKN has been reported in renal transplants of several recipients of combined kidney-pancreas recipients^[115,117-120,123-125,128,129,132-135].

The prevalence of BKV replication and BK viruria in those with combined kidney-pancreas transplants was high in several studies^[116,126-128]. However, one study^[120] reported a low incidence of BKN (2.9%) in recipients of combined kidney-pancreas transplants. CMV viremia may prevent reactivation of BKV in these patients and in recipients of solitary kidney transplants^[130].

Preservation of pancreatic function was reported uniformly in recipients of combined kidney-pancreas transplants with BKV infection^[115,117,119,120,124,128,129,133]. Preservation of normal kidney transplant function was reported in some studies^[129,132-134], while other studies^[117-119,123] concluded that BKN was an important cause of significant deterioration of the transplanted kidney function. A multivariate analysis performed by Heilman *et al*^[121] identified BKN and a serum creatinine level at or above 1.6 mg/dL as independent correlates of renal graft fibrosis in kidney-pancreas transplant

Table 4 BK nephropathy in recipients of lung, liver and pancreas transplantation

Ref.	Gender age	Renal function	Clinical associations
Lung [98]	Male 40 yr	ESRD On dialysis	Metastatic seminoma treated successfully Three rejection episodes
[101]	Female 72 yr	Peak SCr 2.6 mg/dL Last SCr 2.2 mg/dL	Prolonged neutropenia post-transplant No rejection episodes
[102]	Male 9 yr	ESRD Dialysis	Collecting duct carcinoma Death from respiratory and cardiac failure
Liver [112]	Male 59 yr	SCr 1.9 mg/dL at diagnosis	Multiple rejection episodes Follow-up after diagnosis not reported
Pancreas [114]	Male 54 yr	SCr 2.2 mg/dL At diagnosis	Follow-up after diagnosis not reported

ESRD: End-stage renal disease; SCr: Serum creatinine.

recipients. A recent study by Schachtner *et al*^[135] concluded that in comparison to recipients of solitary kidney transplants, recipients of combined pancreas-kidney transplants exhibit a higher incidence and severity of BKN.

The diagnosis of BKN in recipients of combined kidney-pancreas transplants is complicated by the potential absence of decoy cells in the urine. Decoy cells are an important diagnostic clue for BKV infection in the urinary tract. High concentrations of pancreatic enzymes in the urine of transplanted patients may degrade these cells^[122]. Quantitative nucleic acid testing for BKV may assist in the diagnosis of BKN in these subjects^[131]. Kubal *et al*^[125] reported renal transplant nephrectomies and subsequent successful combined kidney-pancreas transplants in two patients who had developed BKN and ESRD in the initial kidney allograft.

In general, BKN in native kidneys of patients with various transplanted organs is substantially less frequent than in transplanted kidneys, but like BKN in transplanted kidneys tends to lead to ESRD and is associated with significant mortality.

BKV INFECTIONS IN OTHER POPULATIONS

BKV infection with various clinical manifestations has been reported more frequently with diagnostic entities either causing immunosuppression or requiring therapeutic immunosuppression than in individuals without an apparent immunosuppressed state. The manifestations of BKV infection in immunosuppressed and non-immunosuppressed states are briefly discussed below.

BKV infections in patients with HIV infection have

been studied extensively^[136-168]. Both BKN^[139,147,151,154,155,159,164,166] and hemorrhagic cystitis^[157,165] have been reported in HIV patients. A series of studies addressed rates of BK viremia and viruria^[136,137,140,141,143,144,162-163,168], the pathogenesis of BKV infection^[157,165] and various clinical aspects of this infection^[138,140,145,146,149,150,152-154,156,158,160,167] in HIV-positive populations.

A patient under treatment for granulomatosis with polyangiitis developed BK hemorrhagic cystitis^[169]. However, in a series of patients with vasculitis associated with ANCA, only those who had received a kidney transplant exhibited BK viremia^[170]. Manifestations of BKV infection in patients with systemic lupus erythematosus (SLE) include viruria and viremia, and the presence of decoy cells in the urine of a patient with BK viruria, hemorrhagic cystitis and hemophagocytic syndrome^[171,172]. The tendency of experimental animals with BKV infection to form anti-double stranded antibodies (anti-dsDNAs) has led to the hypothesis that BKV infection triggers SLE^[171]. Life threatening hemorrhagic cystitis secondary to polyomavirus JC was reported in an adolescent with ataxia-telangiectasia^[173].

BKV infection in patients with various malignancies has been a major focus of the literature^[174-186]. An early study reported BK viruria in patients receiving chemotherapy for malignancy^[174]. BKN has been diagnosed in patients with chronic lymphocytic leukemia^[176,177,180,183], acute lymphocytic leukemia^[178,180,185] and Hodgkin's lymphoma^[175]. BK cystitis was reported in patients with Hodgkin's lymphoma^[182,184,186]. One other patient with lymphoma^[179] developed neurological manifestations of BKV infection.

The potential role of BKV infection in tumorigenesis has received great attention^[187-248]. Urothelial malignancies in association with BKV infection were described in several recipients of kidney transplants^[200,205,213,214,216,220-223,227,229,233,234,236,238,239,245,247] and one heart transplant recipient^[243]. Malignancies in non-transplanted subjects in which BK infection may play a pathogenetic role include bladder carcinoma^[201,211], renal cell carcinoma^[192,230], prostatic carcinoma^[212,217,235,245], Kaposi's sarcoma^[197], neuroblastoma^[199], leukemia, non-Hodgkin's lymphoma^[205], colorectal carcinoma^[215], gastrointestinal B-cell lymphoma^[240], oral squamous cell carcinoma^[244], cervical carcinoma^[224], breast carcinoma^[226] and melanoma^[206].

The role of BKV in tumorigenesis has been disputed. Several studies^[187,203,208,216,223] failed to find an association of BKV infection with various malignancies and published reviews of the role of BKV in malignancies^[202,209,219,231,232,241,247] reflect the current uncertainty about this topic. However, in animal experiments BKV has been shown to play a role in tumorigenesis^[190,191,193,195,196,198] and several reports^[192,194,199,201,204,209,210,217,218,237,242] have addressed pathogenetic pathways potentially linking BKV infection and tumorigenesis. A commonly discussed mechanism is inactivation of the tumor suppressor proteins p53 and pRB

family by the large T antigen T (T-Ag), which is a major antigen of BKV^[199,204]. Other proposed pathways of tumorigenesis include the role of BKV as a cofactor in various malignancies^[217,237] and BKV integration in the human genome^[242].

Finally it is worth noticing that BKV infections with manifestations from the urinary system have been rarely reported in subjects without other systemic diseases. Examples of these infections include a case of BKN, urothelial ulceration and renal pelvic fibrosis with an imaging picture of a renal mass^[249] and the association of BK, and to a greater extent JC, viruria with asymptomatic hematuria in a small sample of Koreans^[250].

CLINICAL MANIFESTATIONS OF BKV INFECTION OTHER THAN NEPHROPATHY OR HEMORRHAGIC CYSTITIS

Table 5 shows clinical manifestations of BKV infection that have been reported so far. Manifestations other than BKN and hemorrhagic cystitis^[15,78,81,145,146,251-287] will be reviewed in this section. In addition to the kidneys and urinary bladder, BKV was detected at autopsy in the epithelial cells of the ureters of a patient with non-Hodgkin's lymphoma^[15]. Ureteral involvement by BKV with various degrees of urinary obstruction was reported in patients with bone marrow or hematopoietic stem cell transplants^[78,81,252,255] and renal transplants^[251,253,254]. Fatal BK pneumonia was reported in three patients with hematopoietic stem cell transplants^[257,259,260] and two patients under treatment for chronic lymphocytic leukemia^[258,261]. BKV infection also accounted for 8% of the acute respiratory infections in non-immunocompromized children^[256]. BKV infections in non-immunocompromized patients are probably under represented.

Various neurological syndromes associated with BKV infection have been reported in patients with acquired immune deficiency syndrome (AIDS)^[138,142,145,150,152,158,262,269]. In addition to AIDS patients, BK meningoencephalitis has been reported in non-immunocompromized subjects^[263,264], in patients with malignancies including chronic lymphocytic leukemia^[261], Hodgkin's lymphoma^[266], and in a kidney transplant recipient^[273]. Progressive multifocal leukoencephalopathy, also often diagnosed in AIDS patients, has been associated primarily with the JCV^[261,265], but has also been reported in association with BKV infection in one patient^[270]. However, this last association needs confirmation^[271]. A case of progressive multifocal leukoencephalopathy associated with both JC and BKV infections in a non-immunocompromized patient has also been reported^[272]. BK retinitis associated with other manifestations of BKV infection has been reported in AIDS patients^[145,146]. Progressive outer retinal necrosis developed in a kidney transplant recipient with BKV and varicella zoster virus in the vitreous fluid^[275]. This retinal disease was probably caused by varicella zoster virus. Neurological synd-

Various other tumors

romes associated with BKV infection were analyzed in two reviews^[268,274].

Deltoid muscle biopsy in a renal transplant recipient who developed progressive weakness and dyspnea, and died after several episodes of life-threatening arrhythmias revealed BK vasculitis^[276]. A detailed description of the glomerular histologic changes in a large study of renal biopsy samples with BKN^[277] failed to identify vascular changes. However, in other reports BKV was found to be localized in endothelial cells of both renal arteries and venules^[278] and venous thrombosis associated with BKN was diagnosed in a renal allograft by ¹¹¹In leukocyte imaging^[279].

BKV is replicating in salivary glands^[280]. High frequency of BKV shedding from the gastrointestinal tract in recipients of hematopoietic stem cell transplants has been reported^[65]. Gastrointestinal bleeding associated with bowel lesions putatively caused by BKV infection was reported in a renal transplant recipient^[281] and a hematopoietic stem cell transplant recipient^[282]. Interestingly, high rates of BK viruria in patients with inflammatory bowel disease have been documented^[283]. However, the clinical significance of this finding will require further study.

Pancytopenia or severe neutropenia associated with BKV infection have been found in kidney transplant recipients^[284-286]. Hemophagocytic syndrome was diagnosed in one of these patients^[286]. Polyclonal gammopathy triggered by BKV infection was reported in a hematopoietic stem cell transplant recipient suffering from B-cell lymphoblastic leukemia^[287]. BKV DNA has been isolated in normal hepatic tissue and elevated hepatic enzymes were reported in bone marrow trans-

plant recipients who had BK viruria^[24].

Key points of part A

Clinical manifestations of BKV infection have been reported in patients with various immunosuppressed states and small numbers of subjects with apparent absence of immunosuppression. Although BKN is much less frequent in the native kidneys of organ transplant recipients than in transplanted kidneys, it is uniformly associated with poor outcomes. BKV infection causes a variety of clinical manifestations in addition to nephropathy and hemorrhagic cystitis.

PART B DIAGNOSIS OF BKN AND PATHOGENESIS OF BKV INFECTION

DIAGNOSIS OF BKN^[10,13,14,16,22,277,288-336]

BKN accounts only for a small fraction of the renal dysfunction encountered in transplant recipients. Its diagnostic features have been extensively studied in renal transplant recipients. Risk factors for the development of BKN including certain immunosuppressive agents, such as mycophenolate, and manifestations of BKV infection in the urinary tract, including BKN, ureteral obstruction, lymphocele, bacterial urinary tract infection, hematuria, and elevated serum creatinine levels have been studied in renal transplant populations^[22,288]. A study from South Korea^[336] identified an accompanying acute rejection episode, in addition to advanced histologic stage of BKN and elevated serum creatinine levels, as factors increasing the risk of renal transplant failure in renal transplant recipients. Reports involving renal transplant recipients constitute the main source of information reviewed in this section.

Renal biopsy constitutes the gold standard for the diagnosis of BKN. Various aspects of the renal biopsy in BKN have been studied^[10,13,14,16,291,294,296,298,299,301-303,307,311,312,314,316,322,324,328]. An early report by Rosen *et al.*^[13] identified tubulo-interstitial nephritis as the main histologic picture of BKN. Viral replication in the tubular epithelial cells, starting in the renal medulla and extended later to the renal cortex, initiates cytopathic changes in the renal tubules that can be confirmed by immunohistochemistry, *in situ* hybridization, electron microscopy or polymerase chain reaction (PCR)^[291,316].

The Maryland classification of BKN^[291,296,298], which is based on the degree of interstitial inflammation and fibrosis, schematically recognizes three histological patterns which are considered to represent successive stages of BKN. The first pattern is characterized by absent or minimal interstitial inflammation and the presence of viral cytopathic changes, including karyomegaly, hyperchromasia, and basophilic nuclear inclusions, in a few tubular cells located primarily in the renal medulla. Cytolytic changes, including cell necrosis, apoptosis, smudged chromatin and hobnail nuclei with desquamation into the tubular lumen and formation of necrotic casts accompany often the cytopathic

changes^[291].

The second pattern of the Maryland classification is characterized by focal or diffuse clusters of tubules with cytopathic and cytosolic changes plus interstitial collections of inflammatory cells, primarily lymphocytes, with tubulitis and tubulo-interstitial atrophy in some cases. The third pattern is characterized by extensive interstitial fibrosis and tubular atrophy, lymphocytic infiltration and paucity of viral cytopathic changes. The course of renal dysfunction roughly correlates with the histological staging^[291].

A key diagnostic feature of BKN is the finding of viral cytopathic changes, which are apparently identical for papovaviruses BKV, JCV and SV40^[296]. The nuclei of the infected cells are large and contain a basophilic inclusion that either replaces the chromatin or displaces it to the periphery of the nucleus (Figure 1A and C). The presence of a halo around the BKV inclusion is used to differentiate between BKV infection and CMV infection. The BKV infected cells have larger nuclei in comparison to cytoplasm and no viral inclusions in their cytoplasm. Immunohistochemical staining for SV40 large T antigen (Figure 1B), which cross-reacts with BKV and JCV, identifies the presence of a papovavirus and allows its differentiation from adenovirus, which can also cause nephritis with intranuclear viral inclusions morphologically identical to those of papovaviruses. Transmission electron microscopy of cells infected with papovavirus shows characteristic intranuclear deposits of polyhedral virions with an average diameter of 40 nm and in some cases fibrillary or microtubular inclusions. Electron microscopy may assist in the differentiation of papovavirus virions from those of CMV, adenovirus and herpesvirus^[296].

The proposed sequence of events leading to the histological changes of BKN is as follows^[296]: Viral infection leads to cell death and disintegration with discharge of virions in the extracellular space. Entrance of virions into adjacent cells leads to spread of the infection. Infected renal tubular cells and virions exfoliate in the urine. If the tubular injury is severe, tubular basement membranes rupture causing spillage of virions and viral proteins into the blood stream. Severe tubular injury also causes an inflammatory response with influx of tubulo-interstitial B cells, T cells, plasma cells and macrophages (Figure 1C). This histological picture can be confused with acute cellular rejection (ACR) in renal transplant recipients. When it is severe or persistent, the tubular injury leads to tubular atrophy and interstitial fibrosis.

The utility of the Maryland staging of BKN, modified by the American Society of Transplantation, has been successfully tested in clinical practice. In one study, the third pattern was associated with higher serum creatinine levels at presentation and greater renal function deterioration in follow-up measurements than the first or second pattern^[299].

The histology of BKN has been reviewed in successive Banff group meetings^[307,312,314,328]. The original

Banff classification also recognizes three histologic patterns, characteristic of the stages of BKN: (1) an early stage without tubular cell necrosis; (2) a stage of active BKN with tubular cell necrosis (Figure 1A); and (3) a late stage characterized by fibrosis (Figure 1D)^[307]. In one study, reasonable agreement between various nephropathologists was reported using this Banff classification^[312]. However, another study failed to demonstrate superiority of the Banff staging of BKN over the Maryland classification^[314]. The latest Banff group meeting stressed the need for improving the reproducibility of large SV40 T antigen immunostaining, which is proposed as an index of the BKV viral load and a potential predictor of the renal graft outcome in patients with BKN^[328]. *In situ* hybridization may offer an alternative to immunohistochemistry in the diagnosis of BKN^[316]. The diagnostic challenges associated with BKN were recently reviewed by Masutani^[324].

In renal transplant biopsies with BKN, the presence of peritubular capillary staining for C4d raises the possibility of coexisting antibody-mediated (humoral) rejection. Some biopsies with BKN show staining of tubular basement membranes for C4d, and this finding is correlated with marked viral cytopathic effect^[303]. Granular immune complex deposits in the tubular basement membranes^[301] and in the subepithelial space of glomerular basement membranes^[302] have been described in patients with BKN. In the latter, BKV was identified ultrastructurally in the immune deposits^[302]. Glomerulonephritis attributed to BKV infection was found in a few renal transplant recipients^[277,321].

The focal lesions of the early stages of BKN may be missed in a renal biopsy^[298,324]. Several diagnostic pathways complementing the renal biopsy have been explored. The value of surveillance renal biopsies in early diagnosis of BKN has been discussed in several reports^[22,310,313]. BK viremia^[22,297,306,308,317,322,332,334] and viremia^[22,289,308,309,317,322,323,332,335] provide another tool for the detection of BKN. High levels of viremia or viremia correlate reasonably with the presence of BKN. Cut-off levels for the diagnosis of BKN have been proposed and tested.

Detection in urinary samples of desquamated tubular or urothelial cells with BKV inclusions provide another tool for the diagnosis of BKV infection in the urinary system^[291]. The cardinal features of these cells, known as "decoy cells", because of their similarity to malignant cells, in a Papanicolaou stain include a greatly enlarged nucleus with a basophilic inclusion next to the chromatin producing a ground-glass or gelatinous look. A halo may surround the basophilic inclusion. Decoy cells may also be detected by phase-contrast microscopy^[292]. Decoy cells led to the diagnosis of BKV infection in an immunocompetent child with otitis media followed by dysuria^[315]. However, decoy cells may be absent from the urine of patients with documented BKN^[333]. In one study, the positive predictive value of decoy cells was low, but improved by immunohistochemical staining of the urine for SV40 large T antigen^[331]. Negative-stain electron

microscopy and semi-quantitative identification of free BKV particles in the urine assists in the identification of patients at high risk of BKN^[300]. Genotyping of BKV by an improved PCR method^[327] and serologic tests^[329] may help in the diagnosis of BKV infection. Ultrasonographic pictures suggesting BKN were recently reported^[330].

In renal transplant recipients, the differentiation between ACR and BKN presents difficulties^[294]. The histologic picture of tubulo-interstitial nephritis is indistinguishable between the two conditions^[319]. Immunophenotyping of the mononuclear cells in the interstitial infiltrates was found to be promising in some studies^[304,318], but could not differentiate between ACR and BKN in others^[305]. Serial monitoring of donor-specific cell-free DNA in the urine may be a sensitive biomarker of acute kidney injury, but does not allow the distinction between ACR and BKN^[320]. Urine analysis methodologies potentially allowing the differentiation of these two conditions are proteomics^[325] and characterization of the percentages and absolute numbers of CD4(+) and CD8(+) effector memory T cells^[326].

Several other questions related to the diagnosis of BK infection in the urinary tract have been investigated. Immunohistochemical analysis of renal biopsies revealed differences in the inflammatory infiltrate between different BKV strains^[290]. Additionally, latent BKV and JCV were found in the urinary tract of immunocompetent subjects in an autopsy study^[295]. One review^[311] analyzed the diagnosis and pathogenesis of BK cystitis in hematopoietic cell transplant recipients. Another study found a high rate of mutations in the coding region VP-1 of BKV in HIV-infected patients with low CD4(+) counts^[330]. The authors of this study postulated that these mutations could affect the clinical manifestations of BKV infection in HIV patients. Whether the diagnosis of BKV infection will require in the future an analysis of the mutations of the virus in various patient groups or individual patients is not clear.

PATHOGENESIS OF BKV

INFECTION^[10,20,35,126,336-436]

BKV is a small, unenveloped icosahedral DNA virus. Its genome sequence contains three functional regions. The early region encodes the large T antigen (T-Ag) and the small T antigen. These antigens are involved in BKV DNA replication and could be treatment targets. As noted earlier, interaction of T-Ag with p53 is believed to be the main pathway of tumorigenesis by BKV. The late region is responsible for the production of the proteins VP1, VP2 and VP3, the role of which in BKV infection will be examined later. Finally, the non-coding control region controls the expression of the viral genes^[423].

The pathogenesis of BKV infection, and specifically of BKN, is a complex process that has not been elucidated completely. Costa *et al.*^[10] listed factors related to the patients, the transplanted organs, and the BKV genotypes as determinants of the development

of BKN. The first contact with BKV occurs early in childhood. Antibodies against BKV are found in 50% of the subjects by age 3 and in 80%-90% by age 20 years, with decrease in the antibody titers in older age^[20]. The incidence of primary infection is similar in immunosuppressed and non-immunosuppressed children^[340].

Age older than 50 years is one of the patient-related risk factors for BKN^[10]. In non-immunocompromised subjects, the rate of BK viremia is low below the age of 30 years and increases progressively after that age^[35]. Older subjects excrete preferentially the BKV viral subtypes I and IV^[35]. In a fraction of the subjects the virus persists without clinical manifestations, but in a state of active asymptomatic replication^[35]. Organs harboring replicating BKV include the kidneys, the bone marrow and the brain^[35]. Persistence of the virus in other tissues, including spleen, normal thyroid glands^[429], pancreas^[342], and lymphocytes in HIV-positive patients^[344], has also been reported. Active BKV disease in various organs is more frequent if another insult to these organs has also occurred. Examples of this sequence include the relatively high frequencies of BKN in kidney transplant recipients and hemorrhagic cystitis in bone marrow or stem cell transplant recipients.

The mode of BKV transmission is not completely understood. Transplacental transmission was described in an early study^[337]. Transmission through the transplanted kidneys has also been documented^[351,430]. Replication of BKV in salivary glands was found *in vitro* suggesting oral transmission^[367]. After the primary infection the virus remains latent in host tissues and is reactivated when an immunosuppressed state supervenes. Following renal transplantation, reactivation of BKV demonstrated by BK viremia is usually noticed after 3-6 mo while reactivation of JCV occurs as early as five days post transplantation^[379]. Early BKV reactivation is associated with viremia^[377] and worse transplant function^[372].

Circulating BKV is taken up by cells. In experimental animals, endothelial cells in hepatic sinusoids and in the kidney were shown to remove rapidly blood-borne BK and JCV-like particles^[409]. Upon contact with the cell membrane BKV is bound to membrane receptors^[381]. The identified specific BKV receptors include polysialated ganglioside GT1b and (2,3)N-linked sialic acid^[351]. Cellular entry of BKV is through caveolar endocytosis^[357,369]. The GT1b receptor, which is involved in caveolar endocytosis^[351], could provide a treatment target in the future.

Differences in cellular entry and trafficking exist between various cell types and viral genotypes^[392]. The capsid proteins VP2 and VP3 have important roles in the nuclear entry of BKV^[414]. BKV genotypes have different potential for pathogenicity^[147,351,356,368,380,389]. The family of transforming-growth factors (TNF) plays a role in BKV gene expression^[359]. BKV infection activates the TNF receptor system in BKN^[432,433]. Monocyte and Th-2 cytokines, including IL-1 RA, IL-3, IL-6 and sIL-6R are

elevated in the urine of renal transplant recipients with BK viremia and may be involved in the pathogenesis of BKN^[370]. In general, BKV infection of renal tubular epithelial cells leads to activation of cellular genes involved in cell cycle regulation and apoptosis and downregulation of a small number of genes^[373].

After entry into the cytoplasm, BKV is transported into the endoplasmic reticulum along the microtubules by a complex mechanism favored by acidic environment^[368]. The ER associated degradation (ERAD) pathway, which is responsible for the transfer to the cytosol of ER secretory proteins that have not attained their proper conformation, where they are degraded by proteasomes, is responsible for transferring BKV into the cytosol, followed by entry of these proteins into the nucleus^[372]. After entry of BKV into the nucleus, BKV genome release takes place^[383]. The Derlin family of the ERAD translocation complex proteins is important for the trafficking of BKV and other polyomaviruses^[370]. Proteasome action is also important in BKV trafficking^[392].

Several reviews have stressed the role of innate immunity in the pathogenesis of BKV infection and the need to monitor both the BK viral load and the state of immunity in populations prone to BKV infection as the first step in the timely management of this infection^[351,395,406]. A recent report reviewed potential preventive and therapeutic approaches for BKV infection related to the mechanisms of innate immunity^[433]. Innate immunity compounds that inhibit BKV infection include lactoferrin^[349], the antimicrobial defensins alpha-defensin human neutrophil protein 1 (HNP1) and human alpha-defensin 5 (HD5) which were shown *in vitro* to aggregate BKV virions thus blocking cellular entry^[363], and the cellular DNA damage response (DDR) which modulates BKV replication^[388,431]. Human leukocyte antigens (HLAs) that are associated with lower risk of BKV infection include HLA-A2, HLA-B44, HLA-DR5^[397] and HLA cw7^[421]. Expression in BKV-infected cells of p53, binding of which to the BKV large T-Ag is proposed as a mechanism of tumorigenesis, may provide a therapeutic target in the future^[353]. In renal tissues, large T-Ag is expressed in decreasing frequency in medullary collecting ducts, distal and proximal convoluted tubules and Bowman's capsule^[350]. Viral replication pathways which could form the basis of therapeutic approaches in the future include agnoprotein, a viral phospho-protein^[364], viral microRNA (miRNA)^[394,410], and autophagy in host cells^[401].

Disruption of adaptive immunity plays a major role in the pathogenesis of BKV infection. Both cellular and humoral aspects of adaptive immunity in BKV infection have been extensively studied. Age affects both the cellular and humoral immune responses to BKV infection^[407]. BKV-specific cellular immunity is vital for control of viral replication and prevention of chronic viral disease^[383]. Low levels of cytotoxic T cell (CTL) response correlate with high BKV loads and high anti-BKV antibody titers, while a high CTL response correlates with low viral loads and low anti-BKV

antibody titers^[347]. The finding that viral capsid epitopes of BKV share homology with other polyomaviruses, including JCV and SV40 suggests that infection with one of the viruses could establish cross-immunity against the other viruses *via* a cellular-immune response^[348].

Loss of BKV-specific T cell immunity in the post-transplant period identifies kidney transplant recipients at high risk for BKV infection^[427]. In patients with BKV infection, recovery of cellular immune responses to large T-Ag correlates with improvement of BKN^[365,384]. However, in one study the percent of activated T cells correlated with the degree of BK viremia^[396]. In the same study, patients with decreased renal function exhibited high levels of activated T cells and BK viremia.

Monitoring of both non-virus specific and virus-specific T cell responses in transplant patients has been advocated^[405,417]. Monitoring these responses post-transplantation may have a role in the detection of BKV reactivation^[423]. T cells respond to different BKV antigens^[419]. The nuclear factor of activated T cells (NFAT) binds to the viral promoter and regulates viral transcription. This factor is involved in a complex regulatory pathway that can affect the course of BKV infection^[375]. The genetic variation of BKV strains is limited^[425]. In HLA-A*0201 individuals, cytotoxic T-cell lymphocyte (CTL) responses are elicited towards two of the VP1 epitopes, VP1(p44) and VP1(p108)^[347]. CTLs directed against VP1(p44) are more abundant than VP1(p108) in healthy individuals, while the opposite is true in kidney transplant patients who present with BKN. This suggests a shift in the epitope immunodominance in the setting of active BKV infection^[347]. Flow-cytometry analysis of BKV-specific T cells also showed that VP3 is an important target of cellular immunity^[386].

CD4 T cells have a role in BKV clearance^[387,412]. Though the pattern of cellular response to BKV antigens has not been fully clarified, it has been discovered that in kidney allograft recipients, VP1-specific interferon-gamma producing T cells were more likely to be CD4⁺, while CD8⁺ lymphocytes are more frequently directed against the large T antigen^[361]. Stimulation of CD28 in T cells is one of the rejection mechanisms blocked by belatacept. Subpopulations of human T cells exposed to antigens may be activated by mechanisms different than CD28 and cause rejection resistant to belatacept. In mice models polyomavirus exposure leads to reduced expression of CD28 in T cells and was proposed as a mechanism of resistant rejection^[422]. Activated CD4 T cells upregulate CD30, another cell marker of B and T cells, causing an increase in serum soluble CD30 (sCD30), which plays a role in the pathogenesis of rejection^[366]. Levels of sCD30 are associated with BK viremia and may be of use in the management of the immunosuppressive regimen for renal transplant patients as well as a prognostic factor for graft rejection^[436].

The role of dendritic cells in antigen presentation to T cells is well known. Dendritic cell deficiency was shown to be a risk factor for reactivation of BKV infection after renal transplantation^[382]. A genotypic analysis in renal

transplant recipients found that low frequencies of the activating receptor KIR3DS1 are associated with the development of BKV infection and that there appears to be a genetic predisposition for BKN linked to natural killer cells^[402].

The interplay between genetics and immunology is reflected in the finding that the NFAT can transcriptionally regulate BKV. During T-cell activation, NFAT translocates to the nucleus where it regulates the expression of various genes^[341]. NFAT regulates BKV transcription, while NFAT inhibition with an NFAT inhibitor peptide, 11R-VIVIT, reduces BKV replication^[375]. In addition there is growing evidence that epigenetic factors may contribute to the regulation of BKV and its tissue propagation. Viral microRNAs (miRNAs) are playing a crucial role in viral replication. BKV-encoded miRNAs (miR-B1) have been studied in patients with BKN. After BKV infection, miR-B1 levels are significantly increased and these miRNAs suppress T-ag-mediated autoregulation of BKV replication. Thus, miR-B1 offers a potential treatment strategy for controlling BKV infection^[410].

In addition to cellular immune response, humoral immunity also plays an important role in BKV infection. Antibodies to various BKV antigens were detected in normal controls and patients suffering from various diseases; patients with urinary bladder carcinoma exhibited the highest frequency and titers of anti-BKV antibodies^[338]. HIV patients with BK viremia and JC viremia have a low frequency of antibodies against these two viruses^[343]. In renal transplant recipients, BKV-specific IgG levels were in the pre-transplant period lower in those who developed active BKV infection than in those who did not develop BKV infection; the rise in the antibody titers post-transplant, however, was higher in patients who developed BKV infection^[360]. In this last group, antibody titers correlated with the intensity of BKV infection. This suggested that specific anti-BKV IgG response is not associated with viral clearance^[360]. A prospective study concluded that determination of the serostatus of prospective kidney transplants and recipients allows stratification of the risk for BKV infection post-transplant^[398].

Pre-kidney transplant levels of anti-BKV antibodies did not clearly predict post-transplant BK viremia in pediatric renal transplant recipients^[374]. However, there is considerable evidence pointing to a link between antibody titers and BKV disease progression in the post-transplant period. Pediatric patients with hemagglutination-inhibition titers < 40 were found to be at greater risk of disease progression, and seronegative recipients were found to be at greater risk of developing BKN if seronegativity was demonstrated by the VP1 enzyme immunoassay^[351]. In patients at different stages of BKN, BKV-specific IgG levels were higher in those who had recovered from BKN than in patients with acute infection. Interestingly, the density of plasma cells in the interstitial infiltrates of BKN was found to correlate with the levels of circulating anti-BKV IgM

in one study^[378]. BKV infection was fatal in a patient with hyper-IgM deficiency. This patient, whose class switching from IgM to IgG was impaired, was not able to produce the protective IgG antibodies against the virus^[351]. This case suggests that immunoglobulin response has an important role in controlling BKV infection.

Measurement of the anti-BKV titers is an important tool to detect the onset of viral replication^[352]. Further research is needed to determine the extent to which these antibodies can neutralize the virus or its active viral components, though some suggest that there are BKV neutralizing antibodies that target VP1^[351,361,378]. *In vitro* coinubation of BKV with human intravenous IgG preparations caused 90% inhibition of viral DNA after 7 d in culture, a finding consistent with a direct neutralizing mechanism. This suggests a mechanism of protection against viral reactivation in an immunocompetent person by virus-specific antibodies^[378].

Other aspects of antibody formation in BKV infection are of importance. In experimental animals, BKV infection induces the formation of anti-double stranded DNA antibodies^[362]. This finding has led to the suggestion that BKV is implicated in the pathogenesis of SLE, as noted earlier in this report^[171,172]. In a recent report, preemptive reduction of immunosuppression for BK viremia was found to be associated with high incidence of formation of HLA-specific antibodies (dnDSA)^[420]. The authors of this report proposed that in order to prevent the consequences of rejection dnDSA levels should be monitored in renal transplant recipients subjected to reduction of immunosuppression for BK viremia.

The effects of interferon on BKV infection have also attracted attention. Exposure of interferon-sensitive cells infected with BKV to high concentrations of interferon resulted in significant reduction of the BKV load in an early study^[339]. However administration of interferon to a renal transplant recipient with BK viremia and viruria had no appreciable effect in the same study. *In vitro*, interferon- γ inhibits the expression of the BKV T-ag and VP1^[353]. Polymorphisms in the interferon- γ gene appear to affect the development of BKV infection in Hispanics^[408].

A review of subversion mechanisms of several viruses causing kidney disease^[354] stressed the role of immunosuppressed state in the pathogenesis of the viral kidney diseases, included BKN. The state of immunosuppression is the major mechanism of BKV reactivation and has been stressed in numerous reports^[10,351,372,393,422]. Immunosuppressive medications that may increase the risk of BKV infection include tacrolimus^[372,393,403], and mycophenolate^[393]. ABO incompatible kidney transplantation is a risk factor for BKV infection^[413,415]. Although immunoglobulin preparations inhibited BKV replication *in vitro*^[378] and administration of intravenous immunoglobulin was found to be effective and safe in treating BK viremia in one study^[385], desensitization of ABO and HLA incompatible kidney transplant

recipients with IVIG and rituximab was associated with higher incidence of BKV infection^[126,391].

Other factors associated with increased risks for BKV infection and BKN include recipient age exceeding 50 years^[10], male gender, comorbidities (diabetes mellitus)^[10], negative recipient BKV serology prior to transplantation^[10], prior rejection episodes^[10,424], renal dysfunction^[10], large BKV loads^[10], deceased donor^[403], positive CMV serology in donor and recipient^[424], more than one transplant^[424] and hypoxia^[428]. In allogeneic stem cell transplant recipients, severe graft vs host reaction and oral mucositis are risk factors for BKV reactivation^[434]. Mathematical modeling of the immune responses to BKV infection^[432] could provide in the future new developments in the prevention and management of this disease.

Key points of part B

Renal biopsy is required for confirmation of the diagnosis and staging of BKN; BK viral loads in blood and urine and the presence of decoy cells in the use assist in the diagnosis of BKV replication; elucidation of the mechanism of BKV entry into cells and nuclei, factors affecting BKV replication and of the roles of cellular and humoral immunity in BKV infection have the potential of leading to novel prevention and treatment strategies.

PART C TREATMENT OF BKV INFECTION AND DISEASES CAUSED BY OTHER PAPOVAVIRUSES. TREATMENT AND PREVENTION OF BKV INFECTION^[10,19,20,79,92,385,437-493]

Current practices in the prevention and management of BKV infection are based on information obtained primarily from renal transplant recipients. In this patient group, reduction in immune responses to infection as a result of immunosuppression has been recognized as the universal risk factor for symptomatic BKV infection^[10]. A large retrospective study of treatment of BKN in United States renal transplant recipients concluded that the incidence of BKN has been on the rise and is associated with increased risk of graft loss^[19]. The same study reported that certain antirejection medications, including rabbit antithymocytic globulin and tacrolimus/mycophenolate combination, are risk factors for BKN.

Reducing the total immunosuppressive dose and converting to medications less prone to be associated with BKV infection has been reported to have beneficial effects on BK viremia and viruria in various renal transplant cohorts^[447,451,455,471,480,481,484]. In a study from China, monitoring renal transplant recipients for BK viremia and preemptive reduction of immunosuppression was associated with resolution of the viremia and good graft function over five years of follow-up^[481]. Reduction of

immunosuppression, with careful monitoring for signs of rejection of the transplanted organ, and discontinuation of immunosuppressives that are associated with higher risk of BKV infection, *e.g.*, mycophenolate, is currently the mainstay of management of BKV infection in transplant recipients.

Prevention and management of BKV infection in vulnerable populations is hampered by the absence of medications specific for papovaviruses. Certain drug classes have demonstrated antiviral properties *in vitro* and have been tried for preventing or treating BKV infection. The antiviral activity of cidofovir, an acyclic nucleoside phosphonate nucleotide analog, is linked to inhibition of viral DNA polymerases. The drug, which is approved for the treatment of CMV retinitis, was found to inhibit *in vitro* BKV replication in human cell series^[439,483], although one study found modest antiviral activity and low selectivity of this compound^[445]. Beneficial effects of cidofovir in transplant recipients with BKV infections, including BKN and hemorrhagic cystitis, have been reported in case reports and case series^[438,443,446,473].

Cidofovir is administered parenterally. A review concluded that intravesicular administration of cidofovir is effective in cases of severe hemorrhagic BK cystitis^[461]. The use of cidofovir in the management or prevention of BKN is limited by nephrotoxicity, which is the main adverse effect of the drug. Mitochondrial changes in renal tubular epithelial cells^[458] and renal dysfunction may develop in patients receiving the drug. Hydration prior to the injection and concomitant administration of probenecid reduce the risk of nephrotoxicity. Reduction of the dose of cidofovir without probenecid administration was reported to have beneficial effects on the renal function of a patient with BKN^[443]. However, renal dysfunction has led to the discontinuation of the medication in several reports.

The issues raised by cidofovir have led to the search for compounds related to it, but with less toxicity and higher selectivity. A systematic *in vitro* study found several acyclic nucleoside phosphonates, including cidofovir, with inhibitory activity on BKV replication^[459]. Brincidofovir, a compound derived by conjugating cidofovir with a lipid and designed to lead to intracellular release of cidofovir, has antiviral activities against several DNA viruses and was shown *in vitro* to inhibit BKV replication in human urothelial cells^[489]. This compound was recently reported to reduce the viremia and stabilize the renal function without reduction of immunosuppression, which included mycophenolate, in a recipient of allogeneic hematopoietic stem cell transplant with BKN^[79]. Despite the stabilization of the renal function, this patient, who had graft *vs* host disease, died from sepsis six months after the initiation of brincidofovir treatment. Treatment of BKV infection by brincidofovir will need further evaluation.

Leflunomide is a pyrimidine synthesis inhibitor used in the treatment of rheumatoid arthritis and has been shown to inhibit BKV replication *in vitro* in human

tubular epithelial cells^[452] and human salivary gland cells^[483]. However, only modest antiviral activity and low selectivity of the drug were found in one *in vitro* study^[439], while no antiviral activity of the compound was found in another *in vitro* study^[459]. In case reports and case series, beneficial effects of leflunomide were reported for BK viremia^[93,478], BKN^[442,444,448] and hemorrhagic cystitis^[465] in organ transplant recipients. In resistant cases, administration of cidofovir concomitantly with leflunomide^[442] or ciprofloxacin followed by leflunomide^[478] had apparent beneficial effects. The side effects of leflunomide include hepatotoxicity and neutropenia. Leflunomide treatment requires monitoring of its active metabolite in the blood to ensure therapeutic levels as well as monitoring of hepatic function tests and hematological parameters. A systematic review did not find any kidney transplant survival benefit by the use of leflunomide or cidofovir^[455]. The need for prospective randomized studies was stressed even in studies reporting beneficial effects of leflunomide^[465].

Fluoroquinolones inhibit *in vitro* the DNA topoisomerase of BKV. Levofloxacin and ofloxacin were reported to inhibit BKV replication in human renal tubular epithelial cells *in vitro*^[457]. This effect of this class of antibiotics was criticized because of its low selectivity index^[441]. Ciprofloxacin failed to inhibit BKV replication in another *in vitro* study^[483]. Two retrospective studies in renal transplant recipients reported beneficial effects of fluoroquinolones on BKV infection. Reduction of BK viremia followed ciprofloxacin or levofloxacin administration in one study^[440] and sequential treatment with ciprofloxacin and leflunomide in another study^[478]. However, one retrospective study failed to show any benefit of ciprofloxacin or levofloxacin in the prevention of BKV infection in recipients of allogeneic hematopoietic stem cell transplants^[469] and two randomized studies failed to show any effectiveness of levofloxacin in the prevention of BKV infection^[472] or the treatment of BK viremia^[474] in kidney transplant recipients.

HMG-CoA reductase inhibitors are another class of drugs that has been tried unsuccessfully for the treatment of BKV infection. After the original *in vitro* observation that pravastatin blocks BKV cellular entry^[449], a retrospective multicenter study failed to show any effect of statin doses that maximize their cholesterol-lowering effect on BK viremia or the development of BKN in renal transplant recipients^[479]. Intravenous (*i.v.*) immunoglobulin administration without reduction of the immunosuppression had beneficial effect in a pediatric case of BKN^[450] and, in association with reduction of the immunosuppression, was associated with clearing of the BK viremia and good graft survival in a retrospective study of renal transplant recipients^[385]. Issues associated with IVIG treatment were discussed in the section on pathogenesis. Following immunoglobulin infusion one kidney transplant recipient developed increase in BK viremia and BKN^[464] and a second kidney transplant recipient with BKN developed severe antibody-mediated rejection^[468]. A retrospective study found no difference in

1-year renal transplant outcomes between patients with BKN treated with reduction of the immunosuppression alone or with active treatment including administration of IVIG, leflunomide and ciprofloxacin^[471]. Plasma exchange, along with intravenous immunoglobulin and cidofovir, has also been used for the treatment of BKV infection in renal transplant recipients^[455]. A recent review concluded that reduction of the immunosuppression is the only proven effective treatment of BKN in renal transplant recipients, while cidofovir, leflunomide, fluoroquinolones and *i.v.* immunoglobulin have not been shown to offer any benefits^[480].

The search for immunosuppressive agents lowering the risk of BKV infection has been the topic of several studies. Induction by alemtuzimab was associated with a higher risk of severe rejection and BKN than induction by antithymocytic globulin^[487], even though antithymocytic globulin has been recognized as a risk factor for BKN^[19]. Beneficial effects on BKV infection were reported with the use of the mTOR inhibitors everolimus^[486,493], or sirolimus^[488] instead of mycophenolate and tacrolimus in transplant recipients.

One report reviewed the conservative and surgical approaches to BK hemorrhagic cystitis in bone marrow transplant recipients^[437]. Hyperhydration is sufficient for mild cases. Severe cases may require blood transfusions, suprapubic catheters, permanent bladder irrigation, or various surgical procedures^[437]. Limited experience exists with certain other treatments. Successful combined kidney-liver transplant was reported in a patient with high grade BK viremia, fulminant hepatic failure and loss of his first kidney transplant to BKN^[482]. The first kidney transplant was not removed in this case. Administration of the protease inhibitor bortezomib, which is used as a chemotherapeutic agent in multiple myeloma and mantle cell lymphoma, to a patient with severe BKN and plasma cell-rich infiltrates in the renal interstitium was associated with substantial improvement of the renal function and renal histology^[491]. Treatment by hyperbaric oxygen was associated with resolution of the hematuria in 94% of a series of patients with BK hemorrhagic cystitis^[462].

In a survey of European transplant centers, 66% of the responders stressed the need for new antiviral agents for BKV infection^[485]. Agents that have been tested with some promise in experimental animals or *in vitro* include cyclosporine A^[456], gamma interferon^[460], two inhibitors of the ATPase of the large T BKV antigen, bithionol and hexachlorophene^[463], the small molecule Retro-2(cycl) which inhibits host retrograde viral trafficking^[470], an expression plasmid for the Large BKV T antigen shRNA delivered by virus-like particles^[475], gallic acid-based compounds^[476] and the anti-malarial artesunate^[477]. In a retrospective study in renal transplant recipients with BK viremia, switching the immunosuppressive regime to a combination of low-dose cyclosporine plus an mTOR inhibitor was well tolerated and was associated with better short-term graft function

than reduction of the immunosuppression alone^[466].

The management of BKV infection in transplant recipients is currently based on reduction of the immunosuppression and, in some cases, substitution of mTOR inhibitors for mycophenolate and calcineurin inhibitors. The induction scheme that is best for prevention of BKV infection is not known. Systematic surveillance for BK viremia and viruria^[335,400,451,492] will assist in the early detection and could benefit the outcome of BKV infections.

HUMAN DISEASE ASSOCIATED WITH OTHER PAPOVAVIRUSES^[2-4,12,27,28,97,107,177,250,262,266,342,344,494-502]

BKV belongs to the *Polyomaviridae* family of viruses. Similar structure and animal species as natural hosts are the common features of the members of this family. Other human viruses in the same family that have been associated with human disease include the JCV, the Merkel virus and, probably, the SV40. The natural hosts of SV40 are monkeys and its role in human disease is disputed. The role of *Polyomaviridae* in human disease has been reviewed in several reports^[2-4].

The structure of JCV has the closest association with BKV among all the known human *Polyomaviridae*. A 75% sequence homology between BKV and JCV has been found^[500]. JCV infection has been studied extensively. Substantial rates of JC viremia, viruria and persistence in tissues of transplant recipients and other populations, including non-immunosuppressed subjects, have been reported^[12,27,28,107,343,345,494,495,499,501]. Renal manifestations associated with JCV infection include a case of nephropathy in a patient with malignancy^[177] and decreased renal function in kidney and liver transplant recipients with JC viruria^[497]. The pathogenetic role of JCV in HIV-positive patients with progressive multifocal leukoencephalopathy has been established^[261,265]. JCV is oncogenic in animal species, including primates. In humans JCV infection has been associated with brain tumors and carcinomas of the gastrointestinal tract, breast and cervix, but this association has not been found universally^[496].

Merkel virus is oncogenic in humans. It is linked to Merkel carcinoma, a rare aggressive skin tumor affecting primarily older individuals^[498,499]. Nephropathy associated with SV40 infection was reported in a lung transplant recipient^[97].

The number of *Polyomaviridae* diseases attributed to this viral family is expanding. A recent revision of the taxonomy of the family recognized 76 viral species, 13 of which have humans as their natural hosts^[502]. In this taxonomy, BKV is listed as human polyomavirus 1, abbreviated as BKVvV, JCV is listed as human polyomavirus 2, abbreviated as JCPyV, and Merkel virus is listed as human polyomavirus 8, abbreviated as MCPyV. No doubt this virus family will have a center

stage in organ transplantation and probably in other immunocompromised states in the years to come.

Key points of part C

Reduction of immunosuppression is the first step in the treatment of symptomatic BKV infection; certain classes of anti-rejection medications are less prone to facilitate BKV replication; the clinical usefulness of drugs putatively inhibiting BKV replication is disputed. The toxicities of these drugs are important; the lists of papovaviruses and of human diseases attributed to them are expanding. Papovavirus-related diseases will be a major study topic in the future.

Abstract

Post-transplant lymphoproliferative disorder (PTLD) is an aggressive complication of solid organ and

hematopoietic stem cell transplantation that arises in up to 20% of transplant recipients. Infection or reactivation of the Epstein-Barr virus (EBV), a ubiquitous human herpesvirus, in combination with chronic immunosuppression are considered as the main predisposing factors, however insight in PTLD biology is fragmentary. The study of PTLD is complicated by its morphological heterogeneity and the lack of prospective trials, which also impede treatment optimization. Furthermore, the broad spectrum of underlying disorders and the graft type represent important confounding factors. PTLD encompasses different malignant subtypes that resemble histologically similar lymphomas in the general population. Post-transplant diffuse large B-cell lymphoma (PT-DLBCL), Burkitt lymphoma (PT-BL) and plasmablastic lymphoma (PT-PBL) occur most frequently. However, in many studies various EBV⁺ and EBV⁻ PTLD subtypes are pooled, complicating the interpretation of the results. In this review, studies of the gene expression pattern, the microenvironment and the genetic profile of PT-DLBCL, PT-BL and PT-PBL are summarized to better understand the mechanisms underlying post-transplantation lymphomagenesis. Based on the available findings we propose stratification of PTLD according to the histological subtype and the EBV status to facilitate the interpretation of future studies and the establishment of clinical trials.

Key words: Epstein-Barr virus; Post-transplant lymphoproliferative disorder; Immunodeficiency; Diffuse large B-cell lymphoma; Burkitt lymphoma; Plasmablastic lymphoma

Core tip: At the moment different post-transplant lymphoproliferative disorders (PTLD) are grouped in broad categories (early, polymorphic, monomorphic and Hodgkin-like PTLD) and the Epstein-Barr virus (EBV) status is not taken into account. However, increasing

evidence demonstrates that different malignant PTLD and EBV⁺ and EBV lesions are clinically and biologically distinct, stressing the need for subtype-specific management. We propose that in future studies patients should be stratified according to the histological lymphoma subtype and the EBV status to minimize bias and to simplify the establishment and analysis of clinical trials.

INTRODUCTION

Despite the increasing incidence of cancer worldwide, only a limited number of cancer-causing factors have been identified. Viruses are amongst them: An estimated 15% of cancers are attributed to viral infections. One of the most widely spread oncogenic viruses is the Epstein-Barr virus (EBV), a gamma human herpesvirus with a seroprevalence of 90%-95% in adults. EBV, discovered in 1964^[1], is best known as the cause of infectious mononucleosis (or kissing disease)^[2]. EBV-driven lymphoproliferative disorders (LPD) are characterized by an EBV-driven immortalization of B-cells. In an otherwise healthy individual, development of such LPD is countered by a strong immune response [mainly of cytotoxic T-cells (CTL)], which ultimately resolves the infection. However, when the immune system is compromised [e.g., in acquired immunodeficiency syndrome (AIDS) patients or in organ transplant recipients under chronic immunosuppression] EBV-driven LPD may eventually progress to overt lymphoma.

During the last decades, the number of solid organ (e.g., kidney, heart, liver, etc.) and stem cell transplantations has increased significantly. In parallel, the risk of graft rejection has dropped thanks to the development of more potent immunosuppressive agents resulting in longer survival of transplant recipients. However, a major drawback of the chronically immunosuppressed status of these individuals is the development of a potentially fatal post-transplant lymphoproliferative disorder (PTLD) in up to 20% of transplant recipients^[3]. PTLD is a relatively new disease entity that is now widely recognized. The first cases were described in renal transplant patients, shortly after the introduction of chronic immunosuppressive drugs in the 1960s^[4]. Despite the strong association between EBV and PTLD (about 70% of PTLD are EBV-positive, EBV⁺), disease biology is not well understood^[3]. The pathological presentation of PTLD is variable, ranging from a localized benign LPD to lymphoma associated with poor survival^[5]. Treatment of PTLD patients is largely based on insights in lymphomagenesis in immunocompetent

patients, in which there is no evident role for EBV in the majority of cases. For application of more adequate therapy it is indispensable to characterize PTLD more thoroughly.

The most common malignant PTLD subtype is post-transplant diffuse large B-cell lymphoma (PT-DLBCL), followed by Burkitt lymphoma (PT-BL) and plasmablastic lymphoma (PT-PBL). PT-BL and PT-PBL are aggressive, but poorly studied malignant PTLD subtypes. The number of reported cases is limited and most studies mainly focus on patient management^[6-9].

In this review we summarize the available data on the genetic profile, the gene expression pattern and the microenvironment of these malignancies to better understand the mechanisms underlying post-transplantation lymphomagenesis. A literature search was performed for "PTLD" or "post-transplant lymphoproliferative disorder" with or without "diffuse large B-cell lymphoma", "Burkitt lymphoma" or "plasmablastic lymphoma" and the available literature regarding PTLD pathogenesis was collected. For a review of the diagnosis and management of PTLD we refer the reader to^[3,10].

DISCUSSION

EBV exploits the germinal center route of B-cell activation

During a normal humoral immune response, a circulating B-cell that encounters its cognate antigen becomes an activated blast with two possible fates.

The B-cell can mature into a short-lived plasma cell that quickly produces IgM class antibodies with limited specificity (T-cell independent pathway). Alternatively, the B-cell may form a germinal center (GC) in a lymph node, mucosa-associated lymphoid tissue or spleen (T-cell dependent pathway). In the GC, the specificity of the B-cell's antibody is enhanced by somatic hypermutation (SHM, random mutation of the antibody's variable chain, IgV) and its functional versatility is altered by class switch recombination from IgM to IgG, IgE or IgA. Eventually, the B-cell matures into a plasma cell or a memory B-cell^[11]. B-cells transiting the GC are germinal center B-cells (GCB). B-cells that have completed the GC reaction are called activated B-cells, non-GCB or post-germinal B-cells (Figure 1).

According to the classic model, EBV infects naive B-cells and promotes formation of a GC. During GC transition, EBV proteins provide a selective advantage and stimulate differentiation to memory B-cells, the presumed reservoir of EBV. This process is enabled by coordinate expression of EBV proteins, primarily latent membrane proteins (LMP1, 2A-B) and EBV nuclear antigens (EBNA1, 2, 3A-C). Based on the pattern of expression, three different latency expression profiles are recognized^[12]. These latency programs are associated with different stages of EBV B-cell infection and with particular lymphoproliferative disorders (Table 1 and

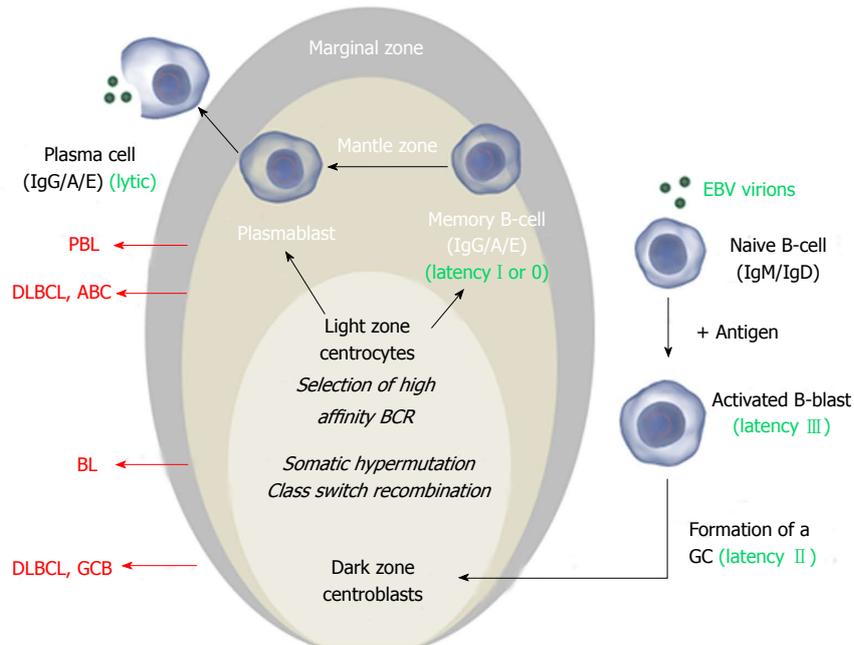

Figure 1 The Epstein-Barr virus exploits normal B-cell activation pathways. Activation of a naive B-cell (that expresses IgM and IgD on its surface) by its cognate antigen results in B-cell activation and differentiation into a memory B-cell or a plasma cell, most commonly via T-cell dependent activation. The antigen-activated B-cell enters a primary follicle in lymph node or spleen and forms a germinal center (GC), transforming the primary follicle into a secondary follicle. This structure is composed of three distinct regions. The marginal zone^[1], which consists mainly of activated B-cells and GC-matured IgM+ B-cells, the mantle zone or corona^[2], which comprises naïve and memory B-cells surrounds the GC^[3]. The GC consists of a dark zone and a light zone. In the dark zone, the activated B-cells (centroblasts) proliferate and downregulate expression of IgM and IgD to allow somatic hypermutation (SHM) and class switch recombination (CSR), increasing the antibody's affinity, specificity and functional versatility. In the light zone of the GC, the B-cells (centrocytes) with the best antibody are selected and ultimately mature into memory B-cells or plasma cells. Instead of IgM and IgD, these express high affinity IgG, IgA or IgE antibodies. Classically, Epstein-Barr virus (EBV) infects naïve B-cells that are stimulated to form a GC. In the activated blast, viral latency III (LMP1+/EBNA2+) is expressed and induces proliferation. In the GC, latency II (LMP1+/EBNA2-) is expressed and infected centroblasts presumably undergo SHM and CSR, involved in antibody maturation. After leaving the GC, they differentiate into plasma cells or (mainly) memory cells (latency I, EBNA1+ or latency 0, no expression of viral proteins). *In vitro* and *in vivo*, plasma cell differentiation results in activation of the EBV lytic cycle. In all stages, the viral DNA (circle in the nucleus) is maintained as an episome. Different stages of this process can give rise to malignancy resulting in different lymphoma subtypes that have features of their normal counterpart. Here the stages at which EBV+ and EBV- B-cell lymphoma may arise are shown for the most common subtypes. Images from www.somersault1824.com were used in this figure. Table 1 Epstein-Barr virus-driven lymphoproliferative disorders are linked with particular Epstein-Barr virus latency programs

Latency	Expressed EBV gene products	Normal B-cell stage	Associated disease
III (growth)	EBER1-2, EBNA1-6, LMP1, LMP2A-B	Activated B lymphoblast	PT-DLBCL AIDS-related lymphoma Acute infectious mononucleosis
II (default)	EBER 1-2, EBNA1, LMP1- 2A	B-cell undergoing the GC reaction	PT-DLBCL Classical Hodgkin lymphoma
I	EBER 1-2, EBNA1	Memory B-cell	(PT-) Burkitt lymphoma (PT-) PBL

EBER: Epstein-Barr virus-encoded RNA; EBNA: Epstein-Barr virus nuclear antigen; LMP: Latent membrane protein; PT-DLBCL: Post-transplant diffuse large B-cell lymphoma; PBL: Plasmablastic lymphoma; EBV: Epstein-Barr virus.

Figure 1). EBV⁺ PT-DLBCL is classically associated with the most elaborate viral expression pattern, latency III. EBV⁺ PT-BL and PT-PBL on the other hand most

frequently express the more restricted latency patterns I or II^[13,14].

LMP1, a constitutively active mimic of CD40 (a crucial costimulatory factor in T-cell mediated B-cell activation), is regarded as the major oncogenic protein of EBV. LMP2A is a functional mimic of a B-cell receptor and provides survival signals to the B-cells. EBNA1 ensures replication of the viral genome during cell division. EBNA2 acts as a master transcriptional regulator of both viral and cellular genes^[12]. Two viral miRNA clusters (BART-miRNAs and BHRF1 miRNAs) are differentially expressed depending on the particular viral latency program^[15]. EBV-encoded RNA (EBER) 1 and 2 are the only gene products that are expressed throughout all latency and lytic phases of the viral cycle and represent the most reliable markers to determine EBV infection^[16].

Key features of EBV latent proteins are shown in Figure 2A. For more details about the viral gene products we refer the reader to other reviews^[17,18].

In vitro and *in vivo*, plasma cell differentiation of an EBV-infected B-cell is associated with activation of EBV lytic replication resulting in production of new viral

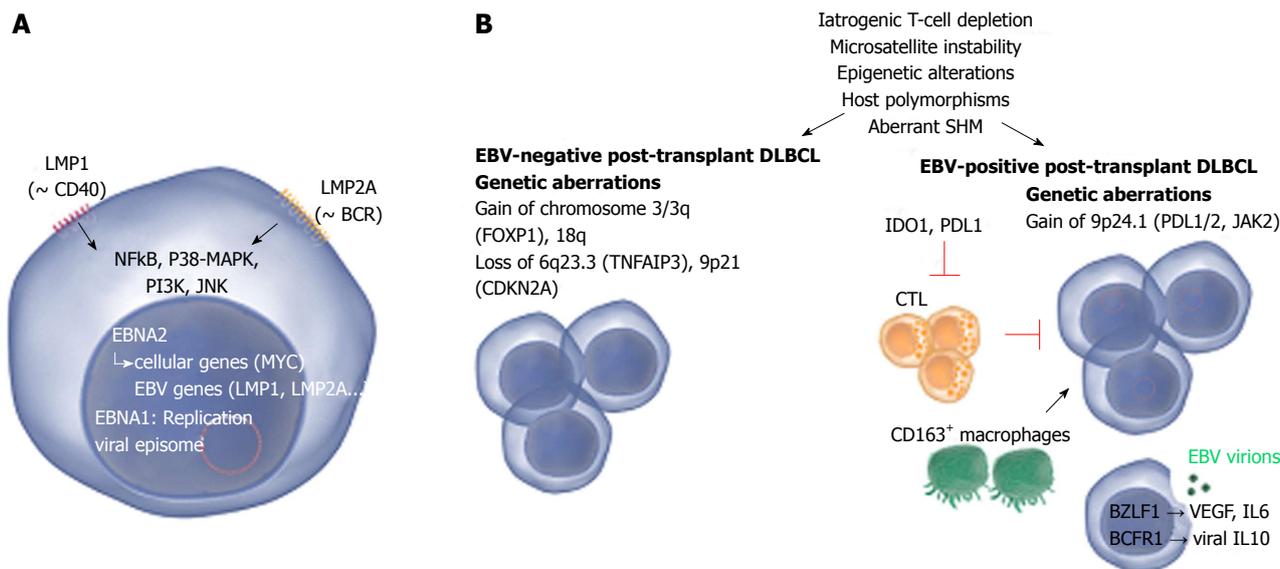

Figure 2 Common and distinct pathogenetic mechanisms in Epstein-Barr virus-positive and -negative post-transplant diffuse large B-cell lymphoma. A: Two Epstein-Barr virus (EBV) proteins that are thought to play a role in EBV-driven lymphomagenesis are LMP1 and LMP2A. LMP1 is analogous to CD40 and promotes cell transformation by inducing NF-κB, that in turn upregulates BCL-2, A20 and C-FLIP, all involved in blocking apoptosis. LMP2A mimics a chronically active B-cell receptor (BCR) and prevents BCR-mediated activation of EBV lytic replication. LMP2A also provides the necessary survival signals which can compensate for the loss of a functional BCR. Other pathways that are induced comprise janus kinase, p38-MAPK and PI3K signaling. Nuclear EBNA1 and EBNA2 are involved in replication of the viral episome and induction of viral as well as cellular genes respectively; B: The pathogenesis of EBV-positive and -negative lymphoma is marked by a number of common as well as distinct pathogenetic mechanisms. Mechanisms that contribute to both EBV-positive and -negative lymphoma involve iatrogenic T-cell suppression, microsatellite instability (resulting in accumulation of mutations), epigenetic alterations (mainly hypermethylation), host polymorphisms (in particular in genes encoding proteins involved in immunity), aberrant somatic hypermutation (SHM, resulting in accumulation of point mutations) and aberrant up- or down-regulation of host miRNAs which may substantially impact gene expression. EBV-negative PT-DLBCL is characterized by genetic aberrations found in EBV-negative DLBCL arising in the general population, e.g., alterations involving FOXP1. EBV-positive PT-DLBCL on the other hand harbors fewer genetic lesions. Gain of 9p24.1 (harboring PDL1/2, JAK2) has been detected and may contribute to tumor immune evasion. A minority of the EBV-positive cells actively produce viral particles. This lytic replication may promote lymphoma growth by expression of IL-6 and VEGF. Also viral IL-10 (vIL10) is expressed which contributes to suppression of anti-tumor responses by antagonizing IFN-γ. The expression of EBV proteins attracts cytotoxic T-cells (CTLs) to the site of the tumor however the question remains whether effective anti-tumor responses can be produced as also tolerant immune responses are induced. IDO1 (expressed in tumor cells and dendritic cells) and PDL1 (expressed in tumor cells and macrophages) suppress T-cells and may substantially impair the activity of CTLs. Also CD163⁺ macrophages (thought to be immunotolerant M2 macrophages) may play a role in immune evasion. Images from www.somersault1824.com were used in this figure. PT-DLBCL: Post-transplant diffuse large B-cell lymphoma; IL: Interleukin; IFN: Interferon; VEGF: Vascular endothelial growth factor; BCR: B-cell Receptor.

particles^[19]. The main activators of this process are viral ZEBRA/BZLF1 and BRLF1 proteins^[20].

Although still highly debated, increasing evidence indicates that also the lytic program of EBV is of importance for B-cell transformation, the early stages in particular^[21-23]. EBV lacking ZEBRA/BZLF1 and BRLF1 has significantly decreased transforming potential *in vivo*, associated with reduced expression of proliferation-promoting factors (IL-6, IL-10 and viral IL-10) (Figure 2B)^[24]. Intriguingly, particular genetic variants of ZEBRA/BZLF1 and BRLF1 have been associated with lymphoma^[25]. So far, few studies have examined lytic replication in human lymphoma biopsies^[26]. In a recent report, EBV lytic replication in PTLT was associated with tumoral XBP-1 expression, early onset and short survival^[27].

In the following sections, the pathogenesis of PT-DLBCL (Figure 2B), PT-BL and PT-PBL, the most common malignant PTLT subtypes, is discussed.

DLBCL

Cell of origin: DLBCL in the general population comprises at least two molecular subtypes: GCB derived

and non-GCB derived DLBCL^[28], thought to arise from normal GC and non-GC B-cells respectively (Figure 1). Both subtypes have been reported in the transplant setting^[29]. The cell of origin is classically determined using a microarray-based surrogate set of three immunostainings (CD10, BCL6, MUM1)^[30] and has prognostic implications: In the general population, GCB DLBCL has a better prognosis than non-GCB DLBCL^[28]. Whether the same is true for post-transplant DLBCL is difficult to determine since the vast majority of EBV-associated cases are of non-GCB origin^[26,31,32] (Figure 1). The induction of pathways like NF-κB signaling by EBV, which is highly characteristic for non-GCB DLBCL could explain this observation^[33] (Figure 2A).

Another way to define the cell of origin is provided by genotypic analysis of SHM. A naïve pre-GC B-cell carries unmutated IgV, intraclonal heterogeneity reflects ongoing IgV SHM in GC centroblasts and a centrocyte/post-GC B-cell carries stable IgV mutations. Using this method the vast majority of EBV⁺ as well as EBV PT-DLBCL were shown to carry IgV mutations indicating that PT-DLBCL derive mainly from GC and post-GC B-cells^[26,29]. The few PT-DLBCL that do lack SHM are

consistently EBV⁺ and arise early after transplantation. They may derive from naïve pre-GC B-cells or from B-cells that have transited the GC without completing the GC program^[34-36].

Genetics: Genetic studies have demonstrated that PT-DLBCL has genomic aberrations in common with DLBCL arising in immunocompetent individuals (gains of 8q24 harboring *MYC*, 3q27 harboring *BCL6*, 18q21 harboring *BCL2*, 7q harboring *CDK6*; loss of 17p13 harboring *TP53*) but also bears distinct alterations (gain of 5p, loss of 4q, 17q, Xp)^[37,38]. EBV⁺ and EBV⁻ PTLD are rarely distinguished, but in one study EBV⁺ PT-DLBCL was associated with gains of 7p, 7q and 11q24-q25 and del(4q25-q35)^[39]. EBV⁺ PT-DLBCL on the other hand frequently harbored trisomies of chromosomes 9 and 11. It has been suggested that overall, EBV⁺ PT-DLBCL carries fewer (recurrent) genetic lesions than EBV⁻ cases^[37].

An aCGH study on a series of 21 non-GCB PT-DLBCL validated these findings^[40]. Overall, EBV⁺ PT-DLBCL harbored fewer copy number alterations than EBV⁻ cases. EBV⁺ and EBV⁻ PT-DLBCL shared only one recurrent aberration (gain 12q21q21); the significance of this lesion is unclear. The most frequent genetic aberration detected in the EBV⁺ cases was gain of 9p24.1 that harbors *PDL1*, *PDL2* and *JAK2* and could contribute to *PDL1* overexpression (Figure 2B). Notably, also in EBV⁺ DLBCL in elderly individuals (DLBCL-E) gain of 9p24.1 was among the most frequently detected lesions^[41] suggesting that overlapping processes underlie the pathogenesis of EBV-driven lymphomas.

In contrast, EBV⁻ PT- and IC-DLBCL shared many common aberrations (gain of chromosome 3/3q and 18q, and loss of 6q23.3/*TNFAIP3* and 9p21/*CDKN2A*) characteristic for non-GCB DLBCL^[42] suggesting EBV-PT-DLBCL and IC-DLBCL are biologically similar (Figure 2B).

SHM may also contribute to oncogenesis when it misfires and results in mutation of proto-oncogenes, like *PIM1*, *PAX5*, *RhoH/TTF* and *MYC*. Because primarily the 5' regulatory region is targeted, aberrant SHM may alter the expression profile of the affected gene(s)^[29]. In one study, aberrant SHM of *PIM1*, *PAX5*, *RhoH/TTF* and/or *MYC* was detected in 40% of PT-DLBCL, independently of the EBV status^[29,43].

Microsatellite instability (MSI) is induced by loss of a gene involved in DNA mismatch repair accelerating the accumulation of mutations (mainly in microsatellite sequences). Interestingly, MSI seems restricted to immunodeficiency-related lymphomas and has been reported in a fraction of PTLD, unrelated to EBV status (in a series of 72 PT-DLBCL, 7% was microsatellite instable^[44]). In colon carcinoma, MSI has been associated with an increased number of tumor-infiltrating lymphocytes (presumably because of the formation of neo-antigens which are then presented in MHC I on the surface of the tumor cell) suggesting that MSI

lymphomas are more immunogenic than microsatellite stable tumors^[45,46]. It is feasible that such immunogenic lymphomas are only tolerated in an immunocompromised host, accounting for the lack of MSI lymphomas in immunocompetent individuals.

Gene expression profile: Two early gene expression profiling studies of PTLD produced partly contradictory results, probably because of the small sample size and the different composition of the case series. Segregation of eight PT-DLBCL cases based on the EBV status in a study by Craig *et al.*^[32] could not be confirmed by a report of Vakiani *et al.*^[26], who suggested that PTLD was distinct from non-Hodgkin lymphoma in immunocompetent individuals. As a result, a number of key questions remained unresolved until recently. Are EBV⁺ and EBV⁻ PTLD different or not? And how do these disease states relate to lymphoma in the general population?

Consistent with the study of Craig *et al.*^[32] a GEP study of 21 PT-DLBCL by our group pointed to a dominant role for cytotoxic antiviral immune signaling in EBV⁺ vs EBV⁻ cases, implying that the presence of EBV in the tumor cells greatly affects the microenvironment^[47].

Cytokines upregulated in EBV⁺ PT-DLBCL and associated with viral infection included *CCL3*, *CCL4* and *CCL8* involved in chemotaxis and/or activation of monocytes (*CCL3*, *CCL4*) and T-cells (*CCL3*, *CCL8*). Notably, *CCL3* and *CLL4* could also be part of an autocrine loop: *In vitro*, these cytokines were highly expressed by EBV⁺ lymphoblastoid cell lines (LCL) and promoted LCL proliferation and survival^[48].

In contrast to Craig *et al.*^[32] we also detected enhanced immunotolerant signaling (*PDL1*, *IDO1*) in EBV⁺ vs EBV⁻ PT-DLBCL (Figure 2B). These networks are likely induced to counter pro-inflammatory signaling. Upregulation of *PDL1* is in line with *in vitro* studies that demonstrated a functional link between EBV and *PDL1* expression in tumor cells^[49], confirmed by histological studies of human EBV⁺ tumor biopsies^[50]. *IDO1* is involved in suppression of T-cells by degradation of tryptophan and was previously found overexpressed in EBV⁺ gastric carcinoma^[51].

Notably, blockade of immune checkpoints (*IDO1* or the *PDL-PD1* axis) results in boosting of the immune response and has already shown promising results in clinical cancer trials^[52]. This approach may be useful also in PTLD where it may increase the efficacy of adoptive T-cell therapy. However, because of the associated increased risk of graft rejection, the safety of checkpoint inhibitors in PTLD treatment requires further investigation.

EBV⁺ PT-DLBCL represents the minority of PT-DLBCL cases, however there is some evidence that its incidence is increasing^[53], potentially (partly) because of the overall longer survival of transplant recipients. The etiology of EBV⁺ PTLD is unknown and therefore a major

question is how these tumors relate to EBV lymphomas in the general population.

A number of hypotheses have been raised to explain the etiology of EBV PTLD.

The hit-and-run theory, based on *in vitro* data^[54], states that after transformation EBV-infected B-cells may eventually lose (part of) the viral genome. However so far, there is no *in vivo* evidence supporting this theory^[55,56].

Given the strong association between EBV and PTLD other infectious agents, *e.g.*, HHV8 or cytomegalovirus (CMV) may be implicated in EBV PTLD. However, PTLD cases in which HHV8 is detected are extremely rare^[57,58] and because CMV does not infect B-cells it can only play an indirect role^[59]. A study of AIDS-related lymphoma found only EBV to be significantly associated with pathogenesis, suggesting that also EBV PTLD is probably not caused by an infectious agent^[60].

Craig *et al.*^[32] suggested that EBV⁺ and EBV monomorphic PTLD are biologically distinct and the results of our GEP analysis support this hypothesis. In the comparison of GEP data of EBV⁺ and EBV PT-DLBCL, BCR signaling was upregulated in EBV cases. As suggested by the authors, this finding could be the result of mimicked BCR signaling by LMP2A in EBV⁺ PT-DLBCL^[32], however it could also be an artifact: Because of dominant immune signaling in EBV⁺ cases tumoral BCR signaling is seemingly upregulated in EBV cases.

To gain more insight in the biology of EBV PT-DLBCL, GEP profiles of EBV PT and IC cases were compared. Only pathways involved in T-cell signaling were significantly differentially expressed and downregulated in PT compared to IC-DLBCL suggesting that the tumoral expression profiles are overall similar. Notably, decreased T-cell signaling explains why some cases of EBV PT-DLBCL respond to RIS^[61,62], which is generally more effective for EBV⁺ lesions. Therefore, restoration of the immune response in EBV PTLD patients should remain one of the cornerstones of treatment.

Notably, gain of chromosome 3/3q (encoding *FOXP1*) in EBV IC/PT-DLBCL had the strongest impact on gene expression (Figure 2B). Bio-informatics analysis of the gene set upregulated in this subgroup predicted that *FOXP1*, a master transcriptional regulator, regulates the expression of the majority of the genes (unreported data), suggesting *FOXP1* is a major network hub in the pathogenesis of these cases. Because several studies support a central role of *FOXP1* in non-GCB DLBCL pathogenesis^[63] the downregulation of *FOXP1* in EBV⁺ non-GCB PT-DLBCL is striking. Also following *in vitro* EBV infection of peripheral blood mononuclear cells *FOXP1* is downregulated^[64], indicating that *FOXP1* expression is incompatible with EBV signaling. An interesting question is whether forced expression of *FOXP1* in EBV⁺ non-GCB DLBCL cells is toxic for the tumor cells.

Microenvironment: The tumor microenvironment

consists of the collection of stromal and immune cells that make up the cellular environment in which the tumor cells reside and has been shown to significantly influence prognosis in different lymphoma subtypes^[65,66], also in PTLD. Particularly the infiltration of CTL has been associated with favorable prognosis (the EBV status was not taken into account). In the same study, the infiltration of regulatory T-cells (Treg), immune response modulators that prevent excessive immune activation, was limited in all PTLD cases^[67]. This may be attributed to obstruction of Treg cell development by immunosuppressive agents. Analysis of the normal intestinal mucosa showed that liver transplant patients on a long-term combination regimen had significantly lower levels of Treg cells compared to healthy controls^[68]. Although the scarcity of Treg cells in PTLD lesions may impede suppression of anti-tumor immune responses, also inhibition of B-cell proliferation by Treg cells is alleviated, potentially contributing to PTLD development^[67]. A thorough review of the microenvironment of PTLD has not been performed but a study of AIDS-related DLBCL may give clues: Increased tumor vascularization and a higher number of infiltrating CTL were detected in EBV⁺ compared to EBV cases^[69].

Cell counts for different immune markers (manuscript submitted) performed on a series of PT-DLBCL showed increased infiltration of CD8⁺ CTL in part of the EBV⁺ compared to EBV cases. CTL, probably attracted to the tumor site by the presence of EBV, expressed granzyme B suggesting they were activated (Figure 2B). In contrast, NK cells, critical cytotoxic effector cells in the early response to viral infection and tumor cells, were virtually absent in all biopsies, based on staining for NCAM1/CD56. However, this does not exclude a role for NK cells in PTLD. In a study involving pediatric transplant recipients, CD56^{high} NK cells were abundant only in asymptomatic transplant recipients whereas in PTLD patients, the functionally impaired CD56^{dim/negative} NK population was increased^[70].

Tumor immune evasion is a major challenge for effective cancer treatment^[71] and several reports have shown that such mechanisms also play a role in PTLD. Tumoral expression of PDL1, involved in T-cell suppression^[72], as well as galectin-1, involved in apoptosis-induction of CTL among others^[73], has been reported^[51]. Also immunoregulatory M2 macrophages (marked by CD163 expression) may be part of a negative feedback loop to prevent excessive CTL-induced tissue damage^[74]. M2 macrophages, which were significantly more abundant in EBV⁺ vs EBV PT-DLBCL (manuscript submitted), are thought to contribute to tissue remodeling and tumor progression in contrast to classical pro-inflammatory M1 macrophages^[75] (Figure 2B). These data are consistent with studies of EBV⁺ DLBCL-E and EBV⁺ Hodgkin lymphoma. Also in these malignancies, the presence of EBV has been associated with upregulation of CD163 expression^[41,74].

It is not clear whether these cells are recruited to the

tumor site or develop *in situ*. Studies have shown that the M2 phenotype can be induced by particular cytokines, among which IL-4 and IL-10^[76]. We speculate that also EBV-encoded IL-10 contributes to M2 macrophage polarization in EBV⁺ PT-DLBCL^[75]. Interestingly, M2 macrophages are themselves producers of IL-10 and may be the source of the high levels of IL-10 detected in PTLD patients^[77].

In a prospective trial of Hodgkin lymphoma, increased tumor-associated macrophage infiltration was associated with inferior outcome^[78]. An interesting question to be resolved is whether also in PTLD macrophages influence prognosis.

BL

Cell of origin: BL is a highly aggressive lymphoma characterized by a high mitotic rate and numerous tingible body macrophages (loaded with debris from apoptotic cells). Three clinical variants of BL are recognized: Endemic BL (with a high prevalence in equatorial Africa), sporadic BL (prevalent in Western countries) and immunodeficiency-associated BL [primarily affecting human immunodeficiency virus (HIV) infected patients, but also reported in transplant recipients]. The association with EBV is different for the three subtypes and strongest in the endemic variant (nearly 100% EBV⁺), followed by the immunodeficiency-associated variant (30%-80% EBV⁺) and sporadic BL (15%-20% EBV⁺). Notably, EBV⁺ Burkitt lymphoma is the EBV transformed tumor with the most limited expression of viral proteins (typically only EBNA1 is expressed)^[79].

BL is classically thought to arise from a GCB cell however analysis of the SHM patterns in a series of endemic, sporadic and AIDS-related BL suggested that BL may arise from different stages of B-cell differentiation, associated with the EBV status. EBV⁺ BL were highly mutated and may derive from a late antigen-selected GC B-cell or memory B-cell for EBV⁺ BL. EBV BL on the other hand harbored only a limited number of mutations and may arise from an early centroblast^[80].

Genetics: The hallmark of BL is the presence of translocations involving MYC [with IgH: t(8;14)(q24;q32)] which are also found in PTLD with Burkitt morphology^[37]. It is highly debated whether MYC-translocation-negative BL is a form of true molecular BL^[81]. In a recent study, an 11q aberration was detected in MYC-negative high-grade B-cell lymphomas resembling BL (both at the morphological as well as the molecular level, but without MYC rearrangement)^[82]. In our series of IC- and PT-BL this peculiar 11q gain/loss was particularly frequent in PT cases lacking MYC translocation, suggesting a different pathogenesis of BL in different immune settings. However, a recent study demonstrated that 11q gain/loss and MYC translocation are not mutually exclusive^[83]. It is possible that both aberrations

have complementary effects: Integrated analysis of genomic and transcriptomic data of our series of MYC translocation-positive and -negative cases suggested that the 11q-gain/loss is a molecular variant of MYC rearrangement, affecting similar pathways.

Gene expression profile and microenvironment:

In contrast to PT-DLBCL, the gene expression profile of EBV⁺ and EBV BL is not significantly different, indicating that MYC signaling rather than the EBV status has the major impact on the expression profile^[84]. BL lesions are composed of very little stromal infiltrate indicating that BL tumor cells are poorly immunogenic. Remarkably, even when BL cells express highly immunogenic EBV antigens EBNA3A, -3B, and -3C^[85] or foreign antigens are introduced by a recombinant virus^[86] they are not recognized by antigen-specific CTL clones. An *in vitro* study pointed to a crucial role of MYC. It was demonstrated that this oncogene negatively regulates NF- κ B and interferon signaling by suppression of STAT1 resulting in decreased immunogenicity^[87].

PBL

Cell of origin: PBL is an aggressive terminally differentiated variant of DLBCL that has many morphological and immunophenotypic characteristics in common with a plasmablast (a B-cell in the final stages of plasma cell differentiation). PBL typically arises in the oral cavity of HIV⁺ patients^[88] but has also been reported in immunocompetent individuals^[89] and transplant recipients^[8].

In a series of AIDS-related PBL (10/12 were EBV⁺), evidence of somatic hypermutation was found in only 4/10 analyzed cases suggesting histogenetic heterogeneity of PBL^[90].

Genetics: Currently, very little is known about the molecular-genetic basis that drives PBL. One study showed that up to 47% of EBV⁺ AIDS-related PBLs are marked by MYC translocations^[91]. Array-comparative genomic hybridization involving 16 PBL demonstrated that, despite the high degree of immunophenotypic similarity between PBL and plasma cell myeloma (PCM)^[92], the genomic aberration pattern of PBL is more similar to DLBCL than to PCM^[93].

Gene expression profile and microenvironment:

A gene expression profiling study reported that PBL was more similar to extraosseous plasmacytoma than to DLBCL^[94] reflecting the plasma cell immunophenotypic features of these malignancies. No significant differences were found between EBV⁺ and EBV PBL, however this may be related to the small sample size.

Reanalysis of our gene expression data (3 EBV⁺ PT-PBL vs 20 EBV⁺ PT-DLBCL, fold change 2, FDR < 0.05^[95]) confirmed enhanced MYC signaling and demonstrated unfolded protein response endoplasmic reticulum stress signaling in PBL (unreported data). These findings

provide an explanation for the success of bortezomib treatment in PBL case reports^[96,97] and suggest that BET bromodomain inhibitors may represent a potential new therapeutic strategy, as has been successfully demonstrated in experimental models of multiple myeloma^[98].

As for EBV⁺ DLBCL, EBV⁺ PBL may be associated with a tolerant microenvironment. In a recent clinicopathological analysis of 82 PBL arising in HIV⁺ and HIV⁻ patients particularly EBV⁺ tumors highly expressed PD1-PD1 in both malignant cells and microenvironment^[99].

CONCLUSION

The findings presented in this review underscore the heterogeneous nature of PTLD and could serve as a basis to revise the current PTLD classification. We propose that within the group of monomorphic PTLD, the different histological lymphoma entities (DLBCL, BL, PBL) should be distinguished. We suggest that also the EBV status should be included to further stratify PTLD patients in future studies and clinical trials.

Abstract

Physical rehabilitation of lung transplant candidates and recipients plays an important role in optimizing physical function prior to transplant and facilitating recovery of function post-transplant. As medical and surgical interventions in lung transplantation have evolved over time, there has been a demographic shift of individuals undergoing lung transplantation including older individuals, those with multiple co-morbidities, and

candidates with respiratory failure requiring bridging to transplantation. These changes have an impact on the rehabilitation needs of lung transplant candidates and recipients. This review provides a practical approach to rehabilitation based on research and clinical practice at our transplant centre. It focuses on functional assessment and exercise prescription during an uncomplicated and complicated clinical course in the pre-transplant, early and late post-transplant periods. The target audience includes clinicians involved in pre- and post-transplant patient care and rehabilitation researchers.

Key words: Lung transplantation; Rehabilitation; Physical therapy; Exercise training; Physical activity

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: This expert review brings together clinical experience and research evidence on physical rehabilitation for lung transplant candidates and recipients. The evaluation of exercise capacity, muscle function, mobility, activities of daily living and physical activity is discussed. Rehabilitation training guidelines for pre-transplant, acute care, early and late post-transplant phases are provided with special attention to complicated and uncomplicated clinical courses. Special populations such as heart-lung transplant and paediatric lung transplant are also included.

INTRODUCTION

Lung transplantation is performed for a variety of advanced lung diseases, with primary indications including interstitial lung disease (ILD), chronic obstructive pulmonary disease (COPD), cystic fibrosis (CF) and pulmonary vascular disease^[1]. Since the world's first successful single lung transplant in Toronto, Canada^[2] physical rehabilitation has played an integral role in preparing individuals for lung transplantation and facilitating their recovery^[3,4].

Although pre- and post-transplant rehabilitation is recommended in the majority of lung transplant centers in Canada^[5], there are currently no clinical practice guidelines for rehabilitation in lung transplant candidates and recipients. Several narrative reviews have been published on rehabilitation^[6,7], however they have focused on guidelines for individuals with a relatively uncomplicated pre- and post-transplant course. As the selection of lung transplant candidates

has evolved over time due to surgical and medical advancements, the demographics of transplant candidates has shifted from only the youngest and fittest candidates to adults of older age and those with increased co-morbidities and functional limitations^[1]. This shift in demographics may have important implications for rehabilitation approaches and functional expectations pre- and post-transplant. In addition, lung transplant candidates can present with acute respiratory decompensation, and several medical strategies are being used to "bridge" candidates to transplantation using mechanical ventilation and/or Extra Corporeal Life Support (ECLS)^[8-11]. These technologies can have a significant impact on the degree of deconditioning that these individuals experience prior to transplant, as their capacity to participate in active rehabilitation is limited. The rehabilitation needs of individuals who have high oxygen requirements, require hospitalization pre-transplant due to respiratory failure, and/or require extensive rehabilitation post-transplant due to a prolonged and complicated clinical course are not well described.

The overall purpose of this review is to provide an evidence-informed clinical approach to rehabilitation based on over 30 years of clinical rehabilitation experience at our center, integrating the research evidence for rehabilitation in lung transplantation. The specific aims of this review are to: (1) provide a practical approach to functional assessment and exercise training pre- and post-lung transplant, including the peri-operative and long-term follow-up periods; (2) describe and contrast exercise training and mobility for lung transplant candidates and recipients with an uncomplicated and complicated clinical course; and (3) discuss rehabilitative approaches for special populations within lung transplantation such as re-transplant, heart-lung transplant and pediatrics.

FUNCTIONAL ASSESSMENT OF LUNG TRANSPLANT CANDIDATES AND RECIPIENTS

The mechanisms of exercise limitation pre- and post-lung transplant are multifactorial, including alterations in lung mechanics and gas exchange, cardiovascular limitations and peripheral muscle dysfunction, and have been described in detail elsewhere^[12,13]. In order to evaluate exercise capacity and function in lung transplant candidates and recipients, a combination of aerobic testing, muscle function, mobility testing and assessment of physical activity is utilized. Measures that may be used in clinical practice for physical assessment in the lung transplant population have been summarized in Table 1. The Rehabilitation Measures Database^[14] provides information on the psychometric properties, normative data, instrument description and equipment, minimally clinically important difference and considerations for a number of rehabilitation

Table 1 Physical assessment of lung transplant candidates and recipients

Measured construct	Clinical tests	Clinical utility
Exercise capacity	Lab-based test: Cardiopulmonary exercise test on cycle or treadmill	Cause of exercise limitation Assess need for oxygen
	Field-based walk tests: 6MWT, ISWT ^[19,27]	Assess functional capacity
	Upper extremity endurance capacity: UULEX ^[28]	Outcome measure pre-post rehab and pre-post transplant Exercise prescription
Muscle function (strength, endurance)	Peripheral muscles: Manual muscle testing or hand held dynamometry	Assess muscle strength and/or muscle endurance
	Handgrip force 1-repetition maximum	Outcome measure Exercise prescription
	Respiratory muscles: MIP/MEP	(1-RM for peripheral muscles, MIP for IMT)
Physical performance and mobility	Gait speed (over 4 m) ^[110]	Assess mobility, balance and physical function
	Sit-stand tests (<i>e.g.</i> , 30 s sit to stand; 5 times sit to stand) ^[111,112]	Assess need for gait aid
	Short Physical Performance Battery ^[113]	Outcome measure
	Timed Up and Go ^[114]	Exercise prescription
	Balance tests (<i>e.g.</i> , Berg balance scale, BESTest) ^[115,116]	Discharge planning
	FIM ^[117]	
Physical activity	Tests specifically for ICU/inpatients: Egress test ^[118]	
	Various ICU physical function tests ^[119-121]	
	Physical Activity questionnaires, <i>e.g.</i> , PASE ^[122] ; IPAQ ^[123] ; DASI ^[124]	Assess physical activity Outcome measure
	Pedometers or accelerometers	Set activity goals (<i>e.g.</i> , target daily step count)

CPET: Cardiopulmonary exercise test; 6MWT: Six-minute walk test; ISWT: Incremental shuttle walk test; UULEX: Unsupported upper limb exercise test; MMT: Manual muscle testing; 1RM: One repetition maximum; HGF: Handgrip force; HHD: Hand-held dynamometry; MIP: Maximal inspiratory pressure, MEP: Maximal expiratory pressure; IMT: Inspiratory muscle testing; SPPB: Short physical performance battery; TUG: Timed Up and Go; FIM: Functional independence measure; PASE: Physical activity scale for the elderly; IPAQ: International physical activity questionnaire; DASI: Duke activity status questionnaire.

assessment instruments included in Table 1.

Aerobic exercise capacity

Exercise capacity is a major predictor of waiting list survival pre-transplant across disease categories^[15,16], and is also associated with post-transplant health outcomes including days on mechanical ventilation, length of hospital stay and survival^[4,17,18]. The six-minute walk test (6MWT)^[19] is the most common functional test of exercise capacity for lung transplant candidates and recipients in Canada^[5], and is used widely internationally. It is a global marker of health status reflecting severity of disease and level of functional impairment, and has been found to correlate with VO_{2max} in lung transplant candidates^[20]. The six-minute walk distance (6MWD) is incorporated into several composite scores

that can determine the urgency for lung transplant including the BODE and Lung Allocation Score^[21,22]. A 6MWD of less than 400 m or a predicted distance of between 45%-55% is common in lung transplant candidates^[4,15,23,24]. The 6MWD improves significantly following transplant reaching 65%-85% predicted, with the largest gains reported in the first three to four months^[23-26]. Other field-based walking tests that have been used in chronic lung disease such as the incremental and endurance shuttle walk tests, (ISWT and ESWT) may also be used to quantify exercise capacity in lung transplant candidates and recipients^[27].

Upper extremity exercise capacity plays an important role in many basic and instrumental activities of daily living and may provide unique information about upper extremity endurance not reflected in the field-based walking tests. In individuals with COPD, arm exercise capacity has been measured using the Unsupported Upper Limb Exercise Test (UULEX)^[28]. A small group of lung transplant candidates with ILD at our center demonstrated reduced arm exercise capacity compared to controls using the UULEX^[29], however this test has not been used in routine clinical evaluation.

Muscle function

Peripheral muscle function can be tested through multiple techniques, some of which are more applicable to the clinical setting due to lower costs and fewer requirements for specialized equipment, training and personnel such as manual muscle testing, hand held dynamometry (HHD), handgrip dynamometry and one-repetition maximum (1-RM; Table 1). The quadriceps is the most common muscle tested in the research literature and lung transplant candidates exhibit quadriceps weakness of 49%-86% predicted^[30]. An immediate drop in quadriceps strength from pre-transplant to post-transplant at the time of hospital discharge of 15%-32% has been reported with a gradual recovery to pre-transplant levels by three to four months post-transplant^[23-26]. Lower extremity muscles (*e.g.*, quadriceps, ankle plantar flexors) show more pronounced weakness than upper extremity muscles (*e.g.*, biceps)^[29-31].

Body composition (muscle and fat mass) can be measured as part of a physical or nutritional assessment using bioelectrical impedance analysis, dual X-ray absorptiometry or skinfolds. More specific measures of muscle size (*e.g.*, cross-sectional area and muscle layer thickness) can be obtained from ultrasound, computerized tomography, or magnetic resonance imaging, however these are not typically performed for clinical assessment. Muscle atrophy has been reported in research studies of lung transplant candidates and recipients using several measures such as low fat free mass, reduced muscle volume and cross-sectional area^[29,30].

Short tests of physical performance and mobility may be a useful addition to the functional assessment in the pre-transplant phase (Table 1). Lung transplant

candidates have shown reduced functional performance on the Short Physical Performance Battery (SPPB) and Timed Up and Go (TUG) compared with controls^[29,30]. The SPPB has recently been used as a marker for frailty pre-lung transplant and shown to be a predictor of disability, delisting and waitlist mortality^[32].

Physical activity

Level of physical activity can be evaluated using questionnaires, however there is no specifically validated scale for lung transplant candidates or recipients. Commercially available pedometers or accelerometers may also be used to obtain daily step counts and activity level. Measurement of physical activity can be an important adjunct to exercise capacity testing, since it is reduced pre- and post-transplant and can be used for physical activity counseling and setting targets for daily activity.

Low levels of physical activity with a reported mean of 1400-3200 daily steps, reduced time spent in moderate intensity activity, walking and standing, and greater time in sedentary activities has been reported in lung transplant candidates^[23,24,33,34]. A research study conducted in our center demonstrated that lung transplant candidates with ILD had increased physical activity levels on days they participated in pulmonary rehabilitation, and the 90 min rehabilitation session accounted for 58% of the total daily steps^[33]. Levels of daily physical activity improve following lung transplant however remain below predicted levels in terms of daily steps, walking time and movement intensity compared to healthy controls; and show great variability^[23,24,34-37].

GENERAL PRINCIPLES OF EXERCISE TRAINING

Exercise prescription should be individualized, include both aerobic and resistance training, and follow general exercise training principles of specificity, overload and progression^[38]. Based on our clinical experience, respiratory and cardiovascular reserve, stability and clinical course of lung disease, muscle strength and muscle endurance can have a significant impact on the frequency, intensity, type and duration of exercise that is prescribed and the rate of progression. Figure 1 outlines general rehabilitation guidelines used at our center during the pre- and post-transplant phases.

Pre-transplant rehabilitation

Pre-transplant exercise training is recommended in Canadian lung transplant centers for a specified duration or during the entire waiting period prior to transplant to optimize fitness and prevent the cycle of inactivity and deconditioning that can occur with advanced lung disease^[5]. There are few randomized controlled trials that examine the effect of exercise training pre-transplant^[39,40], however retrospective and pre-post studies of exercise training in lung transplant candidates have

shown that 6MWD can be maintained or even increased in spite of progressive lung disease^[4,41-43]. Predictors of rehabilitation success pre-transplant (e.g., improved 6MWD) have not been identified in lung transplant candidates^[43].

Pulmonary rehabilitation guidelines for exercise training can be applied to lung transplant candidates with modifications to account for increased severity of lung disease and multiple underlying disease states^[44,45]. If disease progression and functional deterioration occurs during the waiting period, physical function needs to be reassessed on an ongoing basis and exercise prescription modified as needed. Alternative modes of training including high intensity interval training^[39] and Nordic pole walking^[42] have been described in lung transplant candidates. Inspiratory muscle training has been utilized in chronic lung disease, primarily COPD, to improve inspiratory muscle strength and endurance; however studies have not been specific to lung transplant candidates^[46]. Although supervised outpatient pulmonary rehabilitation in a hospital or community setting are common^[5], alternative modes of delivery such as tele-rehabilitation may be an important alternative for individuals living far from a transplant center, however pre-transplant tele-rehabilitation has not yet been studied in lung transplant candidates^[47].

Guidelines for pre-transplant exercise prescription have been summarized in Table 2 from protocols used in research studies and our current clinical guidelines. Exercise intensity and duration are prescribed and progressed according to exertional oxygen saturation, heart rate and symptoms of dyspnea and leg fatigue using the modified 0-10 Borg scale^[48]. A percentage of the 6MWT speed can be used for lung transplant candidates to prescribe walking speed on the treadmill^[49].

Special considerations for pre-transplant rehabilitation

Supplemental oxygen for exercise training: As lung transplant candidates often require supplemental oxygen for rest and/or exertion^[4], oxygen titration is an important component of exercise training. Guidelines for oxygen supplementation for exercise are not clearly defined^[50], so oxygen titration orders, institutional policies and delegation practices may vary between facilities. At our center, all lung transplant candidates have a prescribed oxygen titration range provided by a physician, which is often to maintain an oxygen saturation (% SpO₂) of at least 88% with exercise, however, oxygen prescription may be modified based on patient diagnosis, medical co-morbidities, arterial blood gases, functional capacity and symptoms. Lung transplant candidates are supported with sufficient oxygen to maintain the prescribed oxygen saturation in an attempt to increase aerobic exercise intensity and duration to obtain a greater physiological benefit with training. In our clinical experience, oxygen requirements for exertion may increase during the waiting

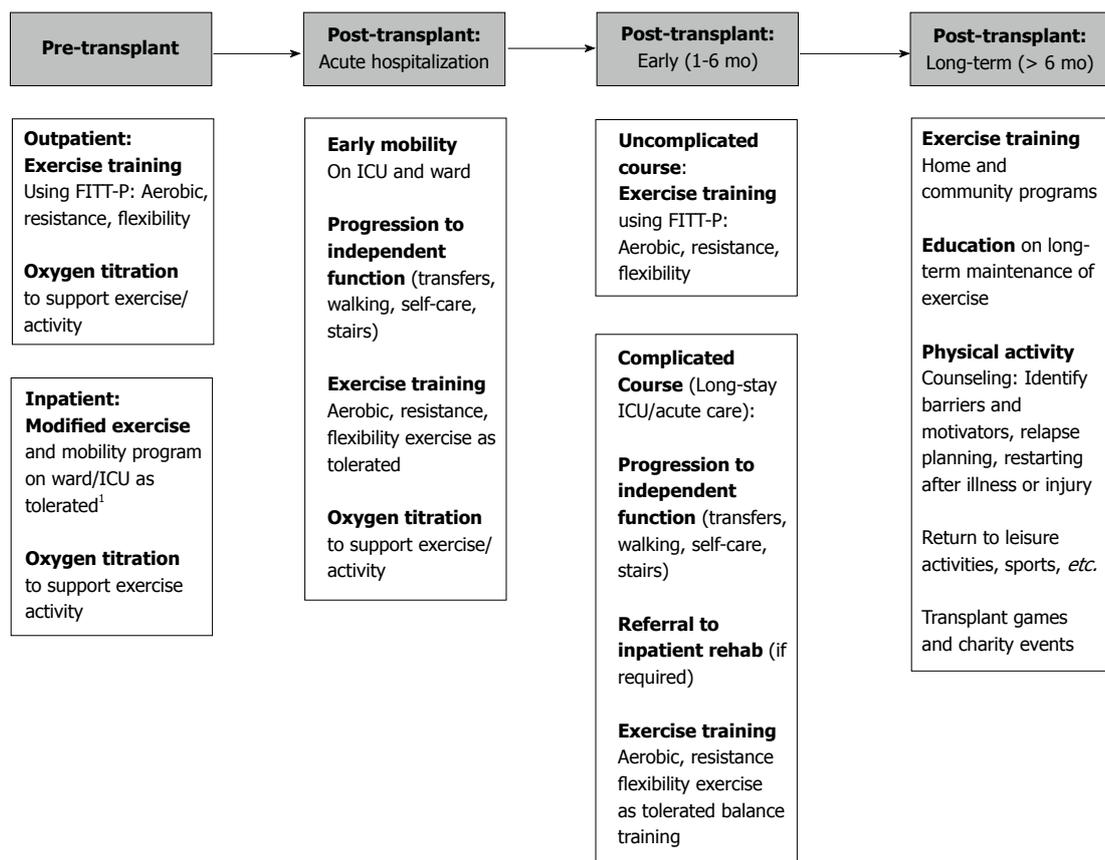

Figure 1 Overview of rehabilitation during the pre- and post-transplant phases. At each phase, monitoring and re-assessment are needed to modify/progress the exercise program. ¹Some hospitalized lung transplant candidates and recipients may require mechanical ventilation and/or extracorporeal life support (ECLS) and can be mobilized on these devices. FITT-P: Frequency, intensity, type, time, progression; ICU: Intensive care unit.

period pre-transplant with some individuals (such as those with ILD) requiring very high levels of oxygen supplementation, high flow oxygen delivery devices and/or non-invasive ventilation. There is a lack of literature on the safety guidelines and hazards of high flow oxygen for exercise training^[51], and our clinical practice is to communicate closely with the medical team regarding arterial blood gases and/or other medical concerns.

Exercise training in pulmonary hypertension: Historically, individuals with pulmonary arterial hypertension (PH) were excluded from exercise training, however alongside changes in medical management, a number of studies over the past decade have shown efficacy and safety of carefully prescribed exercise in stable, medically optimized individuals with PH^[52]. For individuals with moderate to significant primary or secondary PH who are not symptomatic at rest, our clinical practice is to avoid exertional hypoxemia, symptoms of chest pain, dizziness, pre-syncope, nausea and visual changes during exercise training. We prescribe exercise intensity and duration as guided by lower dyspnea scores (e.g., Borg score 2-3 or slight to moderate). High intensity aerobic and resistance training and Valsalva maneuvers are avoided. Changes in weight, abdominal circumference, lower leg edema

and other evidence of worsening right heart failure are monitored with close communication with the medical team, and care is taken to avoid interruption of continual intravenous vasodilators (e.g., prostaglandins).

Infection control: Infection control procedures are essential for preventing spread of certain infections such as methicillin-resistant staphylococcus aureus, mycobacterium abscessus or CF-related infections during group exercise programs. At our center, individuals with CF are physically separated by three meters during group exercise training and individuals with Burkholderia cepacia exercise separately at the end of the day. Guidelines on cleaning equipment, hand-washing, gown and mask use and isolation practices may vary at different institutions.

Team approach to rehabilitation: Education is an important component of rehabilitation, specifically on issues related to safe and effective exercise, exertional oxygen use, home exercise, assistive devices and energy conservation techniques^[53]. Psychosocial support to address stress and expectations during the waiting period and concerns regarding surgery is also beneficial^[54]. Collaboration with the registered dietitian to ensure that nutritional needs are being met and balancing exercise participation with nutritional needs

Table 2 Guidelines for pre-transplant exercise prescription in stable outpatients

	Aerobic	Resistance	Flexibility
Frequency	2-5 d/wk	2-3 d/wk	3-5 d/wk
Intensity	50%-80% HR reserve Dyspnea > leg fatigue: Moderate to hard (3-5 on modified Borg scale) ^[48] SpO ₂ > 85%-90% Continuous or intermittent training ¹ : 60%-80% 6MWT speed for walking ^[41,49] 60% peak workload for cycling ^[39,43] or just above anaerobic threshold ^[40] Interval training ² : 100%: 0% peak work rate (cycle) ^[39]	30%-80% 1-RM or use 8-15-RM ^[125]	
Type	Walking (treadmill, corridor, Nordic poles) ^[42] Cycling (leg and/or arm ergometer)	Major muscle groups of upper and lower body (quadriceps, hamstrings, plantar flexors, gluteals, biceps, triceps, pectorals, latissimus dorsi) Training modalities: Free weights/dumbbells Elastic bands Pulleys Gym equipment Body weight (stairs, squats, heel raises, wall push-ups)	Major muscle groups of upper and lower body Thoracic cage and chest wall mobility
Time/ Training	Continuous: 15-30 min	1-2 sets × 8-15 reps	Hold up to 10-30 s each, repeat 2-4 times
Volume	Intermittent: 5-10 min × 2-3 bouts Interval ² : 30 s exercise: 30 s rest (12-36 min) ^[39]		
Progression	Progress time up to 20-30 min continuous Perform regular 6MWTs and adjust speed accordingly for treadmill training; and increase Watts on cycle Higher level patients may tolerate a treadmill incline of 1%-4%	Increase weights based on tolerance; (approximately 0.5 kg or 1 lb. per week, as tolerated) ^[41] Body weight exercises: Can add hand or ankle weights	Hold stretches to point of tightness/ slight discomfort

¹Intermittent training is regular or irregular intervals of the same low to moderate intensity *vs* interval training, which involves pre-set, alternating, short intervals of high intensity to intervals of rest or lower intensity;

²There are several different interval training protocols described in chronic lung disease^[126]. SpO₂: Oxygen saturation measured by pulse oximetry; HRR: Heart rate reserve; 6MWT: Six-minute walk test; ISWT: Incremental shuttle walk test; HR: Heart rate; BP: Blood pressure; RR: Respiratory rate; ESWT: Endurance shuttle walk test; reps: Repetitions; RM: Repetition maximum.

with close monitoring of weight are performed at our

center. Some individuals are required to lose weight pre-transplant and may benefit from nutritional counseling in addition to aerobic exercise training. A palliative care referral for opioid administration may be beneficial to assist with symptom control of dyspnea, cough and other symptoms that may impact on exercise ability and quality of life. A study at our center observed a trend towards increased caloric expenditure during exercise training in 64 lung transplant candidates referred to palliative care post opioid initiation^[55].

Considerations for a complicated pre-transplant clinical course:

In cases of a prolonged waiting period prior to transplant, we find that exercise intensity and duration may not be progressed if there is significant disease progression, respiratory exacerbations and infections, medical instability and hospital admission for respiratory failure. Maintenance of physical function or slowing the rate of physical deterioration can become important functional goals. Increased dyspnea, decreased function or acute worsening of gas exchange should be investigated as they can indicate underlying infection, respiratory exacerbation or pulmonary embolism. Some lung transplant candidates experience profound respiratory deterioration and need to await lung transplantation on the hospital ward or in the intensive care unit (ICU). Although there is no research evidence on inpatient rehabilitation for lung transplant candidates hospitalized with respiratory deterioration and failure, we provide a modified exercise program based on patient tolerance to help offset functional decline. Corridor ambulation and bedside cycling are encouraged as tolerated, but may not be tolerable by some individuals due to severe gas exchange abnormalities that are not corrected with high levels of supplemental oxygen. Resistance exercises, which do not confer the same degree of exertional desaturation should be continued as tolerated, with a focus on maintaining proximal muscle strength (e.g., shoulder and hip) and lower limb strength in anticipation of early ambulation and return to self-care activities post-transplant^[56]. Neuromuscular electrical stimulation (NMES) has been shown to enhance muscle mass and function in individuals with severe COPD and incapacitating dyspnea, and may be a useful adjunct for individuals unable to participate in a traditional outpatient pulmonary rehabilitation program^[57].

Selected lung transplant candidates require bridging to transplant due to respiratory failure. Mechanical ventilation and ECLS can be associated with significant deconditioning due to increased sedation time limiting mobility and active participation in rehabilitation, and in some cases, irreversible muscle damage from persistent critical illness polyneuropathy and myopathy^[58]. Facilities with an experienced critical care mobility team can mobilize individuals on mechanical ventilation and/or ECLS who are medically stable and cognitively capable^[59]; although guidelines for mobility prescription

Table 3 Exercise and mobility for hospitalized lung transplant candidates and recipients

Setting	Interventions/prescription	Considerations for a complicated hospital course
Intensive care unit	Upright positioning AROM for upper extremities Acupuncture for incisional pain Progressive mobility program, consisting of: Bed mobility > dangling > transfer to chair > standing > marching on spot > ambulation with HWW up to 100-200 m with or without MV In sitting or lying: Resistance training using light weights, elastic resistance bands	PROM, A/AROM for those who are sedated/not actively moving Trunk control and sitting balance prior to standing and walking Specialized equipment to facilitate mobility, such as: Standing frames, sit-stand lifts or mechanical lifts, standing and walking slings, portable treadmills, portable ventilators for ambulation in ICU (with appropriate settings to facilitate exercise), manual resuscitation bag with PEEP valve Bedside cycle ergometer or treadmill for aerobic training Video gaming system (e.g., Nintendo Wii™) for balance and strengthening exercises ^[127]
Step-down unit/ward	AROM upper extremities Progressive mobility program: Up to chair 1-3 ×/day; supervised walking 1 ×/day building up to 100 m; progress to 4-5 ×/day for 10-15 min bouts and increase distance > 100 m Stair climbing Resistance training: Up to 5 lbs. (1 set × 10 reps) Education re: Lifting restrictions Postural correction/re-education Oxygen titration: Maintain SpO ₂ > 88% on exertion	Transfer training Gait training Gait aids: Progress from HWW > rollator > no gait aids, if able Specialized seating Referral to inpatient rehabilitation for those who are not independent for discharge home

ROM: Range of motion; HWW: High-wheeled walker; MV: Mechanical ventilation; AROM: Active range of motion; PROM: Passive range of motion; A/AROM: Active/assisted range of motion; PEEP: Positive end expiratory pressure.

in critically ill individuals are not clearly defined^[60]. A recent systematic review presented evidence that early mobilization and ambulation is safe even in patients awake on veno-venous Extra Corporeal Membrane Oxygenation (ECMO) support^[61]. Physiotherapists at our center undergo specialized training in managing ECMO circuits, and with the support of an early mobility team, close communication with the medical team and a positive ICU culture towards the safe mobilization of selectively assessed critically ill patients^[62].

Post-transplant rehabilitation

Immediate post-transplant rehabilitation in the ICU: The rehabilitation goals in the early phase post-

transplant are to increase general mobility, functional capacity, muscle strength and endurance, and facilitate discharge from hospital. Reduced ICU length of stay has been associated with increased quadriceps muscle strength at hospital discharge in lung transplant recipients^[26]. One study identified factors that contribute to an extended hospital stay which included high urgency listing status, bridging to transplant with mechanical ventilation and/or ECLS, diagnosis of pulmonary hypertension, prolonged intubation post-transplant and colonization with multidrug resistant pathogens^[63]. The functional consequences of a prolonged ICU stay can be profound and long-term^[64].

Physical rehabilitation should begin as early as possible post-operatively and should prioritize upright positioning (e.g., sitting) and mobilization (e.g., out of the bed)^[65,66]. Early mobilization in the ICU has not yet been studied specifically in lung transplant patients, but the same treatment approaches reported for other critically ill patients are likely applicable. Table 3 Muscle wasting related to critical illness is early and impactful^[67,68], highlighting the need for rapid and effective interventions to protect the muscle from atrophy and weakness. To date, several systematic reviews support safety, feasibility and beneficial impact of early physical therapy and mobilization in mechanically ventilated patients^[69-76]. There is evidence that early physical therapy and mobility training can result in improved quality of life^[71], physical function^[71,72], muscle strength^[71,73] and functional outcomes^[69]. Further research is needed to determine whether these improvements translate into decreased hospital and ICU length of stay^[77,78] and better long-term physical function^[60].

Rehabilitation in the ICU should take into consideration pre-transplant function, cardiorespiratory function, muscle strength, range of motion (ROM), balance, cognitive impairments, pain control and medical stability. Early active muscle training and cardiopulmonary conditioning should begin as soon as feasible within the hospital setting (e.g., turning in bed, sitting at the edge of bed, sitting in a chair, standing, and walking). In addition, self-care and activities of daily living should be encouraged as soon as possible^[79]. Low levels of exercise (e.g., with elastic therapy bands or unloaded pedaling on the bicycle) with subsequent increases in the duration and workload can be made as the patient progresses^[79,80]. In critically ill patients, even passive or active exercise training sessions for 20 min/d using a bedside ergometer is able to increase short-term functional recovery^[75].

The emerging literature using NMES has shown that it may be a safe, low cost treatment for early intervention in critically ill patients who may not be able to participate in active exercise^[75,81] since it can passively activate the muscles^[75,81,82]. However, studies to date have included a general, mixed population of ICU patients and the evidence is not specific to lung transplant recipients. Furthermore, the ability to deliver NMES effectively in the context of underlying ICU

acquired myopathy and polyneuropathy^[83] has not been substantiated.

Post-transplant rehabilitation in the hospital step-down unit and ward:

At our center functional reassessment and exercise are resumed following ICU transfer until discharged home or to inpatient rehabilitation, with oxygen titration orders to maintain oxygen saturation at least 88% on exertion. Most lung transplant recipients at our center are weaned off supplemental oxygen prior to hospital discharge, but a few may still require low flow oxygen for exertion for several weeks to months, especially single lung transplant recipients.

Rehabilitation interventions provided at our center during the hospital stay post-transplant are summarized in Table 3. Medical issues that may be encountered in this early post-transplant phase that can impact exercise include infection, acute rejection, anxiety, depression, post-surgical pain at the thoracotomy tube site and chest wall, arrhythmias, veno-thrombotic events, infections requiring isolation, postural hypotension, skin ulcers and poor wound healing. Side effects of medications include fluid retention, anemia, nausea, tremors, decreased visual acuity, hyperglycemia and hypertension^[65], which need to be considered when prescribing exercise so that appropriate modifications should be made.

Outpatient rehabilitation: Structured outpatient rehabilitation within the first three months following lung transplant is available at Canadian transplant centers^[5]. Functional goals in the outpatient phase may include ambulation without gait aids, liberation from supplemental oxygen, return to pre-transplant muscle strength and 6MWD of 65%-85% predicted levels^[23-26,84]. Large functional gains are reported during this period of rehabilitation in individuals with a relatively uncomplicated post-operative course^[23-26]. Lung transplant recipients indicate that exercise training is a valuable part of their post-transplant care and essential to improve physical function^[85]. A greater improvement in 6MWD post-transplant is predicted by greater recovery of muscle strength and a lower pre-transplant 6MWD^[25,84]. Studies examining exercise training following lung transplantation show significant increases in exercise capacity, muscle strength and bone mineral density^[24,86-88] (Table 4).

Considerations for a complicated post-transplant clinical course:

There are a multitude of complications that can significantly increase the length of hospital stay and impact rehabilitation including: Major bleeding, infections, prior multi-drug resistant infections and colonization, difficulty weaning with prolonged mechanical ventilation, pre- and post-transplant ECLS, diaphragmatic paralysis, severe agitation, delirium, depression, acute neurological events, critical illness polyneuropathy, hemodynamic instability, primary

graft dysfunction and acute renal failure requiring hemodialysis^[65,66].

An assessment of functional goals can help inform discharge planning and recommendations for inpatient transplant rehabilitation, complex continuing care or homecare services. A retrospective study from our center showed that lung transplant candidates who were older, had a lower pre-transplant 6MWD, were mechanically ventilated prior to transplant and had a longer total length of hospital stay were more likely to be discharged to an inpatient rehabilitation facility vs home^[89]. Compared to other inpatient rehabilitation patients (*e.g.*, stroke, joint surgery) lung transplant recipients are more likely to require transfer back to acute care for medical management related to complications such as infection, rejection and cardiac events^[90,91].

In our clinical practice, individuals who experienced a complicated post-transplant course may require a referral to a multidisciplinary inpatient rehabilitation program to regain basic mobility (*e.g.*, independent transfers, walking, and the ability to engage in activities of daily living such as self care) prior to discharge home. Upon discharge, these individuals are encouraged to enroll in an outpatient pulmonary rehabilitation program, or be prescribed a program that can be done in the community or home setting to work on improving endurance and strength. These individuals often require a mobility aid (*e.g.*, rollator walker or cane) and their 6MWD is well below predicted values, showing a slow improvement over 12 to 18 mo. Specific exercises to target balance and coordination impairments are sometimes needed to be included in the outpatient or home exercise program. Individuals with a complicated post-transplant clinical course may experience persisting myopathies and/or neuropathies, and not all critically ill survivors recover to the same extent as there may be significant differences in recovery of muscle function and rehabilitation potential^[58]. This remains an area of active research.

Late/ongoing post-transplant maintenance

The 6MWT is reassessed regularly post-transplant^[5], to monitor changes in exercise capacity and exertional oxygen saturation, which may change over time. Although the majority of exercise training programs occur in the first three to four months following transplant, longer-term exercise training may provide additional benefits to exercise capacity and the management of long-term co-morbidities of hypertension, hyperlipidemia and diabetes are prevalent at one, three and five years post-transplant^[1,24]. A randomized trial found that lung transplant recipients who underwent rehabilitation in the first three months following transplant had higher physical activity levels, improved fitness and lower 24-h blood pressure one year post-transplant compared to recipients who did not participate in rehabilitation^[24]. Daily physical activity has been reported to be significantly reduced one year following transplantation as

Table 4 Guidelines for early post-transplant exercise prescription in stable outpatients

	Aerobic	Resistance	Flexibility
Frequency	3-5 d/wk	2-3 d/wk	3-5 d/wk
Intensity	50%-80% HR reserve or < 85% age-predicted HRmax ^[4,23] Leg fatigue > dyspnea: Moderate to hard (3-4 on Borg scale) SpO ₂ > 88% Continuous training: 75%-100% 6MWT speed for walking ^[24,25] 50%-80% peak workload for cycling ^[24,59,128]	60%-80% 1RM ^[24,26] 10-RM No upper extremity lifting/pulling/pushing > 10 lbs. first 3 month Extra restrictions if sternal instability	Hold stretches to point of tightness/slight discomfort
Type	Walking (treadmill, corridor) Cycling (leg); avoid arm ergometry in first 3 month to allow for incision healing	See pre-transplant Avoid abdominal muscle exercises for first 3 month	Major muscle groups of upper and lower body Thoracic cage and chest wall mobility Postural re-education
Time/ Training Volume	Continuous: 20-30 min	1-3 sets × 8-15 reps	Hold up to 10-30 s each, repeat 2-4 times
Progression	Progress time to 30 min, then progress speed on treadmill; increase incline after approximately 6 wk post-transplant (if tolerated) Increase Watts on cycle Walk: Run program for some high level patients (at least 6 wk post-transplant) 30-60 s running bouts interspersed with walking for 20-30 min	Start with sit-stands and when able to perform without arm support progress to squats with hand weights Weekly increase weights based on tolerance; (approximately 0.5 kg or 1 lb. per week, as tolerated) within lifting guidelines (e.g., < 10 lbs. for upper extremities for first 3 month) Body weight exercises: Can add hand or ankle weights (e.g., squats and stair climbing)	Hold stretches to point of tightness/slight discomfort Extra restrictions if sternal instability (e.g., avoid chest expansion stretches)

6MWT: Six-minute walk test; CPET: Cardiopulmonary exercise test; HR: Heart rate; HRR: Heart rate reserve; SpO₂: Oxygen saturation measured by pulse oximetry; RR: Respiratory rate; BP: Blood pressure; ISWT: Incremental shuttle walk test; ESWT: Endurance shuttle walk test.

compared to healthy controls^[35]. Physical activity levels varied in long-term recipients and have been found to be inversely associated with body weight^[37].

Exercise training in lung transplant recipients in the long-term phase (> 6 mo) has been shown to have beneficial effects on endurance capacity and muscle

strength^[87,88,92]. Long-term adherence to exercise may be greater if individuals participate or resume activities they enjoy. Thinking beyond a traditional gym protocol and exploring individuals' interests, access and resources can be helpful when counseling individuals about increasing and maintaining physical activity in their home community. National and World Transplant Games^[93,94] and charity events are excellent opportunities for setting fitness and performance goals and staying active while raising awareness of lung disease and transplantation. As an example of the benefits of this training, lung and heart-lung transplant recipients (> 6 mo post-transplant) who participated in ten weeks of upper extremity training through Dragon boat racing showed improved aerobic and anaerobic fitness^[95].

Inexpensive pedometers, activity watches, fitness monitors and smart phone applications can be used to track daily steps and activity levels, and set targets to increase physical activity. Additional activities such as yoga, Tai Chi, dance and seasonal activities such as swimming, paddling, outdoor cycling, hiking, skating and snowshoeing can be done in a social setting with family and friends. A gradual introduction to new activities should be emphasized, and we counsel transplant recipients to avoid activities with an increased theoretical risk of injury such as contact sports, skydiving, bungee jumping and scuba diving. Episodic medical issues such as illness, infection or injury can interrupt an exercise regimen, so physical activity counseling on how to modify and resume exercise after an episode of illness is important and can be addressed at reassessment.

SPECIAL POPULATIONS

Heart-lung, multi-organ and re-transplantation

At our center individuals who have undergone heart-lung transplantation, multi-organ transplantation (e.g., lung-liver) and re-transplantation participate in a similar pre-and post-transplant rehabilitation program as lung transplant candidates and recipients. Individuals awaiting a heart-lung transplantation may have congenital heart disease with cardiac shunts that can lead to right heart shunting and severe hypoxemia that may not be responsive to supplemental oxygen^[96]. This may necessitate lower training intensity^[97] (e.g., using heart rate and/or Borg dyspnea and fatigue scores) and lower oxygen saturation guidelines for exercise training. Following heart-lung transplantation, a longer warm-up and cool down is recommended to allow for the slower changes in heart rate due to disrupted cardiac innervation^[98]. The modified Borg scale is used to guide exercise training instead of heart rate. There is a lack of information on exercise training for individuals listed for re-transplant^[99], but based on clinical experience at our center, individuals often have a lower functional capacity compared to listing for their first transplant.

Pediatrics

Children (from birth to 18 years of age) are typically followed in specialized pediatric healthcare centers. Clinical assessment of the pediatric lung transplant candidate should include posture, ROM, muscle strength and gross motor function appropriately for the age of the child. The 6MWT has been shown to be a valid measure in children^[100] and is utilized by a majority of pediatric centers in North America^[101]. There are published normative values for 6MWD across various ages^[102], however interpretation of the 6MWT data is sometimes difficult to differentiate from growth and development of the child, so it should be used as part of a thorough clinical assessment to identify issues amenable to rehabilitation. While pre-transplant physical functioning and its relationship to post-transplant outcomes has not been studied extensively, one study in pediatric patients found a correlation between 6MWD and short term transplant outcomes including length of ICU stay, days of mechanical ventilation and time until discharge^[18].

Pre-transplant rehabilitation: There are no studies examining the impact of exercise training in pediatric lung transplant candidates, however clinical experience indicates that it can be of significant benefit for these children and helps to prevent deterioration in function. Due to the limitations of available programs for children, families must often commute to the transplant center. However, older teens may be referred to adult pulmonary rehabilitation programs with support from pediatric specialists. Children may also have exacerbations of their underlying condition requiring hospitalization and modification of their exercise programs. Exercise prescription with slow progression can be approached similarly as for adults including both aerobic and resistance training^[103,104]. Strength training is unlikely to increase muscle bulk for pre-pubertal children, but can improve function. Exercise training for younger children should include activities encouraging gross motor skill development, such as integration of physical education activities and incorporate growth and developmental factors of the child's maturing system. Physical therapists should also encourage regular school attendance, participation in physical education curriculums (within medical restrictions) with appropriate modifications to help ensure adequate levels of physical activity. Collaboration with school professionals, teachers, and physical education instructors may be needed to ensure safe follow through of these recommendations.

Post-transplant rehabilitation: Exercise capacity and general fitness improves for children following lung transplant but remains reduced compared to age-predicted values^[104-106]. Opportunities and access to rehabilitation post-transplant are often limited. A study examining the impact of an early semi-individualized physiotherapy prescribed exercise program early (within the first three months) after hospital discharge found

similar improvements in 6MWD, strength and flexibility in children who attended the hospital three times a week compared to children who performed the exercise at home with parents^[105], suggesting that home-based training may be a way to bridge the gap in accessibility. A study at our center with children who were attending the World Transplant Games showed the positive effects of home-based training, which included general exercise programs and event-specific, skill-based training done independently for three months prior to the Games. The children showed short term benefits in levels of physical activity and each subject demonstrated an increase in at least one parameter of fitness on the Fitness-GRAM[®]^[106]. Taken together, these studies suggest that home-based intervention or exercise prescription can be of benefit for these children when provided with appropriate education regarding safe exercise. The transition of adolescents and young adults to adult care is an increasingly important area of focus since this has been recognized as a vulnerable time for adolescent transplant recipients^[107]. Research on strategies to optimize successful transition highlights the importance of an inter-professional approach with involvement from both the pediatric and adult care centers.

CONCLUSION AND FUTURE DIRECTIONS

Medical and surgical advances continue to improve the availability of lung transplantation^[108]. Exercise training provides an essential role in optimizing functional capacity and fitness pre-transplant, as well as improving outcomes and quality of life post-transplant. Physiotherapists and clinical exercise specialists working with lung transplant candidates and recipients require expertise in general exercise training principles and specialized knowledge of pre- and post-transplant complications, oxygen titration, side effects of medications and a sound understanding of how to modify exercise programs during episodic illnesses/ exacerbations and/or change in lung function pre- and post-transplant. Although studies have been conducted on exercise training in lung transplantation, there is a need for larger studies examining long-term outcomes^[109]. Individuals with a complicated pre- and post-transplant course pose a particular challenge for clinicians, and further research on rehabilitation for this population is needed. The development of standardized physical function measures that can help predict post-transplant outcomes, and the investigation of alternative modes of exercise training are also warranted.

Abstract

The successful of transplantation is determined by the

shared human leukocyte antigens (HLAs) and ABO blood group antigens between donor and recipient. In recent years, killer cell receptor [*i.e.*, killer cell immunoglobulin-like receptor (KIR)] and major histocompatibility complex (MHC) class I chain-related gene molecule (*i.e.*, MICA) were also reported as important determinants of transplant compatibility. At present, several different genotyping techniques (*e.g.*, sequence specific primer and sequence based typing) can be used to characterize blood group, HLA, MICA and KIR and loci. These molecular techniques have several advantages because they do not depend on the availability of anti-sera, cellular expression and have greater specificity and accuracy compared with the antibody-antigen based typing. Nonetheless, these molecular techniques have limited capability to capture increasing number of markers which have been demonstrated to determine donor and recipient compatibility. It is now possible to genotype multiple markers and to the extent of a complete sequencing of the human genome using next generation sequencer (NGS). This high throughput genotyping platform has been tested for HLA, and it is expected that NGS will be used to simultaneously genotype a large number of clinically relevant transplantation genes in near future. This is not far from reality due to the bioinformatics support given by the immunogenetics community and the rigorous improvement in NGS methodology. In addition, new developments in immune tolerance based therapy, donor recruitment strategies and bioengineering are expected to provide significant advances in the field of transplantation medicine.

Core tip: Transplantation is a systematic medical procedure for patients with organ failure and haematological disorders. Immunologically compatible donor

and recipient are determined by several genetic markers which include matching for ABO blood group, human leukocyte antigen, MICA and killer cell immunoglobulin-like receptors. The elucidation of genes code for these markers of tissue identity reviewed here and significant advancement in the field of transplant immunology are expected to have a positive impact on transplantation medicine. These include both the waitlisted and transplanted patients.

INTRODUCTION

Transplantation is a systematic medical procedure for patients with organ failure and haematological disorders^[1,2]. Transplantation can be classified into four categories: Autograft, isograft, allograft and xenograft based on the origins and the recipients of the grafts (cells, tissues or organs). In autograft transplantation (also known as autologous transplantation), a graft is taken and transplanted from different parts of the same individual. The processes of transferring grafts between genetically identical and non-identical individuals of the same species are known as isograft and allograft transplantation, respectively. In contrast, xenograft refers to the transplantation of grafts between two different species such as from baboon to human. Implantation of human cancer cells in mice for tumour study is also assumed to be xenograft transplantation^[3,4].

The current practice of allograft transplantation is to have as many match for ABO and human leukocyte antigen (HLA) loci as possible between the donor and recipient. However, this is not the case for isograft and autograft as the transplanted graft originated from the genetically identical resources. Incompatibility between donor and recipient will cause rejection since the graft will be considered as non-self by the recipient's immune surveillance and the rate of graft rejection will vary depending on time courses, types of tissue or organ grafted and the immune responses involved.

REJECTION AND GRAFT VS HOST DISEASE

In general, there are three types of graft rejections, *i.e.*, hyperacute, acute and chronic rejection^[4]. These types of rejections are categorized based on the speed that the rejection occurs. For hyperacute rejection, this process may occur within minutes or hours, and is usually not longer than 24 h. Sometimes, hyperacute rejection may occur immediately during the surgery process. This type

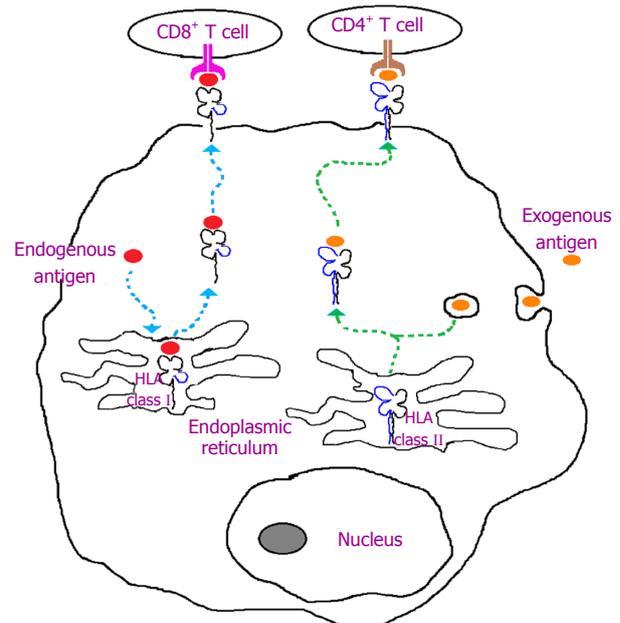

Figure 1 Schematic diagram of human leukocyte antigen class I and II antigenic peptide presentation to CD8⁺ T and CD4⁺ T cells, respectively. HLA: Human leukocyte antigen.

of rejection is due to preformed alloantibodies against the mismatched ABO and HLA antigens between patient and donor. The alloantibodies may exist due to previous transplantation or transfusion, pregnancy or infections^[5]. This pre-existing antibody can activate the complement system and cause injury to the endothelial cells which will then lead to platelet adhesion and thrombosis. Therefore, the graft will never be vascularised and the organ must be removed immediately. The hyperacute rejection may be managed with systematic antibody screening and cross matching between donor and recipient^[6].

The most common type of graft rejection is acute rejection. The onset of rejection varies from weeks to months and is largely attributed to HLA incompatibility. This type of rejection involves both cellular- and humoral-mediated immunity. However, the cellular-mediated immune responses are more significant through either direct recognition of non-self HLA molecules on the surface of the graft or indirect antigenic peptide presentation by self HLA molecules to T cells^[7-9] (Figure 1). The CD4⁺ T cells will also secrete several types of cytokines such as interleukin-4 (IL-4) and IL-2. These cytokines will then lead to several mechanisms including inflammation, recruitment of other inflammatory cells and may also induce T and B cell proliferations^[9]. The major histocompatibility complex (MHC) class I chain-related gene A (*MICA*) molecules are also important markers of tissue identity and have been implicated in transplant immunology^[10,11]. The stress-induced *MICA* has previously known as PERB11.1 glycoproteins and are coded for by the gene located on the classical class I subregion of MHC^[12] (Figure 2) and incompatibility between the donor and recipient for the *MICA* antigen

Table 1 List of killer cell immunoglobulin-like receptors and their human leukocyte antigen ligands

KIR	Alleles	Protein variants	HLA ligands
2DL1	43	24	C2
2DL2	28	11	C1, C2
2DL3	34	17	C1, C2
2DL4	46	22	G
2DL5	41	17	Unknown
2DS1	15	7	C2
2DS2	22	8	Unknown
2DS3	14	5	Unknown
2DS4	30	13	A*11, some C
2DS5	16	11	Unknown
3DL1	73	58	Bw4
3DS1	16	12	Unknown
3DL2	84	61	A*03,-11
3DL3	107	55	Unknown
3DP1	22	0	0
2DP1	23	0	0

The C1 are HLA-C allotypes with serine and asparagines at position 77 and 80 of $\alpha 1$ domain, respectively. The C2 are HLA-C allotypes with asparagines and lysine at position 77 and 80 of $\alpha 1$ domain, respectively. The Bw4 are HLA-B allotypes with isoleucine or threonine at position 80 of $\alpha 1$ domain. This table is adapted from Robinson *et al*^[99] and Parham *et al*^[104]. KIRs: Killer cell immunoglobulin-like receptors; HLA: Human leukocyte antigen.

will trigger cytotoxic activity of lymphocytes (CD8⁺ and $\gamma\delta$ T cells) and natural killer (NK) cells^[11,13-15] (see the following sub-sections). The role of MICA in graft rejection and donor specific antibodies to MICA antigens have been reported by several others^[11,16-18].

The third type of rejection is chronic rejection which takes place months to years following transplantation procedure. It induces chronic damage *via* the production of cytokines and alloantibodies which activate the classical pathway of complement system^[19,20]. However, the actual mechanism of this rejection is not very well understood. It is usually characterized by fibrosis and arteriosclerosis, due to extensive proliferation of smooth muscle cells. Repairing process of damaged tissues and macrophages activation in chronic rejection can lead to fibrosis formation^[21-23].

The transplanted allograft can also trigger immune reactions [*i.e.*, graft vs host disease (GVHD)] against mismatched antigens possessed by the recipients. The GVHD is predominantly occurs in bone marrow transplantation which involves alloreactivity of donor's lymphocytes against the incompatible tissues of the immune-suppressed host^[8]. However, improved outcomes were observed in haplo-identical (*i.e.*, a single HLA haplotype-mismatched) stem cell transplantation^[24-26]. In this context, donor's NK cells will recognize leukaemia cells as non-self and initiate alloreactivity (*i.e.*, graft vs leukaemia effect) against the cancerous cells after haplo-identical stem cell transplantation^[27-29]. The inhibitory and alloreactivity of NK cells are determined by HLA molecules which acting as ligands (Table 1) for their immunoglobulin-like receptors [*i.e.*, killer cell immunoglobulin-like receptors (KIRs)]^[29,30] (see the

following sub-sections). Thus, this receptor-ligand incompatible might lead to either NK alloreactivity against transplanted graft or GVHD. Our understanding of this immune surveillance has provided the basis for the adoptive infusion of NK cells as part of immunological based modality in transplantation and ultimately reduce the potential toxicity effects of other immunosuppression agents^[29,31,32] (see later).

MANAGEMENT OF GRAFT REJECTION

The immunosuppressive therapy is used to increase the survival rate of the graft, especially during acute rejection. However, this therapy cannot be used for chronic rejection since it is difficult to manage. This therapy does not only involve drugs but also antibodies^[33,34]. Examples of the drugs that have been used in immunosuppressive therapy are like mycophenolate mofetil, cyclosporine, tacrolimus and sirolimus^[35-38]. Each of these drugs has their own mechanism of action which will result in immune cells suppression. For example, mycophenolate mofetil is administered to block proliferation of lymphocytes by inhibiting the key enzyme that is important for purine synthesis and DNA replication^[36] while cyclosporine is given to inhibit transcription factor for T-cell activation^[39,40]. For antibodies, a number of monoclonal and polyclonal antibodies have been given to the patients in preventing graft rejection. Most of these antibodies are specific for T cells or T cell sub-populations and they are very effective for blocking T cells activation and binding^[41,42].

However, most of the immunosuppressive agents can cause various side effects to the recipient on their long term use. Besides that, the immunosuppression effects of the agents are not specific only on the graft, but also attack the overall body systems including the lymphocyte maturation. Hence, this will put the recipient at a high risk of getting other infections, cancer, cardiovascular diseases and metabolic bone diseases^[33,43-45]. Additionally, the recipient will have a chance of getting transplant rejection once they stop taking these immunosuppression agents. As an alternative, researchers are working on finding a new therapy that maintains the health of the graft without compromising the immune system. This new method involves inducing immune tolerance and mainly focus on T cell depletion in thymus (*i.e.*, central tolerance) and suppression of mature T cells in lymph nodes (*i.e.*, peripheral tolerance)^[20,46].

The key element in tolerance induction is specificity, which means the recipient immune system is not completely paralyzed. For example, the traditional antithymocyte globulin (TGA) was used as immunosuppressive agent drugs to prevent an acute rejection in organ transplantation^[47-49]. As an alternative, this treatment is replaced with another antibody known as anti-IL-2R α receptor antibodies. This type of antibody is widely used to replace TGA as it does not cause chronic expression of cytokines and improves the development of immune

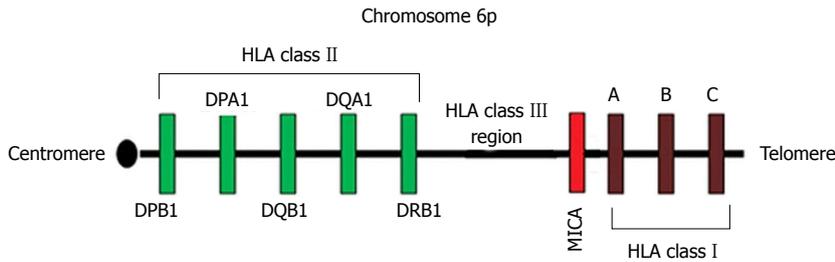

Figure 2 Approximate locations of human leukocyte antigen class I and II and major histocompatibility complex class I chain-related gene A loci on the short arm of chromosome 6. HLA: Human leukocyte antigen; MICA: Major histocompatibility complex class I chain-related gene A.

tolerance^[50-53]. Besides anti-IL-2R α , the combination of costimulatory molecule blockage with inhibitory of signal activation also appear to be effective in inducing tolerance in a few animal studies. Interaction between T cell receptor and costimulatory signals such as CD28 is required for T cell activation. Thus, blockage of the CD28 and its ligands (*i.e.*, B7 family molecules) resulted in transplantation tolerance^[46,54,55] and induction of anergic state in T cells activation^[56]. In addition, another molecule that binds to ligand for T cell activation (*e.g.*, CD152 or also known CTLA-4) also has a potential in inducing tolerance. For example, treatment with CTLA-4 immunoglobulin (Ig) during bone marrow transplantation in murine models was able to induce long-term survival rate of allograft^[57]. Similarly, Ig treatment of other ligand for T cell receptor (*e.g.*, PD-1) and costimulatory molecule (*e.g.*, CD40) have also been shown to limit T cell proliferation and activation^[58-60]. Acute rejection in non-human primates is also preventable by anti-CD40L treatment with or without CTLA-Ig^[61,62].

Besides using inhibitory molecules, Treg (CD4⁺CD25⁺) and NK cells can also be used to suppress CD4⁺ and CD8⁺ T cell proliferation^[63-67] and reduced rejection and GVHD^[68-74]. Other than post-transplant, infusion of Treg cells before a transplant procedure is found to promote immune reconstitution and improve immunity to opportunistic infection, hence, preventing GVHD^[75]. By increasing NK cells by total lymphoid irradiation, the immune tolerance is induced after organ and HSC transplantation^[76]. A study suggests that the interaction of NK cells and Treg cells can promote immune tolerance. IL-4, which is secreted by NK cells, induces the expression of negative costimulatory molecules on the Treg cells^[77]. The purification of NK cells in allogeneic transplantation may be achieved by depleting CD3⁺ cells followed by CD56⁺ cell enrichment^[78]. Donors are also reported safe in completed clinical trials of NK cells infusion^[79-81]. Stimulated NK cells with IFN- γ , IL-2 and anti-CD3 show MHC-independent cytotoxicity effect and NK cells infusion is proven safe to use after autologous HSCT^[82]. The strategies of using immune cell infusion therapy have significantly increased the level of immune tolerance against allogeneic graft. New discoveries on Treg and NK cells administration posit that they appear to be effective in inducing transplant tolerance and rapid

immune reconstitution. This may help to induce a better protection of infection or cancer relapse and consequently reducing GVHD incidence.

GENETIC MARKERS

Immunologically compatible donor and recipient are determined by several genetic markers which include matching for ABO blood groups, HLA, MICA and KIRs (see preceding sections). These antigens are encoded by highly polymorphic and independent loci in our genome and are distributed differently between individuals and populations. Incompatibility between the donor and recipient for these antigens will lead to either allograft lost or GVHD. In the following sub-sections, we discuss the molecular bases for the genes encoded for the determinants of transplant compatibility.

ABO

The ABO is important blood group in transfusion and transplantation and consists of three antigens; A, B and O. These red cell antigens are determined by the ABO allelic variants (*A*, *B* and *O* alleles) on the long arm of chromosome 9. The co-dominant *A* and *B* alleles differ by four nucleotide substitutions (C526G, G703A, C796A and G803C) while the Δ 261G deletion differentiates between the recessive *O* and *A* alleles^[83-85]. The α 1,3-N-acetylgalactosaminyltransferase encoded by *A* allele and α 1,3-D-galactosyltransferase encoded by *B* alleles then convert H antigens, the products of *H* gene located on human chromosome 19 to either A or B antigens, respectively^[86]. In contrast, there is no enzymatic activity on H antigen for those bearing the *O* allele due to the Δ 261G deletion on the background of *O* allele. Thus, the A, B, O and AB phenotypes are determined by the three ABO allelic variants; *A*, *B* and *O* alleles.

HLA

The HLA class I molecules consist of a non-polymorphic β 2-microglobulin and a highly polymorphic α -chain glycoprotein encoded by the genes within MHC on the chromosome 6^[87-89]. There are three types of HLA class I molecules (*A*, *C* and *B*) with their specificities depend on the polymorphic α -chain encoded by *HLA-A*,

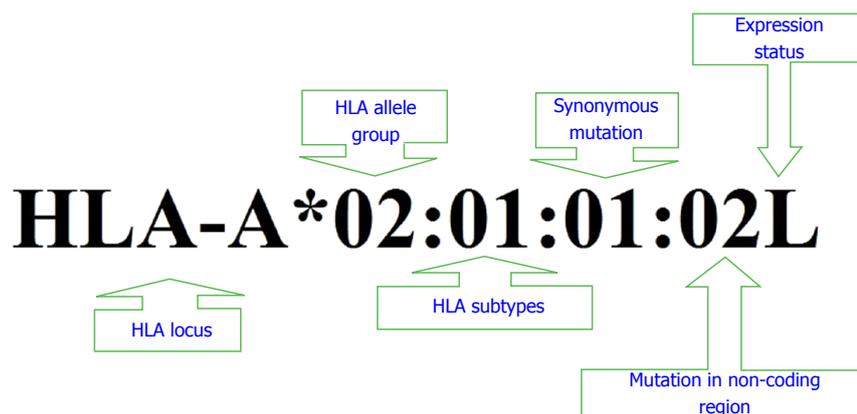

Figure 3 Systematic human leukocyte antigen nomenclature developed by the World Health Organization Nomenclature Committee for Factors of the human leukocyte antigen system. HLA: Human leukocyte antigen.

-B and -C genes in the classical class I sub-region of MHC^[90]. In contrast, both α - and β -chains of class II HLA molecules (DP, DQ and DR) are encoded by genes in the classical class II sub-region of MHC^[12] (Figure 2). The *HLA* class I and II gene clusters within MHC are separated by the class III sub-region which codes for complement components and not part of endogenous and exogenous peptide presentation to CD8⁺ and CD4⁺ cells, respectively^[91-93] (Figure 1).

The World Health Organization has developed an alphanumeric nomenclature to name *HLA* antigens, genes and alleles (Figure 3). This systematic alphanumeric nomenclature begins with letters representing specific *HLA* gene and followed by an asterisk and two sets of digits specific for *HLA* allele group and glycoprotein. Two additional sets of digits are then used to specify synonymous nucleotide changes and mutation outside the non-coding region, respectively. Suffixes (e.g., L: low cell surface expression, N: Null, C: Allele is expressed in cytoplasm but not on the cell surface and A: Aberrant expression) may be added to the end of this string of numbering system to indicate expression status of particular *HLA* alleles^[12,94].

MICA

The MICA molecules are stress induced antigens encoded by a gene within MHC region (Figure 2) and are expressed by a wide range of cells including monocytes, keratinocytes and fibroblasts^[14,87,95-97]. Unlike HLA class I molecule, MICA is not linked to β_2 -microglobulin and NK cells and CD8⁺ T ($\alpha\beta$ and $\gamma\delta$) cells reactivity are stimulated through interaction of MICA and its ligand, the NKG2D receptor^[13-15,98]. Variants of *MICA* gene are largely due to single nucleotide polymorphism and repeated units of alanine (*i.e.*, 4 to 10 Ala residues) in exons 2, 3 and 4 and exon 5, respectively^[99-102] (see González-Galarza *et al.*^[100] for the list of populations characterized for MICA). The diversity within *MICA* gene reflect its role in immunity and as a marker of tissue identity^[96,97].

KIR

The NK cells recognize healthy and unhealthy cells through either their lectin-like or immunoglobulin-like receptors encoded by NK and leukocyte receptor complexes located on human chromosome 12 and 19, respectively^[103,104]. The leukocyte receptor complex also code for KIRs, one of the highly polymorphic transmembrane glycoprotein receptors expressed by NK cells^[105,106]. Currently there are 16 *KIR* genes and more than 570 genotypes (combinations of haplotype A and B *KIR* genes - Table 2) and 600 alleles were documented in public databases^[99,100].

Each KIR is classified according to the number of their extracellular immunoglobulin (two and three domains and assigned as 2D and 3D, respectively) and the length of cytoplasmic (short and long and assigned as S and L, respectively) domains, respectively^[107]. The KIRs with short and long cytoplasmic domains are activating and inhibitory receptors and transduce their signals through DAP-12 and tyrosine-based motifs, respectively. The only exception is for KIR2DL4 which transmits both, inhibitory and stimulatory signals^[99]. The highly diverse and complex of KIRs were also reported for their ligands, the HLA class I molecules (Table 1) and both have significant influences in transplantation and pathogenesis of various diseases^[108].

COMPATIBILITY TESTING BETWEEN DONOR AND RECIPIENT

Typing of ABO and HLA, antibody screening and cross matching are three important procedures in determining the compatibility between donors and recipients. These procedures have been largely conducted using serological approaches (e.g., complement dependent cytotoxicity test, ELISA, Luminex and flow cytometric assays; see Howell *et al.*^[8] for details). Alloantibodies against the transplanted organs/cells are usually developed in highly transfused patients or due to previous transplantation and pregnancy. These are the three main

Table 2 Here are the examples of both, gene content and allelic variations of the genes code for killer cell immunoglobulin-like receptors

^{1,2,3}The haplotype A and B and framework KIR genes, respectively. The X indicates the absent of KIR genes/alleles.

events where individuals might be exposed to non-self antigens including the clinically important transplant antigens such as ABO antigens, HLA and MICA. Thus, antibody screening and cross matching are crucial to avoid allograft lost. Nowadays, molecular typing techniques such as those using sequence specific oligonucleotide primer, and Sanger sequencing have largely been used for genotyping of ABO, HLA and MICA and KIR genes. These molecular techniques have several advantages as they are not dependent on the availability of anti-sera, cellular expression and have greater specificity and accuracy as compared with the antibody-antigen based typing (recently reviewed by Howell *et al.*^[8], Dunn^[109] and Edinur *et al.*^[110]).

FUTURE DEVELOPMENTS AND CONCLUDING REMARKS

Advances in the field of molecular biology and genetics have contributed immense benefits to the medical field including in transplantation medicine. A number of molecular techniques have been developed following the elucidation of molecular bases of the genes encoding for transplant determinants. Currently, several different genotyping platforms can be used to screen blood group, HLA, MICA, and KIR loci (see Howell *et al.*^[8], Dunn^[109], Edinur *et al.*^[110] and Finning *et al.*^[111]). It is now possible to genotype multiple markers and to the extent of complete sequencing of human genome using the next generation sequencer (NGS). This high throughput genotyping platform has been tested for HLA (e.g., see Bentley *et al.*^[112], Holcomb *et al.*^[113], Wang *et al.*^[114] and Skibola *et al.*^[115]) and it is expected that NGS will be used to simultaneously genotype large number of clinically relevant transplantation genes in near

future. This is not far from reality due to bioinformatics support given by the immunogenetics community and the rigorous improvement in NGS methodology (see Robinson *et al.*^[94] and Grada *et al.*^[116]). In addition, new developments in immune tolerance based therapy, donor recruitment strategies and bioengineering (tissue engineering and regenerative medicine) will provide significant advances in the field of transplantation medicine. This paper provides only brief discussions of these new developments, while others^[20,46,110,117,118] have conducted systematic reviews of them.

Hemodynamic monitoring in heart failure and pulmonary hypertension: From analog tracings to the digital age

Ryan Davey, Amresh Raina

Ryan Davey, Amresh Raina, Cardiovascular Institute, Allegheny General Hospital, Pittsburgh, PA 15212-4772, United States

Author contributions: Both authors contributed equally to this work with regards to article conception, writing and final editing of the manuscript.

Conflict-of-interest statement: Dr. Davey has no relevant financial relationships; Dr. Raina is a consultant for St. Jude's Medical.

Open-Access: This article is an open-access article which was selected by an in-house editor and fully peer-reviewed by external reviewers. It is distributed in accordance with the Creative Commons Attribution Non Commercial (CC BY-NC 4.0) license, which permits others to distribute, remix, adapt, build upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited and the use is non-commercial. Abstract

Hemodynamic monitoring has long formed the corners-

tone of heart failure (HF) and pulmonary hypertension diagnosis and management. We review the long history of invasive hemodynamic monitors initially using pulmonary artery (PA) pressure catheters in the hospital setting, to evaluating the utility of a number of implantable devices that can allow for ambulatory determination of intracardiac pressures. Although the use of indwelling PA catheters has fallen out of favor in a number of settings, implantable devices have afforded clinicians an opportunity for objective determination of a patient's volume status and pulmonary pressures. Some devices, such as the CardioMEMS and thoracic impedance monitors present as part of implantable cardiac defibrillators, are supported by a body of evidence which show the potential to reduce HF related morbidity and have received regulatory approval, whereas other devices have failed to show benefit and, in some cases, harm. Clearly these devices can convey a considerable amount of information and clinicians should start to familiarize themselves with their use and expect further development and refinement in the future.

INTRODUCTION

Heart failure (HF) is an increasingly prevalent disease affecting, by some estimates, over 23 million people worldwide^[1]. It is a clinical syndrome characterized by the inability of the heart to adequately provide effective net forward blood flow, either due to left ventricular systolic dysfunction (heart failure with reduced ejection fraction or HFrEF), as a result of left ventricular diastolic dysfunction and/or valvular disease (heart failure with preserved ejection fraction or HFpEF), or due to right sided HF related to pulmonary arterial hypertension (PAH) or primary right ventricular (RV) dysfunction. This may result in both acute and chronic volume overloaded states, poor end organ perfusion and significant morbidity and mortality. In the United States, HF is the most common cause for hospitalizations in those over age 65 with over 1 million admissions per year^[2]. Despite improvements in contemporary medical therapy for HFrEF, long term morbidity and mortality remain unacceptable and 30-d rehospitalization rates remain roughly 23%^[3]. For HFpEF patients, there is still no disease modifying therapy which has been shown to improve survival in randomized clinical trials^[4].

PAH is a far rarer condition affecting perhaps 52 out of one million in the population at any given time^[5]. However, it is a progressive and insidious disease characterized by remodeling of the pulmonary arterial tree, associated with endothelial dysfunction, vascular smooth muscle hypertrophy, and vasoconstriction^[6]. The gradual rise in RV afterload leads to compensatory RV hypertrophy and dilatation, but if left untreated, culminates in RV dysfunction, fall in cardiac output and clinical symptoms^[7].

The right heart catheter (RHC) has long been considered the gold standard for the diagnosis of PAH and also for monitoring disease progression. It has also been shown to be effective in determining the etiology of patients in shock, and hemodynamic parameters obtained from RHC have prognostic utility in HF patients. Moreover, in selected patients with advanced HF, there may be a role for hemodynamically tailored HF therapy with use of an indwelling Swan-Ganz catheter in the intensive care unit, though this approach has not been associated with superior survival^[8,9].

Standard RHC does, however, have significant limi-

tations and over the past two decades, a number of newer implantable hemodynamic monitors (IHMs) have been developed for use in HF patients. The increasing adoption of IHM in HF and PAH patients may afford new opportunities for improving clinical outcomes in these disease states and thus forms the subject of this review.

HISTORY AND LIMITATIONS OF THE RHC

The RHC was first developed by Forssmann *et al*^[10] in 1929 after experimenting on himself to find a way to both measure intra-cardiac pressures and deliver therapies^[10]. After further pulmonary artery (PA) catheter development and refinement by Drs. Swan and Ganz in 1970, it gained widespread use in the management of advanced HF and shock despite relatively limited evidence regarding its efficacy in reducing deleterious clinical outcomes.

Though it is an invasive procedure, RHC has since become recognized as safe with a relatively low rate of complications, especially when performed in referral centers^[11]. However RHC has a variety of limitations, many of which are inherent to the RHC procedure and its associated technology.

In general, at most centers RHC is performed in the supine position at rest, and the catheter does not lend itself well to either ambulatory or frequent measurements outside of an inpatient setting. Indeed, even in-hospital readings must be taken in a meticulous fashion to avoid the issues inherent to the procedure such as respiratory variation in pressures and inappropriate pressure transducer placement and zeroing.

In an effort to limit variation and standardize measurements from a PA catheter, many centers take readings at end-expiration and with the patient supine which, while allowing for reproducibility, is likely not an entirely accurate physiologic assessment of the patient's hemodynamics during their day to day activities^[12].

The Swan-Ganz catheter, in part due to its perceived safety, was widely adopted in a number of clinical scenarios and as a result, a number of significant associated adverse events were reported^[8]. Therefore, the ESCAPE trial was undertaken to assess the value of PA catheterization in HF patients. Published in 2005, ESCAPE showed that the routine use of PA catheterization for patients admitted with HF was not associated with a significantly decreased length of stay, due in part to an increased infection risk; however, its applicability to disease states such as overt cardiogenic shock has not been shown^[9] and such patients were, in large part, excluded from ESCAPE.

IHM AND HF MANAGEMENT

Although the indwelling PA catheter has fallen out of favor with clinicians for uncomplicated HF, the overall

goal of accurate and reproducible hemodynamic monitoring to assess volume status, filling pressures and cardiac output remains very valuable in preventing adverse events in this group, including hospital readmissions. As a part of the Affordable Care Act in the United States, the Centers for Medicare and Medicaid Services has identified HF as a disease state warranting readmission measures and the assessment of penalties are to begin in 2016 for readmission rates deemed to be in excess of the national average^[13].

With a view to managing volume in the ambulatory setting, a number of different IHMs have been developed. Perhaps the most frequently used at present are those devices that measure thoracic impedance *via* the RV lead on an implanted cardiac defibrillation or cardiac resynchronization device. Specifically, these devices attempt to gauge the degree of pulmonary congestion by measuring the resistance to flow of a current passed across the lung. Since tissue will conduct current more readily with increasing amounts of fluid, impedance will drop as a patient's volume status expands. In clinical practice, this is usually reported by the device using an algorithm that indexes these values and can signal the clinician of an abnormal trend upon device interrogation. The FAST study showed that decrements in thoracic impedance were more closely correlated with negative HF endpoints than standard home weight monitoring^[14] but these readings have proved difficult for clinicians to incorporate in clinical practice^[15].

Other IHM devices have targeted intravascular pressures directly with a view to increasing sensitivity and applicability to clinical practice. The first of these devices used a diaphragm-tipped pressure catheter that would be passively placed in a vascular structure. In the case of the Medtronic Chronicle device, a generator was implanted subcutaneously and attached to a lead with its electrode tip placed subcutaneously in the RV by passive fixation. This allowed for remote measurement of RV systolic and diastolic pressure, imputed PA diastolic pressure, heart rate, activity, RV dp/dt, and core body temperature^[16]. The HeartPOD was a device from St Jude Medical deployed *via* a femoral venous approach and then crossing the intra-atrial septum to sit directly in the left atrium. An antenna coil could then be subcutaneously implanted in the femoral region or reflected back into a superior venous position^[17].

COMPASS-HF^[18] was a single-blinded prospective study designed to use the Chronicle device in patients with HFpEF and HFrEF and tailor medical therapy based either on standard assessments alone (control arm) or with the use of the device data. They randomized a total of 274 patients and although the primary endpoint of HF-related events, including hospitalizations and urgent clinic visits, decreased by 21% it failed to reach statistical significance. The device was not granted FDA approval and so did not reach market.

The initial study HeartPOD study^[19] showed promise but the follow-up study LAPTOP-HF was terminated

early for safety reasons due to procedural complications related to the required trans-septal puncture.

More recently, the CardioMEMS device from St Jude was studied in the CHAMPION trial^[20]. This was a multi-center, single-blind, prospective trial which enrolled 550 patients total to both arms and, similarly to previous studies, both HFpEF and HFrEF were included. As with previous studies, medical therapies in the treatment arm were guided by the use of the PA pressures provided by the device. Patients were followed for a mean of 15 mo. The primary endpoint was HF related hospitalizations and this was significantly reduced by 37% with minimal device-related adverse events (1.4%) and 100% device reliability. Follow-up data showing open-access to the PA pressures reported by the device led to a 48% readmission rate reduction in the former control group and, in patients who had repeat RHC, the mean difference in the mean PA pressure between the device and direct invasive measurement was 1 mmHg^[21].

Unlike the aforementioned devices, the CardioMEMS device is a percutaneously delivered pressure sensor that is placed in a PA branch and interrogated *via* a wireless detection system which can then be remotely reviewed by clinicians in close to real-time *via* upload to a website (Figures 1 and 2). This has the benefit to the clinician of understanding a patient's ambulatory right-sided pressures and, by extension, volume status in a format similar to RHC. In addition, this device did not have a percutaneous lead or generator that was prone to failure or infection and could last for the life of the patient. These factors and the success of the CHAMPION trial led to the approval of the device by the FDA in order to reduce hospitalizations in HF patients.

There may also be a role for IHMs in the risk stratification of patients requiring advanced HF therapies including left ventricular assist device (LVAD) implantation and transplantation. Data from the CHAMPION trial showed that treatment group progressed faster to LVAD therapy (167 d vs 266 d), had faster declines in PA pressures and ultimately, a quicker bridge to cardiac transplantation (177 d vs 370 d)^[22]. Furthermore, the CardioMEMS device may provide a way to monitor exercise responsiveness in patients with LVAD implants^[23] and could provide a novel way to measure PA pressure in those with total artificial hearts (TAH) whose PA pressures were not previously measurable due to the inherent limitations of the TAH implant.

IHMS AND PULMONARY HYPERTENSION MANAGEMENT

Although neither the Medtronic Chronicle nor the CardioMEMS device were expressly designed for the management of PAH, ongoing knowledge of a patient's PA pressures in this disease might be extremely valuable, especially if an estimate of cardiac output could be derived from the sensor to calculate total pulmonary

resistance. With regard to therapeutic interventions in PAH, the device could allow for guided up and down titration of therapy and thus prevent the sequelae of RV failure or high cardiac output states *via* direct measurement of these parameters. It could also give some insight into those patients with medication compliance issues. There have been several case series that have been conducted to investigate the role of these monitors in guiding PH therapies.

The Chronicle device was studied in 5 patients with PAH who were prescribed iloprost - a prostacyclin analog - *via* an inhaled, aerosolized delivery. The device clearly demonstrated a drop in RV systolic pressures in the immediate post-inhalation period and importantly showed that the duration of drug effect was much shorter than was expected^[24]. The authors postulated that patients who were at rest during the delivery of the drug may even have a more pronounced pressure lowering and indeed, further study with iloprost and IHMs showed that in fact, with exercise, there was a significantly blunted pressure lowering effect^[25]. The Chronicle device also identified 13 out of 15 PAH

patients who had a greater than 30 m decrease in 6 min walk distance on the basis of improvement in pressure measurements^[26].

The CardioMEMS device is currently being studied in PAH as part of an NHLBI funded pilot study in PAH. This is a single center study investigating long-term pressure measurements and titration of therapy based on device interpretations. Early data has shown that instead of titrating to a pre-specified, protocolled dose of parenteral prostacyclin, IHM-guided therapy has allowed for early recognition of optimal dosing. As compared with standard therapy, this has allowed for enhanced cost savings due to lower drug dosing (in one case, approximately United States \$ 29000 was saved), minimization of prostacyclin-related side effects, and decreased risk associated with repeat RHC izations^[27].

CONCLUSION

Ambulatory hemodynamic monitoring in HF and PAH is clearly still developing but the use of these devices is being gradually expanded outside the traditional role of

fluid management in HFREF. As we gain more experience with the current generation of devices such as the CardioMEMS IHM in clinical practice, device design will continue to evolve and already a variety of even more sophisticated sensors are under development.

As the CardioMEMs sensor continues to be evaluated in the management of PAH, IHMs hold the promise of a more precise and accurate titration of medical therapies and may also allow for determining which patients are at higher risk of adverse events, thus allowing for earlier and more aggressive interventions.

Clinicians should eagerly await and critically scrutinize data from forthcoming studies looking at expanding roles for these devices.

Abstract

Kidney transplantation is recognised as the most effective treatment for patients with end-stage renal disease (ESRD). Kidney transplantation continues to face

several challenges including long-term graft and patient survival, and the side effects of immunosuppressive therapy. The tendency in kidney transplantation is to avoid the side effects of immunosuppressants and induce immune tolerance. Regulatory T-cells (Tregs) contribute to self-tolerance, tolerance to alloantigen and transplant tolerance, mainly by suppressing the activation and function of reactive effector T-cells. Additionally, Tregs are implicated in the pathogenesis of diabetes, which is the leading cause of ESRD, suggesting that these cells play a role both in the pathogenesis of chronic kidney disease and the induction of transplant tolerance. Several strategies to achieve immunological tolerance to grafts have been tested experimentally, and include combinations of co-stimulatory blockade pathways, T-cell depletion, *in vivo* Treg-induction and/or infusion of *ex-vivo* expanded Tregs. However, a successful regimen that induces transplant tolerance is not yet available for clinical application. This review brings together certain key studies on the role of Tregs in ESRD, diabetes and kidney transplantation, only to emphasize that many more studies are needed to elucidate the clinical significance and the therapeutic applications of Tregs.

INTRODUCTION

Immunological self-tolerance in the periphery is achieved by the negative regulation exerted on the immune response by a variety of cells of which the best characterized populations are the regulatory T cells (Tregs)^[1]. Tregs mediate self-tolerance and tolerance to alloantigens by suppressing the activation of effector T-cells (Teffs), and exerting anti-inflammatory activity^[2]. Of Tregs the best characterized and studied cells are the CD4⁺CD25⁺Foxp3⁺ Tregs, especially in the context of autoimmune diseases and organ transplantation^[2,3].

Kidney transplantation is considered the most effective therapy for end-stage renal disease (ESRD); however, a major unresolved challenge is to avoid the side effects of immunosuppression by inducing immune tolerance^[4]. Transplant tolerance has been defined as graft acceptance without long-term use of immunosuppressive drugs^[5]. Transplant tolerance is characterized by decreased alloreactive Teffs and increased Treg count in grafts and associated lymphoid tissues in the periphery^[4].

Diabetic nephropathy is the leading cause of ESRD^[6]. Diabetes type I is a chronic autoimmune disease^[7] and Tregs have been implicated in the pathogenesis of insulin resistance^[8]. On the other hand, in a model of murine diabetes, adoptive transfer of Tregs improved insulin resistance and diabetic nephropathy^[8], suggesting a complicated relationship between Tregs, diabetes and kidney transplantation^[8,9].

Several strategies to achieve immunological tolerance to grafts have been tested experimentally, and include combinations of co-stimulatory blockade pathways, T-cell depletion, *in vivo* Treg-induction and/or infusion of *ex vivo* expanded Tregs^[5,10]. However, a successful regimen that induces transplant tolerance is not yet available for clinical application.

TREGS

Several subsets of regulatory or tolerogenic cells have been characterized or partially characterized so far.

In the 1970s, Gershon *et al.*^[11] reported that a subset of T-cells called "suppressor cells" might exhibit suppressive activity. In recent years, the term "suppressor T-cells" was replaced by the term "Tregs". In 1995, Sakaguchi *et al.*^[12] reported that a subset of CD4⁺CD25⁺ T-cells exhibit regulatory functions *in vitro* and *in vivo*. In addition, Piccirillo *et al.*^[13] observed that murine CD4⁺CD25⁺ T-cells suppress the proliferation of CD4⁺ or CD8⁺ Teffs *in vitro*^[13]. Subsequently, Dieckmann *et al.*^[14] identified a similar population of T-cells in humans. These cells play an important role in autoimmunity, allergy, inflammation, maintenance of

maternal tolerance to the foetus, infections and cancer. In 2002, Graca *et al.*^[15] reported that the presence of Tregs mediated transplant tolerance. In addition, the authors observed that Tregs in tolerant skin grafts transfer transplant tolerance to fresh skin allografts if re-transplanted into naive recipients^[15]. In 2007, Lair *et al.*^[16] reported that in a rat heart transplant model, long-term survival is achieved in rat recipients by pre-graft donor-specific blood transfusion that resulted in splenic Tregs that were not only able and sufficient to mediate graft tolerance, but were also able to transfer long-term survival to naive recipients.

Tregs include natural (n)Tregs that are generated in the thymus and inducible (iTregs) that are generated in the periphery. nTregs arise in the thymus and express the forkhead/winged helix transcription factor Foxp3 that, in turn, controls nTreg differentiation^[4]. iTregs arise in the periphery from memory and naive CD4⁺ Teffs following stimulation by self- or allo-antigens in the presence of IL-4, IL-10, TGF- β and IL-2. iTregs may or may not express the transcription factor Foxp3, and exert their suppressive activity mainly *via* the secretion of anti-inflammatory cytokines, mainly TGF- β and IL-10^[17,18]. TGF- β induces the expression of Foxp3, converting CD4⁺CD25⁻ naive Teffs to Tregs in the periphery. nTregs are antigen non-specific, while iTregs are usually antigen-specific^[17,18].

iTregs are further subdivided into Tr1 cells that mainly secrete IL-10 and Th3 cells that mainly secrete TGF- β . Both iTreg types inhibit the maturation of dendritic cells (DCs) and the activation and proliferation of both memory and naive Teffs^[18].

Regulation of Tregs

A well-studied regulator of Tregs at the molecular level is the transcription factor Foxp3, the expression of which is critical for their development and function^[19-21]. Data from animal studies have provided evidence that Foxp3 deficiency causes loss of Treg suppressive activity leading to the development of a lethal autoimmune syndrome^[5]. In accordance, adoptive transfer of CD4⁺CD25⁺Foxp3⁺ T-cells from wild-type mice can prevent the development of severe autoimmune diseases observed in Foxp3-deficient mice^[5]. In humans, Foxp3 deficiency has been associated with immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome^[22-24].

Both DNA and histone protein modifications are implicated in the epigenetic regulation of Foxp3^[25]. Regarding DNA modifications, the methylation status of cytosine at cytosine-phosphate diester-guanine sites in the locus of Foxp3 influences its expression^[25].

Histone modifications entail the acetylation of lysine residues at the amino terminus of the histone tail, inducing *Foxp3* gene expression. Interestingly, these epigenetic regulators can be used to enhance the function and number of Tregs, for potential therapeutic applications^[26].

Suppressive mechanisms of Tregs

Tregs express the T-cell receptor and may suppress innate and adaptive immune responses^[4]. Tregs exert a cell-cell contact-dependent suppression, and they also exert suppressive activity mediated by cytokines, mainly IL-10 and TGF- β ^[27,28]. Tregs can block Teffs at any stage of their activation, proliferation, differentiation and effector functions^[5,28,29].

Tregs suppress the activation of antigen presenting cells (APCs) through the expression of membrane-associated inhibitory molecules such as the cytotoxic T lymphocyte antigen 4 (CTLA4) and lymphocyte activation gene-3, a CD4-related trans-membrane protein that binds HLA II on APCs (DCs in particular) and inhibits their activation and the ensuing antigen presentation^[30].

In addition, Tregs induce the apoptosis of target cells by producing several cytolytic molecules such as granzymes A and B, perforin and galectin 1^[5]. Tregs also exert suppressive activity by causing metabolic disruption of Teffs through IL-2 consumption (IL-2 is an essential growth factor for naive Teffs), suppression of cyclic adenosine monophosphate synthesis, and inhibition of the CD39-CD73 pathway^[28,31]. Specifically, CD39 hydrolyzes ATP or ADP to AMP. CD39 is a dominant ectoenzyme expressed by Tregs. Catalytic inactivation of extracellular ATP by CD39 can be considered as an additional anti-inflammatory mechanism mediated by Tregs. Co-expression of CD39 and CD73 generates pericellular adenosine. Adenosine is an inhibitor of T-cell responses and exerts its effect *via* binding to the A2A receptor^[28,31].

Wu *et al.*^[32] reported that the suppressive function of Tregs is mediated through a complex formed by the transcription factors NFAT and Foxp3, whereas in Teffs, NFAT forms a complex with the activator protein-1 (AP-1). The authors suggested that a strategy to induce tolerance is to inhibit the NFAT:AP-1 interaction by small molecules, without interfering with the NFAT:FoxP3 interaction.

The recent finding that NFAT is a common regulator for both Teffs and Tregs^[32,33], indicate that NFAT is an essential transcription factor for the functional integrity of both populations^[32,33]. Therefore, immunosuppressive drugs targeting NFAT activity in stimulated T-cells, such as calcineurin inhibitors, may also suppress the activity of Tregs.

Both nTregs and iTregs also suppress B cell activation and the ensuing antibody production^[34]. It has been reported that nTregs kill B cells directly by secreting perforin and granzyme B, whereas iTregs inhibit B-cell activation through the secretion of IL-10 and TGF- β ^[35].

Site of action of Tregs

In the setting of autoimmune diseases, Tregs are activated in the draining lymph nodes to prevent priming and clonal expansion of autoreactive Teffs; they then migrate to the inflamed tissues, exerting their suppressive activity in the periphery^[36].

In the setting of transplantation, Treg migration to the graft is required to prevent graft rejection. Early trafficking of Tregs to the graft prevents the exit of donor-derived DCs to the drained lymph nodes, decreasing thus the extent of alloimmune priming^[10].

TREGS AND DIABETIC NEPHROPATHY

Diabetes is one of the major causes of ESRD^[6]. Type 1 diabetes (T1D) has been described as a chronic autoimmune disease due to T-cell mediated destruction of pancreatic β -islets leading to insulin deficiency^[7]. Data from experimental studies indicate that Treg cells are involved in the pathogenesis of T1D^[37-39].

It is not clear whether the peripheral blood count of CD4⁺CD25⁺ Foxp3 Tregs is altered in T1D patients^[40]. Jailwala *et al.*^[41] reported that the frequency of Tregs in T1D patients is not altered but that these cells have an increased sensitivity to apoptosis. Studies in non-obese diabetic (NOD) mice showed that depletion of CD4⁺CD25⁺ T-cells, leads to T1D development^[42]; in addition, abolishment of the CD28 and ICOS co-stimulatory pathways, that are critical for Treg homeostasis and function, exacerbate T1D^[43]. Also in NOD mice, T1D progression is linked with a reduction in Treg number and suppressive activity in the inflamed pancreatic islets, together with a diminished IL-2 production by Teffs. In addition, Tregs may lose Foxp3 expression with concomitant loss of their suppressive activity during T1D progression^[37].

Although type 2 diabetes is considered to be a metabolic disorder with no autoimmune etiology, recently an adiposity-associated chronic inflammation process mediated by immune mediators has been proposed as an underlying mechanism of this disease^[44-46]. Interactions between metabolic disorders, hemodynamic changes, oxidative stress, inflammation and genetic predisposition, seem to contribute to the pathogenesis of diabetes and diabetic nephropathy. Interestingly, an increased expression of CD4⁺CD25⁺Foxp3 cells has been revealed in type 2 diabetic patients with micro and macroalbuminuria^[47,48] suggesting a potential link between Tregs and disease progression. However, the relationship between CD4⁺CD25⁺Foxp3 Tregs and type-2 diabetic nephropathy is not well studied. In the db/db mouse with type 2 diabetes, CD4⁺CD25⁺Foxp3 Treg depletion with anti-CD25 monoclonal antibody, enhanced insulin resistance, albuminuria and glomerular hyperfiltration^[8]. Adoptive transfer of CD4⁺CD25⁺Foxp3 Tregs increased FoxP3 mRNA synthesis in the recipients and improved insulin sensitivity and type 2 diabetic nephropathy^[8].

TREGS AND KIDNEY TRANSPLANTATION

Tregs in transplantation tolerance and acute rejection

A large body of evidence supports the notion that CD4⁺CD25⁺Foxp3⁺ Tregs play a fundamental role in the establishment and maintenance of operational tolerance

Table 1 Regulatory cells in humans

Cell	Phenotype	Properties	Ref.
T-cells (Treg)	CD4 ⁺ CD25 ⁺ CD4 ⁺ CD25 ⁺ FoxP3 ⁺ CD4 ⁺ CD25 ⁺ CD127 ^{low} CD4 ⁺ CD45RO ⁺ CD8 ⁺ CD28 ⁺ CD8 ⁺ CD28 ⁺ (FoxP3 ⁺)	Secrete mainly IL-10 and TGF-β; some secrete IL-35 or IFN-γ Secrete mainly IL-10 but also TGF-β, IFN-γ, CCL4; downregulate APC or DC maturation; direct killing of CD4 ⁺ Teffs and APCs	[1-4,17,77-79] [80]
	CTLA-4	Mainly inhibition of Teffs	[81]
	CD4 ⁺ CD8 ⁺ TCRαβ ⁺	Suppress antigen-specific T-cells; secrete mainly IFN-γ but also IL-4	[82]
	TCRγδ ⁺	Secrete IL-10, TGF-β, IL-4	[83]
T-cells or monocytes	HLA-G	Secrete IL-10, IL-35, TGF-β, soluble HLA-G	[84,85]
iNKT	CD3 ⁺ CD16 ⁺ CD56 ⁺	Can secrete IFN-γ ± IL-4 ± IL-10 ± TGF-γ, direct killing of target cells	[86]
B-cells (Breg)	CD19/20 ⁺ , CD80/86 ⁺ , CD40 ⁺ , TLR4 ⁺ , mainly IgG and IgA BCR	Secrete IL-10 and IL-35, induce Tregs, downregulate DC maturation	[87]
tDC	PD-L1/L2 ⁺ , FasL ⁺	Secrete IL-10 and TGF-β; downregulate Teff activation	[88]

APC: Antigen presenting cell; DC: Dendritic cell; BCR: B-cell receptor; tDC: Tolerogenic dendritic cells; iNKT: Natural killer T regulatory cells; TGF: Transforming growth factor; IL: Interleukin; IFN: Interferon; HLA-G: Human leukocyte antigen-G; CTLA-4: Cytotoxic T lymphocyte-associated antigen 4.

to renal allografts^[15,49].

In animal models of transplantation, Tregs were present in tolerant allografts and were shown to migrate to the allograft tissue^[15,50]. It was also shown that Tregs, induced *in vitro*, *in vivo* or expanded *ex vivo* after alloantigen stimulation, promoted transplant tolerance to the allograft^[16,51-54].

Salama *et al.*^[55] were the first to demonstrate the existence of antigen-specific Tregs capable of suppressing alloresponses to donor HLA peptides in human kidney transplant recipients. In accordance, data from renal liver and lung transplantation in humans showed a high number of circulating and intragraft Tregs in tolerant stable recipients^[56-59]. On the other hand, recruitment of Tregs into the graft, as part of an allogeneic inflammatory response, suggests a role for Tregs in immune-mediated graft injury^[60].

Reports on the clinical and prognostic significance of Foxp3⁺ cell infiltrates in renal allograft recipients with acute rejection are contradictory^[61]. Muthukumar

et al.^[62] reported that renal transplant patients with an acute rejection episode expressed high levels of Foxp3 mRNA in the urine, and that the lower levels of Foxp3 were associated with a poorer response to anti-rejection therapy, postulating that this could be a future non-invasive marker for the level of renal graft function. Bunnag *et al.*^[63] reported that Foxp3 expression in human kidney biopsies was linked to rejection and did not correlate with a favourable outcome. In accordance, data from studies that used Foxp3 analysis from graft biopsy cores, have demonstrated a higher Foxp3 expression in the allografts with acute rejection in comparison with stable renal allografts or with those displaying antibody-mediated rejection^[64,65]. It should be emphasized that these studies did not report any potential benefit of Foxp3-enriched infiltrate on renal allografts outcome, or even associated the level of *in situ* Foxp3 expression with tubulitis, higher scarring scores and worse prognosis of renal allografts survival^[61]. Contradictory, in the context of lower graft inflammation such as borderline changes and subclinical episodes of acute rejection, it seems that Treg-enriched graft infiltrate has a protective role in interstitial inflammation and graft function^[66-68]. Data from protocol biopsies in recipients with episodes of subclinical cellular rejection, reported a correlation of low Foxp3/CD3 ratio with a poor graft function up to five years post-transplantation^[67,68].

Tregs in chronic allograft nephropathy

The number of CD4⁺CD25⁺Foxp3⁺ Tregs usually decreases after transplantation. Renal transplant recipients with chronic rejection have a lower number of peripheral CD4⁺CD25⁺Foxp3⁺ Tregs compared to those with stable renal graft function^[69,70]. In accordance, Al-Wedaie *et al.*^[71] reported a decreased count of CD4⁺CD25⁺ Tregs in the blood of renal allograft recipients with chronic rejection.

A decreased synthesis of Foxp3 mRNA in renal recipients with chronic rejection has been reported in comparison to stable or operationally tolerant renal allograft recipients or healthy controls^[69,70]. On the other hand, an increased frequency of infiltrating Foxp3⁺ T-cells in renal grafts with chronic rejection and poor graft function has been reported^[57,72]. It can be hypothesized that higher numbers of Tregs reflect an effort to suppress the immune response at the site of inflammation.

Interestingly, Ashton-Chess *et al.*^[73] reported that the expression of Foxp3 both in blood and renal graft did not distinguish rejecting from non-rejecting renal recipients. The authors suggested that Foxp3 expression does not correlate with rejection but it depends on the time post-transplantation and the age of the patients.

An important issue that needs to be addressed is whether Tregs in renal allograft recipients have a normal suppressive capacity. Data from several studies on the development of chronic rejection have shown a quantitative defect of Tregs whereas data from other studies a functional deficit of Tregs^[61,74]. Given that

immunosuppressive drugs can have detrimental effects on the number^[74], induction, function and survival of Tregs, the answer to this question is difficult because all the renal allograft recipients enrolled in these studies were on double or triple immunosuppressive regimens. Thus it could be assumed that the decreased number of Tregs or their functional deficit reported in recipients with chronic rejection was partially due to the effect of immunosuppression.

In addition, Tregs may contribute to chronic allograft nephropathy through new onset post-transplant diabetes, hypertension^[75] and hyperlipidemia^[76], but these hypotheses need to be explored in experimental models and in the clinic.

CONCLUSION

Regarding the entire spectrum of studies on chronic kidney disease and renal transplantation, Tregs are clearly implicated both in the pathogenesis of diabetic nephropathy and in the induction of transplant tolerance. Nevertheless, up to date, a relatively small number of clinical and experimental studies have explored the mechanism of Treg involvement in diabetic nephropathy. In addition, although a large body of evidence implicates Tregs in the immune mechanisms of acute and chronic rejection, their exact role remains unclear. The therapeutic potential of Tregs in kidney transplantation is promising but challenging for human patients. More studies are needed to elucidate the clinical significance and the therapeutic applications of Tregs and, also, of all the emerging types of regulatory and tolerogenic cells (Table 1) in kidney diseases and transplantation.

Abstract

For a long time, it was considered medical malpractice to neglect the blood group system during transplantation. Because there are far more patients waiting for organs than organs available, a variety of attempts have been made to transplant ABO-incompatible (ABOi) grafts. Improvements in ABOi graft survival rates have been achieved with immunosuppression regimens and plasma treatment procedures. Nevertheless, some grafts are rejected early after ABOi living donor liver transplantation (LDLT) due to antibody mediated rejection or later biliary complications that affect the quality of life. Therefore, the ABOi LDLT is an option only for emergency situations, and it requires careful planning. This review compares the treatment possibilities and their effect on the patients' graft outcome from 2010 to the present. We compared 11 transplant center regimens and their outcomes. The best improvement, next to plasma treatment procedures, has been reached with the prophylactic use of rituximab more than one week before ABOi LDLT. Unfortunately, no standardized treatment protocols are available. Each center treats its patients with its own scheme. Nevertheless, the transplant results are homogeneous. Due to refined treatment strategies, ABOi LDLT is a feasible option today and almost free of severe complications.

Key words: Living-donor liver transplantation; ABO-incompatible; Rituximab; Desensitization; Iso-titer; Biliary complications

Core tip: Due to refined treatment strategies, ABO-incompatible living donor liver transplantation (ABOi LDLT) is a feasible option today and almost free from severe complications, but biliary complications still affect the quality of life after ABOi LDLT. Until now, the best improvement could be reached with the prophylactic

use of rituximab more than one week before AB0i LDLT.

INTRODUCTION

Blood group antigens are expressed in almost every cell in the body, and an individual develops antibodies against blood group antigens (anti-A/B antibodies) absent in his or her own tissue. Grafts expressing foreign A/B antigens are usually hyperacutely rejected^[1]. For a long time, it was considered medical malpractice to neglect the blood group system during cadaveric transplantation. Because there are far more patients waiting for organs than organs available, a variety of attempts have been made to transplant AB0-incompatible (AB0i) grafts. Most AB0i liver transplantations (AB0i LTs) have had a lower graft survival rate due to hepatic arterial thrombosis, various biliary complications or acute rejection episodes^[2-4]. In those rejection episodes, the graft was damaged by necrosis or disseminated intravascular coagulopathy^[4,5]. This susceptibility to rejection can be explained sufficiently by blood group antigens that are expressed on the vascular endothelium and in large bile ducts for up to 150 d after transplantation^[6-10].

Young children with an incompletely developed immune system seem to be an exception. In 1979, Starzl's group reported eleven human AB0i LTs without evidence of acute rejection after transplantation^[11].

Because AB0i LTs need a certain amount of prearrangement, we focus in this review on AB0i living donor liver transplantation (LDLT), which is conducted electively, and neglect cadaveric AB0i LT.

In Western Europe and the United States, few case reports of AB0i LDLT exist, even though new techniques are available to overcome the blood group barrier^[6,12-17]. In Asia, Japan and South Korea, elective AB0i LDLT is performed with excellent results. Due to religious beliefs, fewer organs of deceased individuals are donated, and AB0i LDLT has become well established^[18,19]. Patients demonstrate survival with an AB0i graft for nearly as long as patients with an AB0-compatible (AB0c) graft^[18-21]. Improvements in AB0i graft survival rates have been achieved with immunosuppression and plasma treatment procedures (PTPs). The antibody titer (iso-titer) level cannot explain all clinical findings. However, hyperacute or acute antibody-mediated rejection (AMR) is closely related to hepatic necrosis or intrahepatic biliary complications^[22]. Additionally, patients with a history of immunizations are at higher risk for AMR. Blood group incompatibility, recipient age, etiology of liver disease and transplant era were found

to be significant predictors of overall survival, too^[23].

Various treatment protocols have been used for iso-titer elimination in AB0i LDLT patients. They originate from AB0i kidney transplantation protocols and do not follow a common standard. The iso-titer itself has also not been standardized. The results as well as its interpretation depend on the examining laboratory. Therefore, this review compares several treatment possibilities and their effect on graft outcome from 2010 to the present.

INDICATIONS FOR AB0i LDLT WITH SPECIAL REFLEXIONS

Pediatrics

The younger the child, the fewer iso-titers have been developed. In the first month of life, children are able to tolerate an AB0i graft very well. Preformed antibodies are absent, and the immune system is highly tolerant^[24].

Gurevich *et al*^[25] examined 58 pediatric patients undergoing AB0i LDLT with a preoperative iso-titer of < 1:16. No graft rejection or death occurred and 93% survived beyond the first 10 years. Patients with biliary atresia had fewer rejection episodes in situations where the graft was donated by the mother (mother:father vs 40%:55%)^[25-27]. Most data in children have been collected in Asia^[25,28]. Okada *et al*^[29] described rituximab to be successful in pediatric AB0i LDLT. Kasahara *et al*^[23] analyzed 2224 pediatric transplantations, the largest cohort worldwide. They found 1-, 5-, 10- and 20-year patient survival rates of 88.3%, 85.4%, 82.8% and 79.6% in the 294 patients undergoing AB0i LDLT.

Acute liver failure

In Europe and the United States, emergency AB0i LDLT is conducted only if no compatible donor can be acquired in time^[8,30]. In Asia, this concept is more common. Shen *et al*^[31] for example, reported 3-year patient survival rates in AB0c vs AB0i LDLT of 83.1% vs 86%. The graft survival was 80% vs 86%. Two AB0i patients developed AMR, but no other patients had cellular rejection, biliary complications or infections. A model of end stage liver diseases (MELD) score > 30 put patients at high risk for mortality. For this reason, in the Asian Medical Center, the largest LDLT center in the world, Lee *et al*^[18] excluded high-urgency patients from AB0i LDLT. Shinoda *et al*^[32] in contrast, found no difference between AB0c and AB0i LDLT.

Hepatocellular carcinoma

Living donation provides an alternative curative treatment option for patients with hepatocellular carcinoma (HCC) in cirrhosis if no offers for deceased donor organs exist. This can be due to low laboratory MELD scores or if the tumor burden is beyond the Milan criteria. There are only a few reports of successful AB0i LDLT in patients with HCC outside Milan^[33]. After Lee *et*

a^[34] experienced a recurrence of 57% in the first year after ABOi LDLT, they recommended refraining from transplanting HCC patients^[34].

Peter and Werny investigated a distinctly higher anti-A/B titer in patients with severe emaciating diseases compared to healthy blood donors^[30]. HCC patients seem to have very high anti-A/B titers and a strong rebound. This increase could relate from altered expression of blood group antigens on the biliary tree in pathological conditions^[23]. Neexpression or aberrant expression of A or B substances in malignant cells possibly boost the production of antibodies^[24]. In this situation, the tumor bulk might define the antibody titer and rebound.

Hepatitis B/C

Lee *et al*^[34] described ABOi LDLT in 20 patients. The etiology of liver diseases consisted mostly of HBV infections (*n* = 15) and one hepatitis C virus (HCV) infection. To prevent hepatitis C virus (HBV) recurrence, Lee *et al*^[34] used entecavir or tenofovir with a high dose of intravenous (IV) HB-hyperimmune globulin. If HCV was confirmed by a liver biopsy or an abnormal liver function test with elevated HCV RNA loads, PEGylated-interferon and ribavirin were administered. Other authors describe ABOi LDLT in patients with HBV or HCV cirrhosis and in patients with HCC, as well. Unfortunately, they provide

no information about their hepatitis therapy or antibiosis (Table 1)^[20,35,36]. No data are available on ABOi LDLT in HCV patients with the new antivirals.

TREATMENT STRATEGIES TO OVERCOME BLOOD GROUP BARRIER

ABOi LDLT requires careful planning and logistical preparation prior to surgery. As treatment regimens vary distinctly, we would like to present them in the following way. All regimens have the focus on antibody reduction in common. To reach this goal and to prevent antibody rebound as well, therapeutic apheresis is combined with immunosuppressive therapy. A good overview is given in a South Korean treatment schedule: Prior to transplantation rituximab and plasma exchange is started. When the anti-A/B titer has decreased to at least a titer of 1:8, transplantation takes place without local infusion or splenectomy. Afterward, immunoglobulins and quadruple immunosuppression are administered.

Anti-A/B iso-titer

As Warner *et al*^[37] summarized, "The durable survival of ABOi solid organ allografts seems to be primarily dependent on 3 conditions: (1) the low expression of antigen on the graft, as in case of A2 positive organs; (2)

a low titer of anti-donor ABO antibodies in the recipient before transplantation; and (3) the ability to maintain low titers of antidonor ABO antibodies in the recipients after transplantation, at least for the first 3 to 6 week^[37]. In the setting of ABOi LDLT, iso-titers naturally rise during the first two days after transplantation^[38]. In addition to the natural rebound, de novo alloantibodies have the potential to develop. This alloimmune reaction induces a higher rebound and can lead to AMR, putting the graft at risk. This makes the first two weeks, or even four to six weeks, after ABOi LDLT critical for AMR^[39].

After this period, the graft has been mostly adapted to its new environment. This state is called accommodation.

Furthermore, the target titer for IgG and IgM in ABOi LDLT varies from center to center. Some centers estimate 1:8 to be appropriate, others 1:16^[39]. However, a titer of 1:64 or above should be avoided due to an increased risk of complications during transplantation and AMR^[30,40]. In the studies we compared in Table 1, titers of 1:64 or above were not accepted and lead to further PTPs (Table 1).

Therapeutic apheresis

Therapeutic apheresis is the most effective way to control the humoral antibody response to prevent rejection^[41]. There are a variety of PTPs, which differ mainly in their selectivity toward immunoglobulin elimination.

Therapeutic plasma exchange: Therapeutic plasma exchange (TPE) is a widely accepted nonselective PTP to eliminate antibodies in patients with solid-organ transplants which are sensitive to HLA antigens or undergo ABOi transplantation. Still, no controlled studies of TPE in ABOi LDLT or therapy standards have been published. With TPE, usually 1.2 times (1.0-1.5) the patient's plasma volume is treated. The amount of treated plasma volume correlates with the removal of 63% to 72% of the original plasma constituents. At the end of a TPE procedure, IgM is very low. High levels of IgM are usually reduced with one or two TPE^[42]. The American Society of Apheresis guidelines designate the perioperative use of TPE in ABOi LDLT as a category I with 1C recommendation^[43]. Moreover, the use of double-volume TPE pre-transplant eliminated more than 90% of the antibodies, lead to an iso-titer of < 1:16 and decreased the episodes of rejection^[44]. In the studies we reviewed, PTP was conducted before and after ABOi LDLT. Almost all centers used TPE to eliminate anti-A/B iso-titers (Table 1).

Immunoabsorption: Immunoabsorption (IA) is mainly performed in Western Europe. Controlled studies of IA are still lacking in the setting of ABOi LDLT. With IA, it is possible to deplete a large amount of circulating antibodies without considerable loss of essential plasma constituents. Two IA-methods are available to selectively reduce antibodies. The first is the blood group

antigen-specific apheresis (Glycosorb[®] ABO, Glycorex Transplantation, Lund, Sweden). This technique is preferred to reduce the iso-titer. Because the IA-column is highly selective for anti-A/B antibodies, other antibodies are not affected and no replacement fluid is required. With each plasma volume treated with Glycosorb[®], the iso-titer of IgG and IgM is reduced by one titer. Compared to the baseline, a reduction to 59% for IgG iso-titer and to 30% for IgM iso-titer is considered average^[45].

The second is the semiselective antibody removal (Immunosorba[®], Globaffin[®], Fresenius Medical Care, Bad Homburg, Germany, Therasorb[®], Miltenyi Biotec GmbH, Bergisch Gladbach, Germany). These columns mainly bind IgG and, to a lesser degree, IgM, regardless of their specificity. This unspecific removal is beneficial for transplant candidates with an additional sensitization. In ABOi kidney transplant patients, a single session of IA decreased anti-A/B IgG iso-titers more effectively than antigen-specific apheresis. IgG was reduced to 28% of the baseline value and IgM to 74%^[45]. In the studies we compared, the use of IA was not reported, as IA is only common in Europe. Asian centers use TPE or double-filtration plasmapheresis instead (Table 1).

Double-filtration plasmapheresis: Outside of Japan, the use of double-filtration plasmapheresis for ABOi LDLT is very limited. The Evaflux[™] 2A (Kawasumi laboratories, Japan) eliminates IgG as well as IgM. After processing 1000 mL plasma, the ratio of solute returned to the patient, or the sieving coefficient, is 0.00 for IgM and 0.19 for IgG. As the value of 0.00 for IgM indicates, these pore-based filter columns are most effective for IgM depletion. The target iso-titer < 1:16 was reached with only 4 treatments, even in cases with very high initial iso-titers (> 1:2048)^[46].

Intravenous immunoglobulin G

Intravenous immunoglobulin G (IVIG) are suggested to be beneficial in immunoregulation because they block Fc receptors on mononuclear phagocytes and directly neutralize alloantibodies. They also inhibit the expression not only of CD19 on activated B cells and the complement system but also of alloreactive T cells^[13]. In the field of transplantation, IVIG was used with PTPs in pre-sensitized recipients or to treat AMR^[47,48]. IVIG can be used as a rescue therapy, in the case of severe AMR, if there is not enough time (three days) for rituximab to exert an effect^[39]. When IVIG is part of the therapeutic protocol, graft survival is estimated to be greater than 87%^[47,49,50]. Hanto *et al.*^[44] compared ABOi recipients receiving TPE and IVIG with patients receiving only TPE during the post-transplant period. In this study, the patient group with IVIG did not develop AMR, but 27.3% of the patients in the other group did develop AMR post-transplant. Unfortunately, a transient increase of anti-A/B titers is observed after IVIG administration due to the passive transfer of anti-A/B. Thus, IVIG should not be administered prior to ABOi LDLT. All

centers that we have compared report using IVIG after ABOi LDLT (Table 1).

Immunosuppression

Immunosuppression consists of steroids, calcineurin inhibitors and antimetabolites. In our center, we use quadruple immunosuppression: Monoclonal antibodies, calcineurin inhibitors, antimetabolites and steroids.

In 1998, Tanabe *et al.*^[51] described a new protocol in which they, in addition to perioperative TPE and splenectomy, supplemented systemic immunosuppression with portal vein infusion therapy (PVIT). Methylprednisolone, prostaglandin E1 and gabexate mesilate were used in the PVIT. If PVIT causes portal vein thrombosis, Kozaki *et al.*^[41]'s hepatic arterial infusion therapy (HAIT) could be conducted. The two most feared complications after PVIT or HAIT were thrombosis and bleeding.

In 2013, local graft infusion, in the form of hepatic arterial infusion (HAI) or portal vein infusion (PVI), with PGE1 was only performed by Kim *et al.*^[20] and Song *et al.*^[52]. Since 2010, only Song *et al.*^[52] have also administered cyclophosphamide as immunosuppression. The therapeutic regimen after LDLT includes antifungal, antimicrobial and cytomegalovirus prophylaxis. However, dosage, medication and duration of the medication have not yet been standardized.

MONOCLONAL ANTIBODIES

Rituximab is a monoclonal chimeric human-murine anti-CD20 antibody that depletes B cells. It acts by complement- and antibody-dependent cell-mediated cytotoxicity. The CD20 antigen is expressed on pre- and mature B cells, but not on long living plasma cells persisting in the bone marrow. Hence, rituximab does not directly affect antibody-producing plasma cells. A single dose of rituximab in ABOi LDLT suppresses B cells for more than six months after transplantation in the peripheral blood^[4,50]. However, because B cells in the lymph node are unaffected, they are activated by the ABOi graft, and the anti-A/B titers rise for the first four to six weeks after transplantation^[4,50,53]. But even if antibody production is possible at low levels, de novo production of antibodies is sufficiently delayed due to rituximab^[28]. Monteiro *et al.*^[54] reported the first case of ABOi LTX using rituximab in 2003. Usuda *et al.*^[55] reported the first case of rituximab prophylaxis in ABOi LDLT in 2005. Egawa *et al.*^[4] reported in 2014 that rituximab prophylaxis significantly decreased the incidence of AMR, especially severe AMR leading to hepatic necrosis ($P < 0.001$)^[4]. However, other B cell desensitization therapies have shown no additional effects in the rituximab group. Multiple or large rituximab doses significantly increased the incidence of infection and early administration held no advantage^[4]. All the transplantation centers we compared treated their ABOi LDLT patients with rituximab, with most of them administering it before transplantation. Two weeks before surgery tends to be an opportune time

(Table 1). Regarding the safety of rituximab in ABOi LDLT, pharmacodynamic studies have to be conducted to determine the safest dose. Currently, therapeutic regimens are adopted from the kidney transplantation protocols.

Basiliximab is a chimeric mouse-human monoclonal antibody to CD25 of the interleukin (IL)-2 receptor, located on the surface of activated T lymphocytes. It inhibits T cell proliferation and prevents cell-mediated rejection in liver transplantation^[56,57]. It prevents T-helper cells from replicating, blocks the activation of B cells and restricts the production of antibodies, including anti-donor isoagglutinin antibody. Recently, the regimen that combines rituximab with basiliximab in ABOi LDLT has been questioned^[4].

Splenectomy

The spleen is a major antibody reservoir, containing large amounts of B cells and plasma cells. Splenectomy before ABOi LDLT to prevent antibody rebound is becoming more controversial. Most Asian centers use protocols with splenectomy in addition to other immunosuppressive measures^[18]. However, several reports have shown that splenectomy does not offer any immunological advantage in ABOi LDLT. For example, Raut *et al.* observed no statistically significant differences in anti-A/B IgM and anti-A/B IgG titers between "splenectomy" and "non-splenectomy" groups^[58]. Several reports have also shown that splenectomy may not offer any immunological advantage in ABOi LDLT. The clinical outcomes, including AMR, biliary complications, infections and survival, were also similar in the two groups^[52,59,60]. An exception to this general rule are patients with imminent "small for size" syndrome, who have better outcomes after splenectomy^[4,61]. Only two centers of the ones compared carried out splenectomy. In these centers, 21 of 23 patients had AMR occurrence (Table 1).

Complications after ABOi LDLT

Biliary complications, which are still a major issue in ABOi LDLT, are likely related to immunological mechanisms. Donor blood group antigens are expressed for up to 150 d on the bile duct's epithelium after transplantation^[59,62-64]. Song *et al.*^[7] reported a higher incidence of biliary strictures, especially diffuse intrahepatic biliary strictures (DIHBS), in ABOi LDLT than in ABOc grafts. These strictures significantly affected the overall survival^[15]. In Lee *et al.*^[18]'s study, 5.6% of the patients developed complications, such as DIHBS, 2.1-5.2 mo post-transplant. In 2005, Kozaki *et al.*^[41] showed that high preoperative anti-IgM iso-titer led to bile duct complications. High preoperative anti-IgG iso-titer led to hepatic necrosis and high postoperative anti-IgM and anti-IgG iso-titers lead to hepatic necrosis as well. Once hepatic necrosis occurred, no patient survived.

Biliary complications developed in 54%-82% of the ABOi allograft recipients, compared to 6% in

ABO matched allografts. Hepatic artery thrombosis also occurred in 24% of ABOi allografts^[3,28]. In 2011, the meta-analysis of Wu *et al*^[64] showed increased complications and AMR in ABOi LDLT, as well.

Another complication, such as the “small for size” syndrome in ABOi LDLT, can be avoided *via* a new dual split technique from Asia^[65]. Dual LDLT with ABOi and ABOc grafts is a feasible solution for simultaneously overcoming both the ABO blood group barrier and small-for-size graft.

CONCLUSION

Since 2010, no new techniques in ABOi LDLT have been reported in medical journals, but the treatment options have been refined. The outcomes of ABOi LDLT are still inferior to those of ABO-compatible and identical LDLTs, and anti-A/B antibodies reappear after the transplant. However, due to refined treatment strategies, ABOi LDLT is a feasible option today and is almost free from severe complications. We compared the regimens of 11 transplant centers, as well as their outcomes from 2010 to the present. The best improvement in outcomes next to PTPs has been observed with the prophylactic use of rituximab more than one week before ABOi LDLT. Although each center treats its patients with its own scheme, the transplant results are homogeneous. In our center, we have had positive experiences starting quadruple immunosuppression with basiliximab before transplantation. We also use TPE or IA and reduce the iso-titer at least down to 1:8 prior to transplantation. If the iso-titer rises again afterward, we mainly perform TPE.

A new approach for overcoming both the ABO blood group barrier and small-for-size grafts seems to be the dual split LDLT with ABOi and ABOc grafts that has been conducted in Asia.

Still, ABOi graft survival in adults is poorly understood. Neither is the emergence of *de novo* anti-A/B, nor their impact. Graft accommodation gives a possible explanation for ABOi graft survival in the presence of donor specific antibody titers.

In the long term, iso-titer rebound prevention might be necessary to lower the risk of iso-titer mediated rejection even further. However, no specific medication is available yet to meet this need.

indicates that donor-specific antibodies can mediate and promote acute and chronic rejection after ITx. However, diagnostic criteria for ABMR after ITx have not been established yet and the mechanisms of antibody-mediated graft injury are not well-known. Effective approaches to prevent and treat ABMR are required to improve long-term outcomes of intestine recipients. Clearly, ABMR after ITx has become an important area for research and clinical investigation.

Core tip: Antibody-mediated rejection (ABMR) has increasingly surfaced as an important cause of allograft loss after intestinal transplantation. The presence of donor-specific antibodies (DSAs) should alert the clinician of the increased risk of ABMR. The avoidance of a known donor-specific antibody target at the time of transplant remains a primary preventive strategy. The development of newly-formed DSAs usually portends a poor prognosis with an increased risk of refractory acute rejection, chronic rejection, and allograft loss. The better understanding of mechanisms of antibody-mediated graft injury, establishment of the diagnostic criteria, and optimal management of these antibodies may improve clinical outcomes of intestine transplants.

Abstract

Antibody-mediated rejection (ABMR) has increasingly emerged as an important cause of allograft loss after intestinal transplantation (ITx). Compelling evidence

INTRODUCTION

The intestine is often deemed one of the most difficult

organs to be transplanted because of its unique structure and enhanced immune response^[1-3]. Over the past several decades, intestinal transplantation (ITx) has achieved remarkable advancement not only in volume of transplants but also in outcomes, owing to progress in various aspects of organ preservation, surgical technique, immunosuppression, and postoperative management^[4-7]. Despite improvements in short-term outcome, long-term survival of both patient and graft after ITx has been well behind other solid-organ transplants, with 10-year survival rates under 50%^[5,8]. Allograft dysfunction and/or loss due to acute and chronic rejection continue to be major barriers to the success of intestinal allografts^[6]. Therefore, it is essential to further delineate mechanisms for graft failure and to develop treatment strategies that will provide long-term intestinal graft function.

Traditionally, intestinal allograft rejection has mainly been regarded as a T-cell-mediated process, whereas the humoral immunity has received less attention in the evaluation of intestinal rejection. A potential role for antibodies in graft rejection has long been suspected because antibodies to human leukocyte antigens (HLA) are often detected in patients with rejection^[9-11]. To date, HLA antibodies are well recognized as causes for hyperacute rejection, acute antibody-mediated rejection (ABMR) and chronic ABMR following kidney or heart transplantation^[12-14]. Isolated reports suggest that HLA antibodies also affect lung, liver, or pancreas transplants^[15-17]. Much of the evidence indicates that an early diagnosis and aggressive treatment of acute ABMR are critical for improving graft and patient outcomes in kidney or heart transplantation^[18,19]. In recent years, several groups demonstrate that, as with other solid-organ transplantation, HLA antibodies appear to be a significant risk factor for the development of acute and chronic rejection after ITx and worsen the overall prognosis for both patient and graft^[20-22]. ABMR has increasingly emerged as a potential form of graft dysfunction after ITx. The strategies to decrease or eliminate preformed HLA antibodies, early recognition and appropriate management of newly-formed (*de novo*) antibodies may further improve outcomes in intestinal allograft recipients.

This review summarizes what is currently known regarding antibody-mediated injury to the intestine and potential solutions to this problem and to emphasize the areas that require further study.

DONOR-SPECIFIC ANTIBODIES AND PRETRANSPLANT SENSITIZATION

Alloantibodies directed against donor HLA, called donor-specific antibodies (DSAs), may be present at the time of transplantation (preformed DSA) or develop *de novo* following organ grafting. These donor HLA antigens are commonly expressed on endothelial cells, epithelial cells, or other organ specific targets. Over the past several

decades, analyzing transplant recipients for DSAs has become an important part of immune monitoring before and after transplantation^[23]. The earliest method developed in the 1960s was complement-dependent cytotoxicity (CDC) cross-matching of the recipient's serum with the donor's lymphocytes in the presence of complement. This simple test substantially reduces the occurrence of hyperacute rejection, but its sensitivity and specificity (due to non-HLA antibodies) are very low. Flow cytometry cross-matching developed in the 1970s is based on the detection of serum antibodies binding to donor lymphocytes, and it is more sensitive than CDC cross-matching. Current solid-phase immunoassays such as Luminex single-antigen beads provide important advantages in sensitivity and specificity over cell-based assays and are widely used in most transplant centers around the world^[24].

Compared with other solid-organ transplants, sensitization is relatively higher in intestinal allograft recipients, most likely due to previous multiple operations, blood transfusions, recurrent line infections, or pregnancies. High panel reactive antibody (PRA) levels are observed in 18%-30% of intestinal transplant candidates on the waiting list, compared to the sensitization rate of 10%-15% in kidney and heart transplant candidates^[22,25,26]. Indeed, in our experience the incidence of sensitization was as high as 30%, implying that intestine recipients are an immunologically high-risk population^[21].

HYPERACUTE REJECTION

As with other solid-organ transplants, an intestinal allograft placed into a highly sensitized recipient may be subject to very rapid loss because of hyperacute rejection. This severe form of acute rejection was originally described for clinical kidney allografts transplanted into recipients with circulating antibody against the donor^[27]. The kidney graft rapidly develops a beefy red or blue appearance and immediately fails^[28]. The pathogenesis involves the binding of preformed DSA to HLA on endothelial cells and the subsequent activation of the classical complement cascade leading to the formation of the membrane attack complex and endothelial damage. Because of its strong clinical relevance, cross-matching of the recipient's serum and the donor's lymphocytes prior to transplantation became a standard protocol of kidney transplant programs throughout the world.

The kidney and heart are most susceptible to hyperacute rejection, and the liver is relatively resistant^[29,30]. To date, hyperacute rejection has not been sufficiently studied in ITx^[31]. Hyperacute rejection, although rare, can occur in intestinal allograft recipients who are highly sensitized with the presence of DSAs. This aggressive form of rejection occurs almost exclusively in the pre-sensitized patient with a very high titer of preformed HLA antibodies and is the result of a severe antibody-mediated response to the vasculature

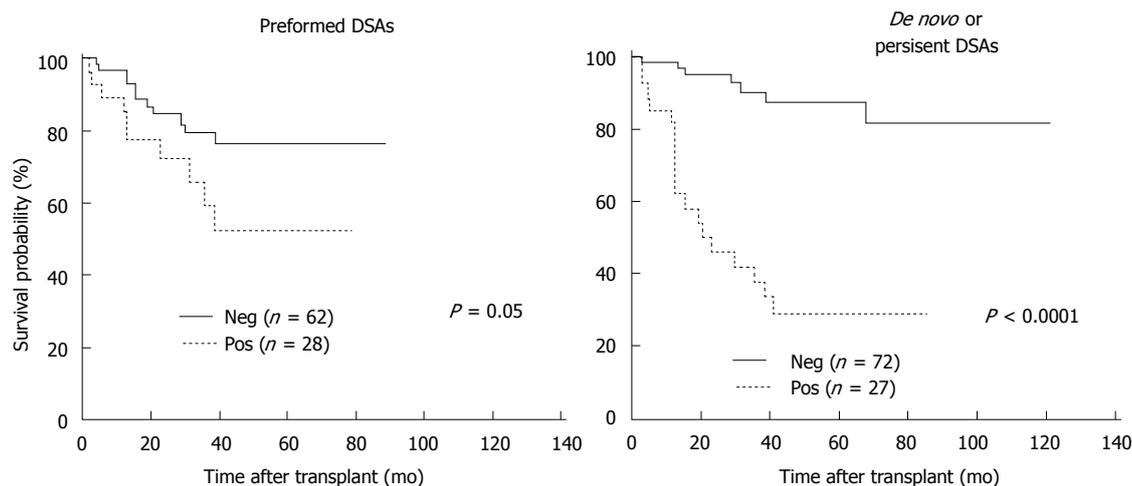

Figure 1 The Kaplan-Meier graft survival for the presence of performed donor-specific antibodies before transplant and newly formed (*de novo*) donor-specific antibodies after transplant. Patients with preformed donor-specific antibodies (DSA) had significantly lower graft survival than those without preformed DSA. The graft survival was markedly worse in patients with *de novo* DSA or persistent DSA.

endothelium, characterized histologically by vascular injury, thrombosis, and ischemia. In a case report of hyperacute rejection, Ruiz *et al*^[32] described an isolated intestinal allograft recipient with the presence of a positive cross-match and multiple preformed DSAs. The intestinal allograft became dusky immediately following graft reperfusion and the recipient showed hypoxia, hypotension, and acidosis. Subsequent mucosal biopsy specimens exhibited severe vascular congestion with thrombi, hemorrhage, and leukocyte infiltration. Immunofluorescence revealed the deposits of IgG, IgM, C4d, and C3 on the endothelium, suggesting that antibodies can directly injure the intestinal allograft. In this isolated case, the intestinal graft was successfully saved after a combination of intensified tacrolimus, alemtuzumab, rituximab, and plasmapheresis.

ACUTE ABMR

In the earlier series, Bond *et al*^[9] reported outcomes of 23 cross-matching positive grafts in 124 recipients (18%) and illustrated that a positive cross-match was associated with increased frequency of acute rejection after ITx, especially with an isolated intestine. They showed 43.5% (10 out of 23 positive cross-matching) allografts failed at a follow-up of two years. The simultaneous liver allograft as part of a composite visceral transplant appeared to improve the negative effect of the preformed antibodies and positive cross-matching. Later, Ruiz *et al*^[33] in Miami and Wu *et al*^[10] in Pittsburgh respectively described the vascular changes of intestinal allograft recipients in the setting of a positive cross-match. In the recipients with a higher PRA and a positive cross-match, the pathology showed significant vascular congestion and submucosal hemorrhage with deposition of C4d, IgG, and IgM. They found a lower graft survival in the recipients with the early significant vascular lesions^[33]. Based on these early results and lessons learned from the other solid-organ

transplantation, a positive CDC cross-match has been considered relatively prohibitive for an isolated intestine transplant in most intestinal transplant programs.

A decade later, Wu *et al*^[34] evaluated an adverse impact of HLA antibodies on intestinal allograft outcome. This study initially retrospectively analyzed a total of 117 recipients who received a primary liver-exclusive intestine allograft during the period between 2000 and 2009. The results further confirmed that a positive cross-match with preformed DSA significantly increased rate and severity of acute rejection after transplant and the formation of *de novo* DSA after ITx was associated with the worst clinical outcome (Figure 1). Tsai *et al*^[20] prospectively examined the impact of pre- and post-transplant DSA on intestinal allograft rejection. Thirteen recipients were subsequently followed up for DSA levels by a sensitive Luminex assay pre- and posttransplant. They found that the presence of DSA was closely related to an increasing number of rejection episodes and severe acute rejection grading. A combination of rituximab, plasmapheresis, IVIg, or bortezomib therapies to eliminate DSA was associated with clinical improvement of acute rejection. The authors suggest that frequent intestinal graft biopsies combined with serial measurement of DSAs are valuable for evaluation of cellular and humoral immunity of acute rejection.

Our group further analyzed 194 primary intestinal/multivisceral allograft recipients in which one-third had a positive CDC cross-match prior to surgery^[21]. In 156 recipients, 49 (31%) had preformed DSA before ITx; 19 (39%) had persistent DSA after ITx; and 19 (18%) developed *de novo* DSA. The authors again showed preformed DSA significantly increased frequency and severity of acute rejection. Overall cumulative risk of acute rejection was significantly higher in a positive cross-match compared to a negative cross-match. The recipients with higher levels of DSAs, as measured by a single antigen Luminex assay, developed an increased incidence of steroid-resistant rejection which responded

poorly to OKT3 treatment, and 1-year graft survival in DSA-positive recipients was significantly inferior to that of DSA-negative recipients. Twenty-one (11%) of recipients were diagnosed with acute ABMR, and most ABMR cases occurred in the first three months after transplant. The incidence of acute ABMR was substantially elevated in recipients with performed, persistent DSA and *de novo* DSA and 11 (52%) of acute ABMR cases led to allograft failure.

It is important to note that intestinal transplant recipients can mount humoral immune response after transplantation even in the setting of a negative cross-math. Gerlach *et al*^[35] reported thirteen patients undergoing intestinal/multivisceral transplants with non-donor-specific HLA antibodies before ITx and found that the development of *de novo* DSAs after ITx was associated with severe graft dysfunction. They observed that only three recipients had non-donor-specific HLA antibodies before transplantation; 15 (50%) cases developed *de novo* DSA during the first 6 mo; and only two recipients developed DSA 10 years after transplantation. In their small series, all patients with *de novo* DSAs showed simultaneous acute cellular rejection at the time of DSA occurrence. Luckily, nine of the 10 patients diagnosed with acute ABMR were successfully treated with a combination of plasmapheresis and intravenous immunoglobulin (IVIg). In case of persistence of DSA and/or treatment-refractory rejection, additional rituximab and/or bortezomib were beneficial.

DIAGNOSIS OF ACUTE ABMR

Up to date, diagnostic criteria for acute ABMR after ITx have not been established and there is no consensus on the characteristic clinicopathologic features. However, several reports addressing a unique form of allograft rejection that is consistent with the definition of acute ABMR which was defined by The National Conference to Assess Antibody-Mediated Rejection in Solid Organ Transplantation in kidney and heart transplantation^[36,37].

Wu *et al*^[10] initially described a characteristic clinical and pathologic syndrome during the early postoperative course in intestine recipients with a positive cross-math. They observed that the strongly positive cross-match recipients exhibited serious mucosal damage instantly after graft reperfusion, including mucosal congestion, bluish discoloration, and focal hemorrhage in the allograft. Pathology showed severe capillary congestion, neutrophilic infiltration, hemorrhage, epithelial injury, and thrombi within the lamina propria microvasculature, but without evidence of histologic neutrophilic or necrotizing arteritis, and the immunofluorescent findings were unremarkable. In contrast, the recipients with a weakly positive crossmatch, as well as the cross-match negative recipients, had none of these characteristic clinical, endoscopic, or microscopic findings.

C4d is a footprint of antibody-triggered classical complement activation and its deposition has become

pivotal to the diagnosis of acute ABMR in kidney and heart transplants^[37,38]. However, there is no generally acceptable consensus on the use of C4d staining in diagnosing acute ABMR after ITx. Earlier studies showed that C4d deposition had no difference in biopsies between acute rejection and no rejection and claimed that C4d had no clinical relevance as diagnosing humoral rejection in intestinal allografts^[39,40]. Unfortunately these earlier studies neither correlated C4d with the levels of HLA antibodies nor examined these antibodies by a relatively sensitive methodology. Ruiz *et al*^[33] demonstrated that post-transplant vascular lesions in intestinal allografts at earlier time periods were associated with higher levels of pre-transplant PRA or a positive CDC cross-match. In intestinal recipients with the vascular changes, C4d staining can be seen in the small vasculatures. Of the patients with no significant vascular alterations, C4d deposition was negative or trace. Our team evaluated the utility of C4d in intestinal biopsies at the time of suspected acute ABMR and showed a diffuse C4d staining was mainly observed in recipients with a positive DSA, while focal or minimal C4d staining was observed in intestinal biopsies with no evidence of rejection^[21]. Similar to other solid-organ transplants, our results emphasize clinical significance of a diffuse C4d deposition in intestinal allografts, suggesting that C4d together with higher titers of DSA, is a very useful marker to detect acute ABMR after ITx.

Based on the established diagnostic criteria for kidney transplant, including the presence of circulating DSAs, acute tissue injury, C4d deposition and clinical allograft dysfunction, we performed a retrospective single-center analysis to investigate the incidence, risk factors and clinical outcomes of acute ABMR after ITx (unpublished data). Acute ABMR was diagnosed in 18 (10.3%) out of 175 primary intestinal/multivisceral transplants with a median occurrence of 10 d (range, 4-162) after ITx. All eighteen patients were sensitized to HLA class I and/or II antigens with the presence of performed DSAs. A cross-match was positive in 14 (77.8%) recipients. Twelve of 18 patients (66.7%) developed *de novo* DSA after ITx. Pathological features of acute ABMR include C4d deposition, prominent hemorrhage and congestion with scattered fibrin thrombin in the lamina propria (Figure 2). Despite initial improvement after treatment, eleven (61.1%) lost graft due to rejection. Of those, nine (50%) received enterectomies and four (22.2%) underwent retransplantation after acute ABMR. At a median follow-up of 32.3 mo (range, 13.3-76.4 mo), eight (44.4%) recipients died. We conclude that acute ABMR can be a fulminant form of intestinal rejection, especially in a liver-free transplant and survivors are at an increased risk of developing refractory rejection. Our studies suggest that no morphologic findings are specific for acute ABMR in intestinal allografts, and the diagnosis is best made using serologic, clinical, and histologic data

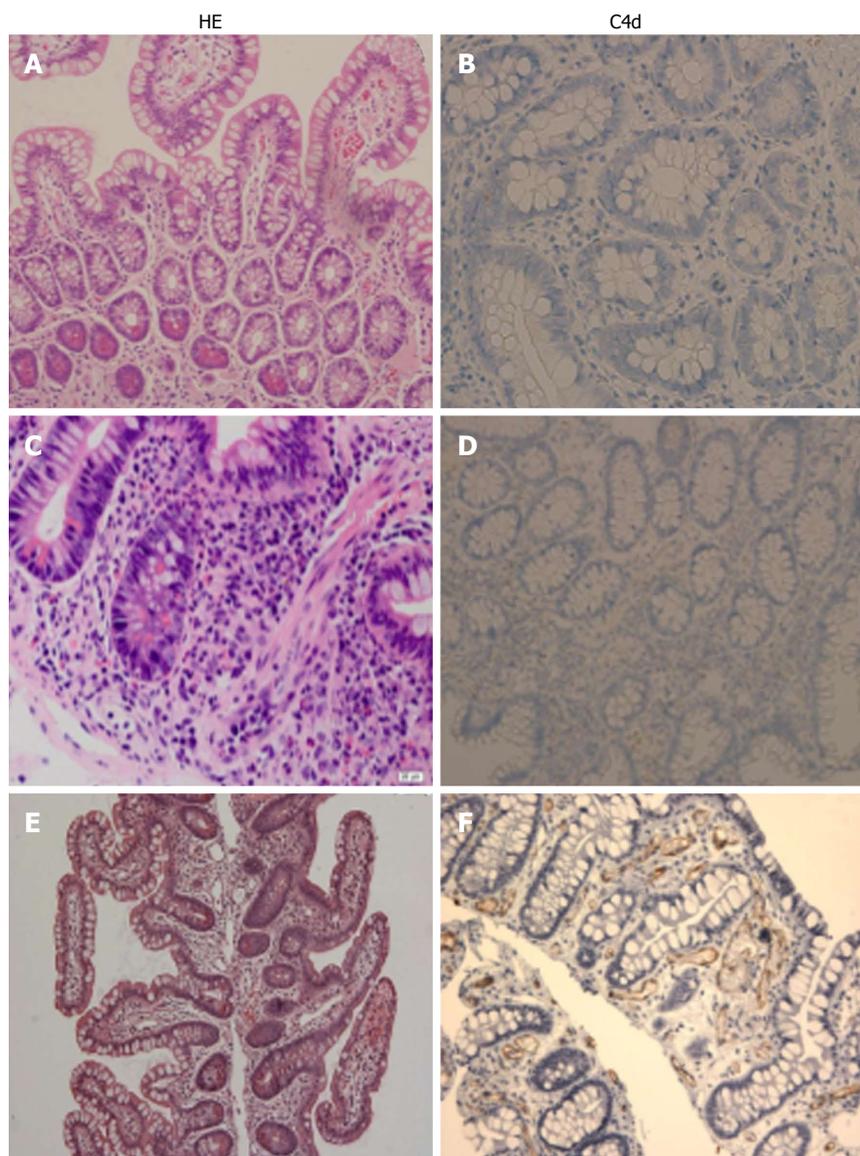

Figure 2 Histopathology of the intestinal allografts. A and B: No rejection: Normal mucosal architecture of small bowel biopsy after transplant. No staining for C4d is seen in the capillaries of the lamina propria; C and D: Acute cellular rejection (ACR): There is mononuclear infiltration, crypt epithelial injury, and apoptotic bodies in the lamina propria. A weak staining for C4d is sometimes present in a patient with ACR; E and F: Acute antibody-mediated rejection: There is prominent hemorrhage and congestion with scattered fibrin thrombin in the lamina propria. Widespread and bright staining for C4d is present in the capillaries of the lamina propria.

together.

PREVENTION AND TREATMENT OF ACUTE ABMR

Due to rarity of ITx, no standard protocols are currently available for prevention and treatment of acute ABMR. Therapeutic strategies are predominantly based on case reports, small series, and renal transplant data.

The avoidance of a known HLA DSA target at the time of transplant remains a primary preventive strategy. With the development of solid-phase assays, the ability to detect and minimize DSA prior to transplantation is possible. Luminex single-antigen assay of DSA has led to the application of the virtual cross-match, in which known recipient HLA antibodies are compared to donor HLA prior to transplantation. At the time of a donor organ offer, the

titer, MFI, and total number of DSA can be evaluated for the virtual cross-match. Hawksworth *et al*^[25] evaluated the virtual cross-matching for organ allocation and immunological risk reduction in sensitized isolated intestinal transplants. In their study, higher DSA titers (more than 1:16) were considered a contraindication for an isolated intestinal transplant. They observed that clinical outcomes were comparable between sensitized (PRA > 20%) and control (PRA < 20%) recipients in terms of 1-year freedom from rejection, 1-year patient survival, and 1-year graft survival. The authors conclude that a virtual cross-matching strategy to optimize organ allocation is valuable in sensitized patients to successfully undergo isolated ITx with good short-term outcomes. However, this strategy may affect the sensitized potential recipient's access to ITx.

The use of preoperative desensitization strategies

to decrease DSA titers with plasmapheresis, ATG, IVIg, and mycophenolate has been described with good tolerability and reduction of early rejection episodes and equivalent posttransplant outcomes to unsensitized patients^[41]. The Indiana group reported their experience with combined rabbit ATG and rituximab as induction therapy, a positive cross-match was not related to an increased risk of acute rejection and graft failure. They suggested that combined use of anti-IL2 receptor antibody may be beneficial in the liver-free intestinal transplant. The authors conclude that with anti-thymocyte globulin plus rituximab induction, a positive cross-match had reasonable outcomes after intestinal/multivisceral transplantation. Garcia-Roca *et al*^[42] recently presented two living donor intestinal candidates with a positive cross-match that was successfully converted to a negative cross-match using desensitization protocol prior to transplantation. The first case had 67% for PRA HLA class I and 100% for class II and had DSA with a positive flow cytometry cross-match with a potential donor. The second case was sensitized with 80% for PRA class I and 26% for class II; no DSAs were identified. In this case, the standard cytotoxic cross-match was negative, but the flow cytometry cross-match was positive for B cell. Both cases were successfully desensitized with steroids, thymoglobulin, multiple plasmapheresis, followed by IVIg, achieving a complete negative cross-match at the time of transplant. ITx was successfully performed in both cases after desensitization protocol. Humoral rejection did not occur during the initial 6 and 9 mo follow-up.

It has been well-known that combined liver and ITx can be performed against a positive cross-match, suggesting that the liver graft protects the subsequent intestinal transplant from the harmful antibodies. Testa *et al*^[43] described a highly sensitized case in which a cross-match remained positive after multiple plasmapheresis. With a liver transplant, the cross-match quickly became negative allowing subsequent bowel grafting in one week. We described our single-center experience in retransplanted recipients and compared cases who underwent liver-free retransplants with those who underwent liver-inclusive retransplants^[44]. The graft survival rates at 1, 3 and 5 years in liver-free retransplants were markedly worse than those in liver-inclusive retransplants. The majority of liver-free retransplants underwent enterectomy due to either severe acute cellular rejection or chronic rejection. Six recipients died due to rejection-related complications. Compared to liver-free retransplants, the frequency and grading of acute rejection were markedly decreased in liver-inclusive retransplants. We did not see cases with chronic rejection during the study period and two patients died due to graft-vs host disease and infection in this group, respectively. We conclude that a liver-inclusive retransplant offers a better long-term clinical outcome, suggesting that the liver-intestine combined transplantation should be considered when

retransplantation is unavoidable.

The treatment of confirmed acute ABMR has routinely included a combination of corticosteroids, IVIg, plasmapheresis, ATG, and rituximab. Bortezomib, a proteasome inhibitor, has been reported to reduce or eliminate DSA after transplantation^[45]. Gerlach *et al*^[46] described ten intestinal recipients with a diagnosis of acute ABMR. After combined therapies including bortezomib, 9 cases were successfully treated with a good graft function. DSAs were completely cleared in 8 patients, and detectable in only one. Eculizumab, a humanized monoclonal antibody against complement C5, has successfully been used to treat acute ABMR in renal transplant. Recently, Fan *et al*^[47] described a case in which eculizumab was administered to reverse acute ABMR in a desensitization-resistant intestinal retransplant patient. His primary intestinal allograft failed due to ABMR eight years after ITx. Two donors were used in his initial allograft (one for the intestinal graft and another for the abdominal wall graft). He underwent a second intestinal graft which had to be resected a month later due to uncontrolled severe acute ABMR. The patient became highly immunized due to three HLA unmatched different organs, as reflected by 100% PRA and serum high titers of DSAs. He received the third liver-inclusive multivisceral transplant and developed severe acute ABMR on day 3 post-transplantation. Acute ABMR was successfully salvaged with antibody-targeted desensitization regimens. Although PRA levels remained higher, the titers of DSAs significantly decreased below the cut-off level of 3000 MFI (mean fluorescent intensity) within a month after the third transplant. The favorable outcomes in this extremely difficult case may be attributed to the use of Eculizumab and the immunoprotective effect of the liver graft.

CHRONIC REJECTION

Chronic rejection or enteropathy is a significant barrier to long-term graft and patient survival of intestinal allograft. The incidence of chronic rejection ranges between 15%-20% after ITx^[6,48]. Pathologically, it is characterized by concentric vasculopathy, luminal occlusion, leukocyte infiltration, and a marked fibrotic change^[49]. These histologic findings are the end results of a complex, multi-stage process of repeated immune- and non-immune-mediated cellular injury and inflammation. Repetitive insults exhaust the recipient's natural repair mechanisms leading to fibrotic replacement and intestinal failure^[50]. An isolated small bowel transplant appears to render the graft more susceptible to chronic rejection compared to a liver-inclusive transplant^[6,44,51] (Figure 3).

The causes of chronic rejection resulting from graft tissue injury are multifactorial and both immune- and non-immune-mediated factors can contribute to graft injury. Emerging evidence suggests that immune-mediated injuries to the graft are the fundamental cause

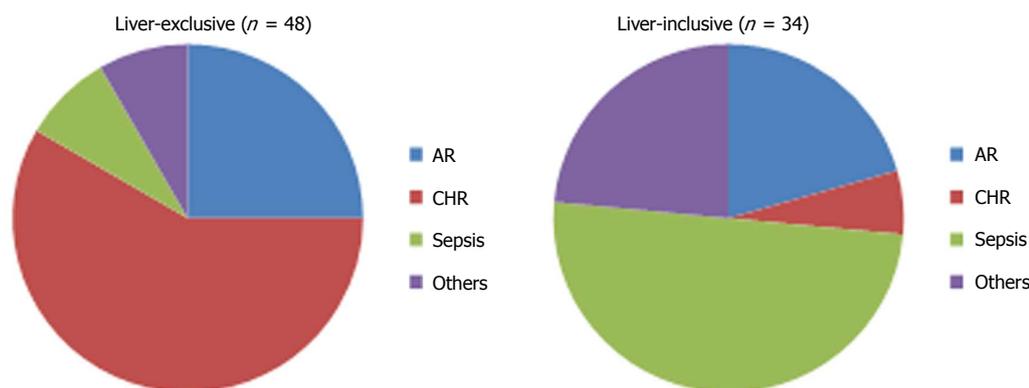

Figure 3 The causes of graft loss in the liver-exclusive and liver-inclusive intestinal transplants. In liver-exclusive transplants, chronic rejection was the leading cause of graft loss. In liver-inclusive transplants, however, infection was the major cause of graft loss. AR: Acute rejection; CHR: Chronic rejection.

of chronic rejection^[3,52]. Several studies have identified severe acute rejection, recurrent episodes of rejection, the cumulative burden of acute rejection, and late-onset acute rejection as risk factors for chronic rejection^[6,21]. Recently, the role of humoral alloimmunity has also appeared to be closely related to chronic rejection^[21,53]. The major target of humoral immunity appears to be the graft endothelium, which can be activated and injured by HLA antibodies. However, the mechanism by which humoral alloimmunity leading to chronic rejection is not well understood, and whether the presence of antibody is an initiating event or merely a response to tissue damage remains to be defined.

A large observational study investigating the potential effect of HLA antibodies on the intestinal chronic rejection came from our group^[21]. We retrospectively analyzed 194 consecutive intestine transplants which showed the incidence of chronic rejection at 36 cases (19%) with an average of 21 ± 10 mo (range 2-88 mo) follow-up. Cumulative risk of chronic rejection was slightly higher in recipients with a positive cross-match vs a negative cross-match. Cumulative probability of chronic rejection was markedly elevated in recipients in the setting of the presence of preformed DSAs before ITx together with persistent DSAs after ITx. The formation of *de novo* DSAs was closely related severe chronic rejection and subsequent graft loss. The graft survival was markedly decreased in the DSA-positive patients and the graft loss due to chronic rejection was irreversible in one-third patients. The liver-inclusive transplant was associated with better clearance of preformed DSAs, lower rates of *de novo* DSA formation, and therefore reduced rates of chronic rejection. The results illustrate a strong relationship between DSAs and an increased risk of chronic rejection and allograft failure.

CONCLUSION

Increasing and compelling evidence indicates that antibody-mediated graft injury is closely related to poor outcomes in ITx. The presence of preformed

DSAs should alert the clinician of the increased risk of ABMR. The avoidance of a known DSA target at the time of transplant remains a major preventive strategy and may improve unsatisfactory outcomes in intestine recipients. The development of *de novo* DSA after ITx usually portends a poor prognosis with an increased risk of uncontrolled acute rejection, chronic rejection, and allograft loss. The better understanding of mechanisms of antibody-mediated graft injury, establishment of the diagnostic criteria, and optimal management of DSAs are needed to improve clinical outcomes of ITx.

Abstract

AIM

To investigate the therapeutic potential of vasculotide (VT) - a Tie2 activating therapeutic - in kidney transplantation.

METHODS

We performed a murine MHC-mismatched renal transplant model (C57Bl/6 male into Balb/c female) with 60 min cold and 30 min warm ischemia time. 500 ng VT was administered *i.p.* to donor mice 1 h before organ removal. In addition, recipients received 500 ng VT *i.p.* directly and 3 d after surgery. Survival was monitored and remaining animals were sacrificed 28 d after transplantation. In this model, we analyzed: (1) organ function; (2) Kaplan-Meier survival; (3) organ damage (periodic acid Schiff staining) *via* semi-quantitative scoring [0-4 (0 = no injury/inflammation to 4 = very severe injury/inflammation)]; (4) expression of renal endothelial adhesion molecules (ICAM-1) *via*

immunofluorescence (IF) staining, immunoblotting and qPCR; (5) infiltration of inflammatory cells (IF Gr-1, F4/80); and (6) fibrosis *via* staining of α -smooth muscle actin (α SMA), Sirius red staining and immunoblotting of SMAD3 activation.

RESULTS

Exogenous activation of Tie2 with VT resulted in diminished expression of peritubular and glomerular endothelial adhesion molecules. Consequently, infiltration of inflammatory cells (analyzed as ICAM-1, Gr-1 and F4/80 positive cells) was reduced in VT-treated mice compared to controls. Additionally, VT was protective against fibrogenesis after kidney transplantation. Trends towards lower serum creatinine (vehicle: $142 \pm 17 \mu\text{mol/L}$ *vs* VT: $94 \pm 23 \mu\text{mol/L}$), urea (vehicle: $76 \pm 5 \text{ mmol/L}$ *vs* VT: $60 \pm 8 \text{ mmol/L}$) and lactate dehydrogenase (vehicle: $1288 \pm 383 \text{ iU}$ *vs* VT: $870 \pm 275 \text{ iU}$) were observed on day 6 after transplantation. Kaplan-Meier survival analysis showed improved survival rates in the VT-treated mice that did not reach statistical significance (27% *vs* 54%, $P = 0.24$, $n = 11$ per group). Exogenous activation of Tie2 *via* VT might reduce infiltration of inflammatory cells into renal tissue thereby protecting the transplant from early graft dysfunction potentially affecting long-term function.

CONCLUSION

Protection of the endothelial microvasculature *via* the Tie2 axis in the early transplant setting might hold promise as a therapeutic target.

Core tip: Activation of the Tie2 receptor has been shown to be beneficial in different models of disease. Here, we demonstrate that agonistic stimulation of Tie2 *via* the drug-like putative therapeutic termed "vasculotide" (VT) ameliorates outcome in a murine MHC-mismatched kidney transplant model. VT treatment (*i.e.*, activation of endothelial Tie2) prevented inflammation and fibrosis thereby preserving graft function. Moreover, single administration at the time of transplantation was also sufficient to prolong survival compared to control group.

INTRODUCTION

Graft failure and ultimately graft loss are still major

problems in solid organ transplantation. The endothelium hereby plays a pivotal role in mediating inflammation and subsequent organ dysfunction. In general, a healthy endothelium is essential for vascular homeostasis, and preservation of endothelial cell (EC) function is critical for maintaining transplant allograft function. Damage to the microvascular ECs is a characteristic feature of acute vascular rejection, an important predictor of later graft function and loss^[1]. Innovative therapeutic strategies preventing IRI and maintaining stable renal function are highly desirable.

The angiopoietin (Angpt)/Tie2 system consists of the transmembrane endothelial tyrosine kinase Tie2 and its four circulating ligands (Angpt1-4)^[2-5]. This system regulates baseline endothelial barrier function and its response to injury^[6,7]. Previous work has shown that the balance between the Tie2 agonist (Angpt-1) and the antagonist (Angpt-2) controls Tie2 phosphorylation^[6]. Angpt-1 which is mainly secreted by pericytes binds Tie2 as a natural agonist thereby promoting vascular quiescence^[8]. Canonical downstream effects of Tie2 signaling are activation of PI3K/Akt^[9,10], inhibition of the inflammatory transcription factor NF κ B^[11] and consecutive control of adhesion molecule expression^[12] as well as cytoskeletal regulation *via* the scaffolding protein IQGAP1^[13]. All together Tie2 activation promotes an anti-inflammatory, pro-survival, and anti-permeability phenotype of the vasculature. In contrast, Angpt-2 which is released from ECs upon pro-inflammatory stimuli inhibits Tie2 phosphorylation and consequently disrupts protective Tie2 signaling^[14].

Few data indicate a beneficial role of Tie2 activation in solid organ transplantation. In kidney transplant recipients, it has been shown that increased Angpt-2 levels (the natural Tie2 antagonist) correlate with mortality indicating that a dysbalanced Angpt/Tie2 system might be unfavorable in renal transplantation^[15]. Interestingly, it has very recently been demonstrated that a chimeric Angpt-1 mimetic, termed COMP-Ang1, is able to reduce endothelial permeability and inflammation in a murine heart transplantation model^[16].

Vasculotide (VT) - a PEGylated synthetic Tie2 agonistic peptide (CHHHRHSF) - has proven its potency to activate Tie2 *in vivo* even stronger and longer than its natural ligand Angpt-1. The therapeutic use of VT was first described in a murine diabetes model where it improved wound healing^[17]. Additionally, we and others have shown that VT can reduce vascular leakage and endothelial inflammation in different murine models of acute systemic inflammation^[18-21].

Given the beneficial properties of Tie2 activation on multiple levels of intracellular signaling with clinically relevant functional effects, we hypothesized that exogenous manipulation of the Angpt/Tie2 system might be protective in transplantation. To test this, we exogenously activated the Tie2 receptor with VT. The aim of our study was to investigate the potential beneficial effects of VT treatment in a murine kidney transplant model on graft

function. We analyzed inflammation, fibrous tissue deposition, renal function and overall survival to better understand if Tie2 activation might improve outcome after transplantation.

MATERIALS AND METHODS

Mouse studies and experimental design

All experiments were approved by the local authorities and conducted in accordance with institutional and governmental guidelines. Mice were housed in a room with 12 h day/night cycle, constant temperature and humidity as well as water and food ad libitum. All appropriate measures were taken to minimize pain or discomfort. Eight-week-old male C57Bl/6 or Balb/c mice were purchased from Charles River Laboratories (Sulzfeld, Germany). Briefly, kidneys from C57Bl/6 male (donor) were transplanted into Balb/c female (recipient) ($n = 23$). Donor mice received 500 ng VT ($n = 11$) or vehicle (PBS) ($n = 11$) intraperitoneally (*i.p.*) 1h prior to surgery. Recipients were injected with 500 ng VT or vehicle directly and on day 3 after kidney transplantation *i.p.*. Dosage of VT was carefully adjusted before^[18]. Mice were anesthetized with isoflurane and the donor kidney, ureter, and bladder were harvested en block, including the renal artery with a small aortic cuff and the renal vein. Cold ischemia time is 60, and warm ischemia time 30 min. After explantation, kidneys are stored in vehicle solution at 4 °C for 60 min. These ischemia times induce a moderate degree of ischemia-reperfusion injury (IRI) in this model. After left nephrectomy of the recipient, vascular cuff and vein are anastomosed to the recipient abdominal aorta and vena cava, respectively, below the level of the native renal vessels. The ureter is directly anastomosed into the bladder. A second dose of VT or vehicle was administered systemically (*i.v.*) 30 min post-transplantation. The right native kidney was removed on post-transplantation day 4 so that survival becomes graft dependent. Within a given experiments/analysis, we only used samples from single mice. We did not pool samples to increase protein amounts. Blood was taken on days 0, 6, 14, 21 and 28. Survivors were sacrificed 28 d after transplantation for further analysis. Renal function was estimated by serum lactate dehydrogenase (LDH), creatinine and urea measurements (Olympus).

Antibodies and reagents

All chemicals and reagents were purchased from Sigma-Aldrich (St. Louis, MO) unless otherwise specified. GR-1 (AbD Serotec, MCA7716), F4/80 (Biolegend, 122602), Alexa Fluor 555 (Life Technologies), intercellular adhesion molecule (ICAM-1) (M-19) (Santa Cruz, sc-1511), α -smooth muscle actin (α SMA) (Abcam, ab7817) and pSMAD3 (Cell Signaling, C25A9) were utilized for immunoblot or immunohistochemistry. Glyceraldehyde 3-phosphate dehydrogenase (GAPDH) (FL-335) (Santa Cruz, 25778) served as loading control

for immunoblots.

Immunoblotting

Protein was extracted by using RIPA buffer [including 1 mmol/L Na₃VO₄, 50 mmol/L NaF, protease inhibitors (Roche Diagnostics, Mannheim, Germany)] and resolved with a 10% polyacrylamide gel, followed by blotting on a polyvinylidene fluoride membrane (Merck Millipore, Darmstadt, Germany). Membranes were blocked with 3% bovine serum albumin and incubated with a primary antibody overnight (4 °C). Incubation with the second antibody was performed for 1 h at room temperature. All washing steps were carried out in TBST [20 mmol/L Tris, 150 mmol/L NaCl, 0.1% Tween20 (Merck)]. Bands were visualized with SuperSignal™ West Pico Chemiluminescent Substrate (Life Technologies) and Versa Doc Imaging System Modell 3000 (BioRad).

Immunohistochemistry

Ice-cold acetone-fixed cryosections (6 μ m) were blocked with 10% donkey serum (Dianova) and stained with primary antibodies against ICAM-1. Paraformaldehyde-fixed (Merck, Darmstadt, Germany) and paraffin-embedded tissue sections (1.5 μ m) were dehydrated and rehydrated with ascending and descending ethanol series including deparaffinising with Histoclear (Biozym, Hessisch Oldendorf, Germany). After blocking with 10% donkey serum, paraffin sections were stained with primary and a secondary antibody. Mounting was accomplished with VectaShield DAPI (Vector Laboratories Inc., Burlingame, CA).

Periodic acid Schiff and sirius red staining

Paraffin-embedded sections were prepared as described above. Periodic acid Schiff staining was performed with periodic acid (0.5%) (Merck), Schiff's reagent (Merck) and hematoxylin (Fluka). For Sirius red staining, sections were treated with 0.2% phosphomolybdic acid, 0.1% Sirius red in 3% picric acid, 0.01 mol/L HCl, 70% and 100% ethanol in the order specified.

Quantitative real-time polymerase chain reaction

Total RNA was extracted from murine kidneys using the RNeasy Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. Equal amounts of total RNA were reverse transcribed with the Transcriptor First Strand cDNA Synthesis kit from Roche Diagnostics. Real-time-quantitative polymerase chain reaction (RT-qPCR) was performed by a LightCycler 480 II (Roche). Triplicate RT-qPCR analyses were executed for each sample, and the obtained threshold cycle values (CT) were averaged. Gene expression was normalized to the expression of the housekeeping gene, yielding the Δ CT value.

Statistical analysis

Statistical significance was assessed by independent samples and unpaired *t* test as well as Mann-Whitney

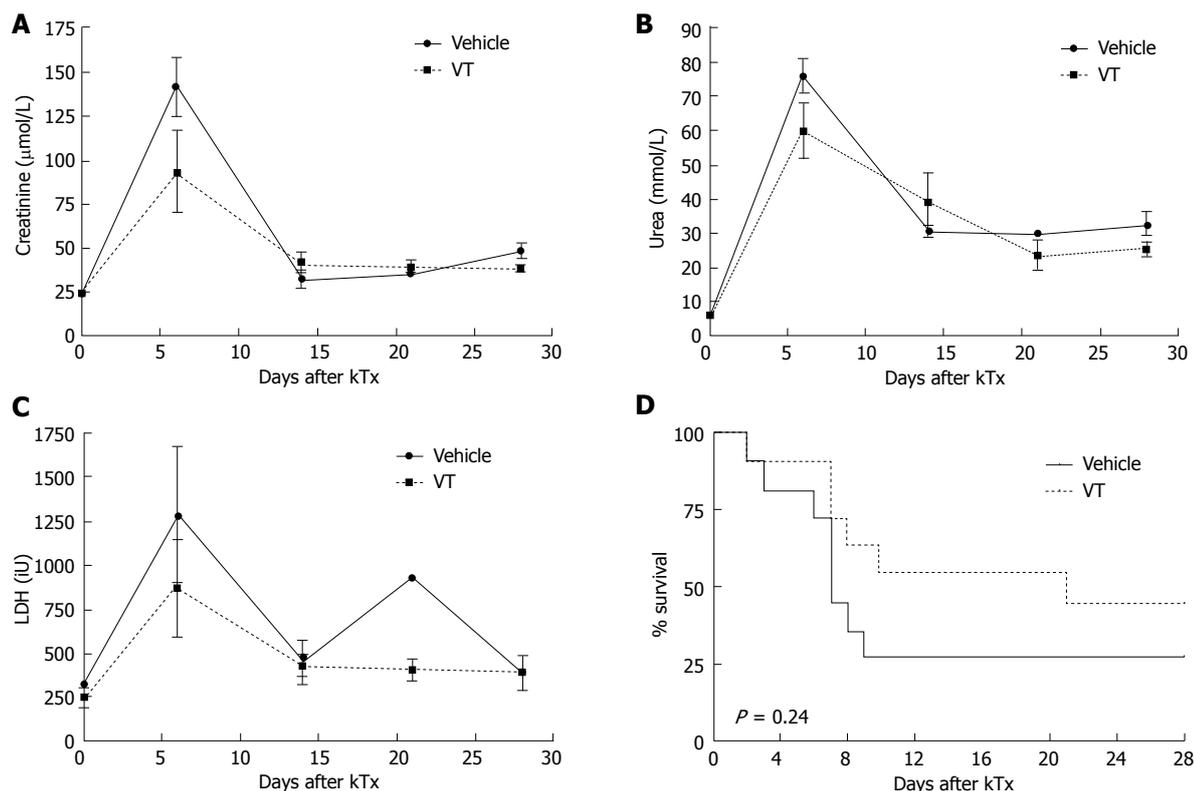

Figure 1 Vasculotide shows trends to improved kidney function and survival in an MHC-mismatched renal transplant model. C57Bl/6 donor mice received 500 ng VT or vehicle prior to surgery (-1 h). Balb/c recipients were injected with 500 ng VT *i.p.* or vehicle directly and on day 3 after kidney transplantation. A-C: Kidney function [serum creatinine, urea and lactate dehydrogenase (LDH) levels] was monitored on day 6, 14, 21 and 28 after transplantation in murine serum and analyzed with unpaired *t* test (day 6, $n = 7-10$); D: Kaplan-Meier survival after MHC-mismatch kidney transplantation ($n = 11$ per group). VT: Vasculotide.

test as indicated. Survival data were analyzed by Log-Rank test. All experimental results are presented as mean \pm SEM or median and a two-tailed *P* value of less than 0.05 was considered to be statistical significant. Analysis and graph generation were performed in GraphPad Prism 6.0 (La Jolla, CA).

RESULTS

VT improves renal transplant function and survival

Given the beneficial properties of Tie2 activation on the endothelial function, we hypothesized that early exogenous activation of Tie2 might also be beneficial in long-term transplant function. Therefore, we established an MHC-incompatible murine kidney transplant model^[22] and treated the mice with 2 doses of VT or vehicle control. Serial blood measurements after transplantation (day 3, 6, 14, 21, 28) showed that renal function was indeed slightly improved upon VT treatment at early time points (serum creatinine vehicle-treated ($n = 8$): 142 ± 17 $\mu\text{mol/L}$ vs VT-treated ($n = 9$): 94 ± 23 $\mu\text{mol/L}$, $P = 0.12$; urea level vehicle-treated ($n = 8$): 76 ± 5 mmol/L vs VT-treated ($n = 10$): 60 ± 8 mmol/L , $P = 0.13$ using unpaired *t* test) was observed on day 6 (Figure 1A and B). LDH as a broad surrogate marker for cell death showed a similar trend in vehicle-treated animals compared to the VT group potentially indicating that VT might reduce apoptosis/necrosis [vehicle-treated ($n =$

7): 1288 ± 383 iU vs VT-treated ($n = 8$): 870 ± 275 iU, $P = 0.38$ using unpaired *t* test] (Figure 1C). Additionally, we analyzed survival after transplantation and observed a trend towards improved survival in VT- compared to vehicle-treated mice (27% vs 54%, $P = 0.24$, $n = 11$) (Figure 1D). Together, these data indicate that early VT treatment might improve kidney function after renal transplantation.

Infiltration of inflammatory cells is diminished upon VT treatment

We next studied histological changes to investigate graft rejection and inflammation in transplanted kidneys. One can easily appreciate the glomerular as well as the interstitial inflammatory infiltrates in the vehicle-treated mice on day 28 after transplantation (Figure 2A and C, left side). In the lower left panel (Figure 2C, left side) almost no intact tubular structures are detectable anymore. VT treated mice exhibited a much weaker inflammatory burden both in the glomerulus as well as the interstitium (Figure 2, right side). These results were confirmed by a histological semi-quantification (Table 1) regarding interstitial inflammation [vehicle ($n = 3$): Median = 4.0 (25% quartile: 4.0%-75% quartile: 4.0) vs VT-treated ($n = 5$): 2.0 (2.0-2.0), $P = 0.02$ using Mann-Whitney test] and glomerular injury [vehicle ($n = 3$): 4.0 (3.0-4.0) vs VT-treated ($n = 5$): 2.0 (1.0-2.0), $P = 0.04$ using Mann-Whitney test] (Figure

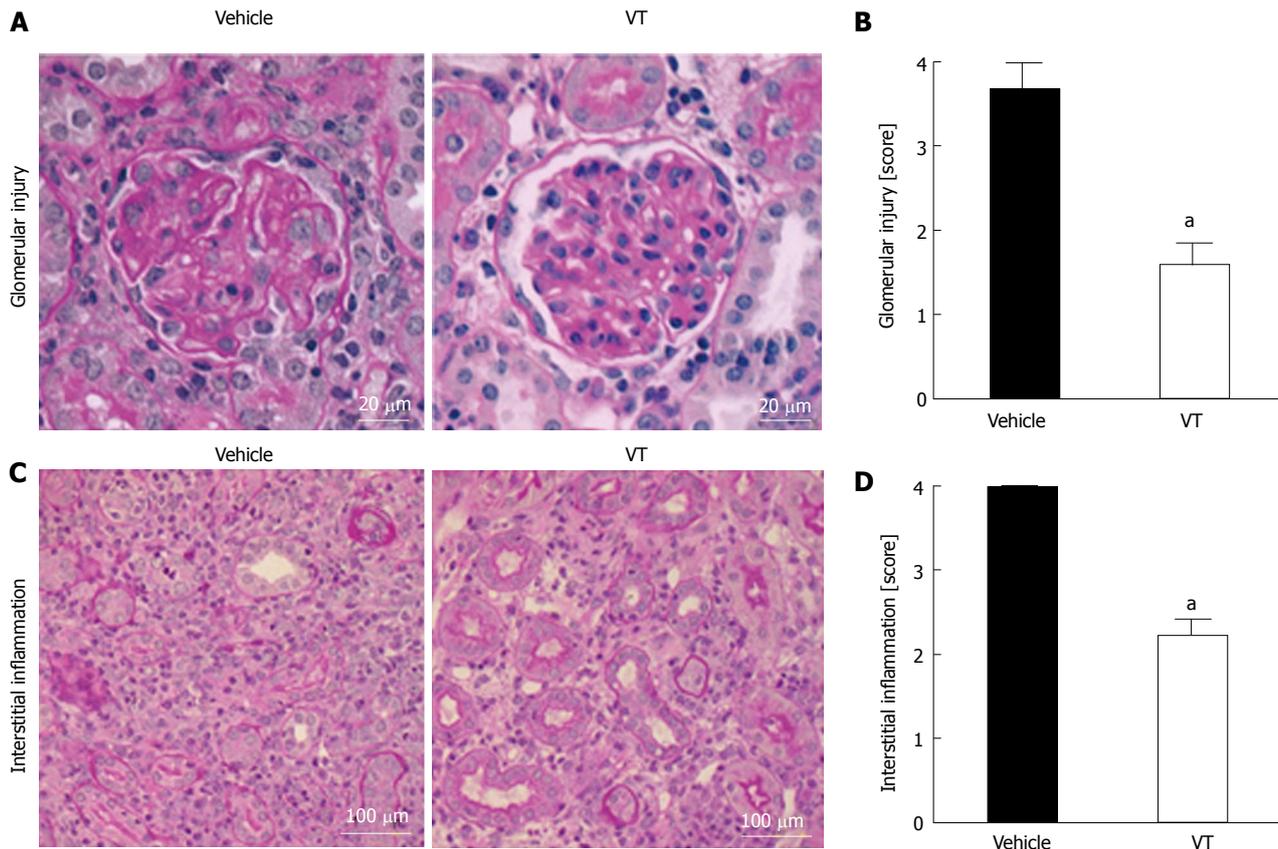

Figure 2 Vasculotide-treated mice show less infiltration of inflammatory cells in the kidney. A: Exemplary PAS staining of kidneys from mice treated with vehicle or VT. Glomerular injury was evaluated on day 28 after transplantation; B: Semi-quantification of glomerular injury by surveying kidney cross-sections. Scoring was done as described above (see Table 1) (vehicle $n = 3$; VT $n = 5$) ($^*P < 0.05$); C: PAS staining for peritubular injury in transplanted kidneys from mice treated with vehicle or VT; D: Semi-quantification of interstitial inflammation by surveying kidney cross-sections from transplanted mice ($^*P < 0.05$). Scoring was done as described above (Table 1) (vehicle $n = 3$; VT $n = 5$). Semi-quantification was assessed using Mann-Whitney test. VT: Vasculotide; PAS: Periodic acid Schiff.

Table 1 Scoring system for semiquantification of periodic acid Schiff staining

Interstitial inflammation	0 = no interstitial inflammation, < 5% of interstitium affected
	1 = mild interstitial inflammation, 5%-25% of interstitium affected
	2 = moderate interstitial inflammation, 25%-50% of interstitium affected
	3 = severe interstitial inflammation, 50%-75% of interstitium affected
	4 = very severe interstitial inflammation, > 75% of interstitium affected
Glomerular injury	0 = no glomerular injury
	1 = mild glomerular injury, < 10% of glomeruli damaged
	2 = moderate glomerular injury, 10%-50% of glomeruli damaged
	3 = severe glomerular injury, 50%-75% of glomeruli damaged
	4 = very severe glomerular injury, > 75% of glomeruli damaged

2B and D). These results suggest that two early doses of VT are sufficient to reduce infiltration of inflammatory cells into the graft thereby potentially preventing graft dysfunction and rejection.

VT reduces vascular inflammation and tissue infiltration

Keeping in mind the profound histological changes indicating that VT prevents infiltration of immune cells, we wanted to further analyze vascular inflammation and the infiltrative cell population. Therefore, we performed fluorescent immunohistochemistry for ICAM-1, for Gr-1 (a marker of granulocytes), as well as F4/80 (macrophages). Kidney cross-sections from VT-treated mice exhibit much less ICAM-1 expression than vehicle-treated mice (Figure 3A). Additionally, whole kidney homogenates also depicted less ICAM-1, as shown by immunoblotting (Figure 3D). Presumably as a consequence of less adhesion molecule expression we also noted a reduction of Gr-1 and F4/80 in the peritubular interstitium of VT-treated mice (Figure 3B and C). Together these data indicate that early VT regulates vascular adhesion molecule expression thereby reducing overwhelming tissue infiltration of inflammatory cells in the later post-transplant course.

VT ameliorates fibrosis progression

Fibrosis as a consequence of acute or chronic inflammation is a key contributor to organ dysfunction. After kidney transplantation we observed an increased expression of α SMA, a broad marker of fibrosis (Figure

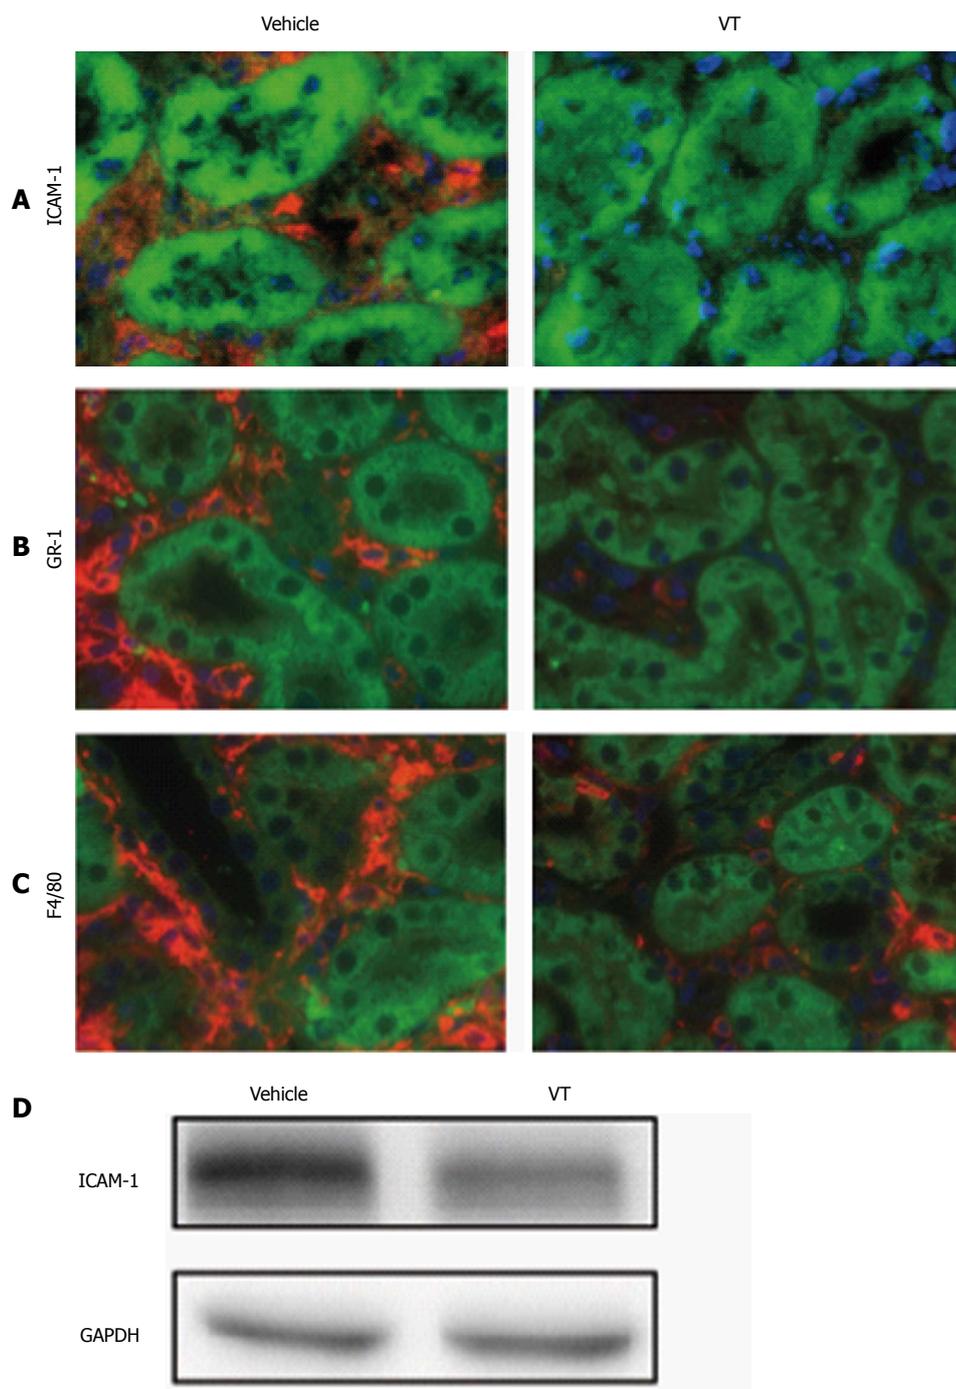

Figure 3 Vasculotide treatment reduces vascular inflammation and tissue infiltration in kidney transplantation. Fluorescent immunohistochemistry for (A) ICAM-1 (red), (B) Gr-1 (red) and (C) F4/80 (red) in kidney cross-sections of transplanted mice (vehicle or VT-treated) on day 28 after transplantation. Autofluorescence is shown in green. Images are exemplary for $n = 5$ /condition; D: Immunoblot of murine kidney homogenate for ICAM-1 and GAPDH for the same conditions. VT: Vasculotide; ICAM-1: Intercellular adhesion molecule; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

4A and B, left side). However, upon VT treatment tubular as well as glomerular damage were reduced with regard to α SMA expression (Figure 4A and B, right side). To further substantiate our finding, we visualized collagen fibers by Sirius red (Figure 4C) and observed profound differences between vehicle and VT-treated mice. VT appears to prevent inflammation-driven collagen formation. Pathological phosphorylation of SMAD3 a canonical downstream target of TGF β signaling after transplantation was also reduced in mice treated with

VT (Figure 4D). Taken together, VT might prevent the induction of TGF β signaling and collagen formation leading to reduced fibrosis and organ dysfunction.

VT does not prevent induction of inflammation on the transcriptional level

To further investigate the anti-inflammatory properties of VT in murine kidney transplantation, we analyzed different markers of inflammation (ICAM-1, VCAM-1, TGF β , collagen-1, collagen-3 and fibronectin) on the

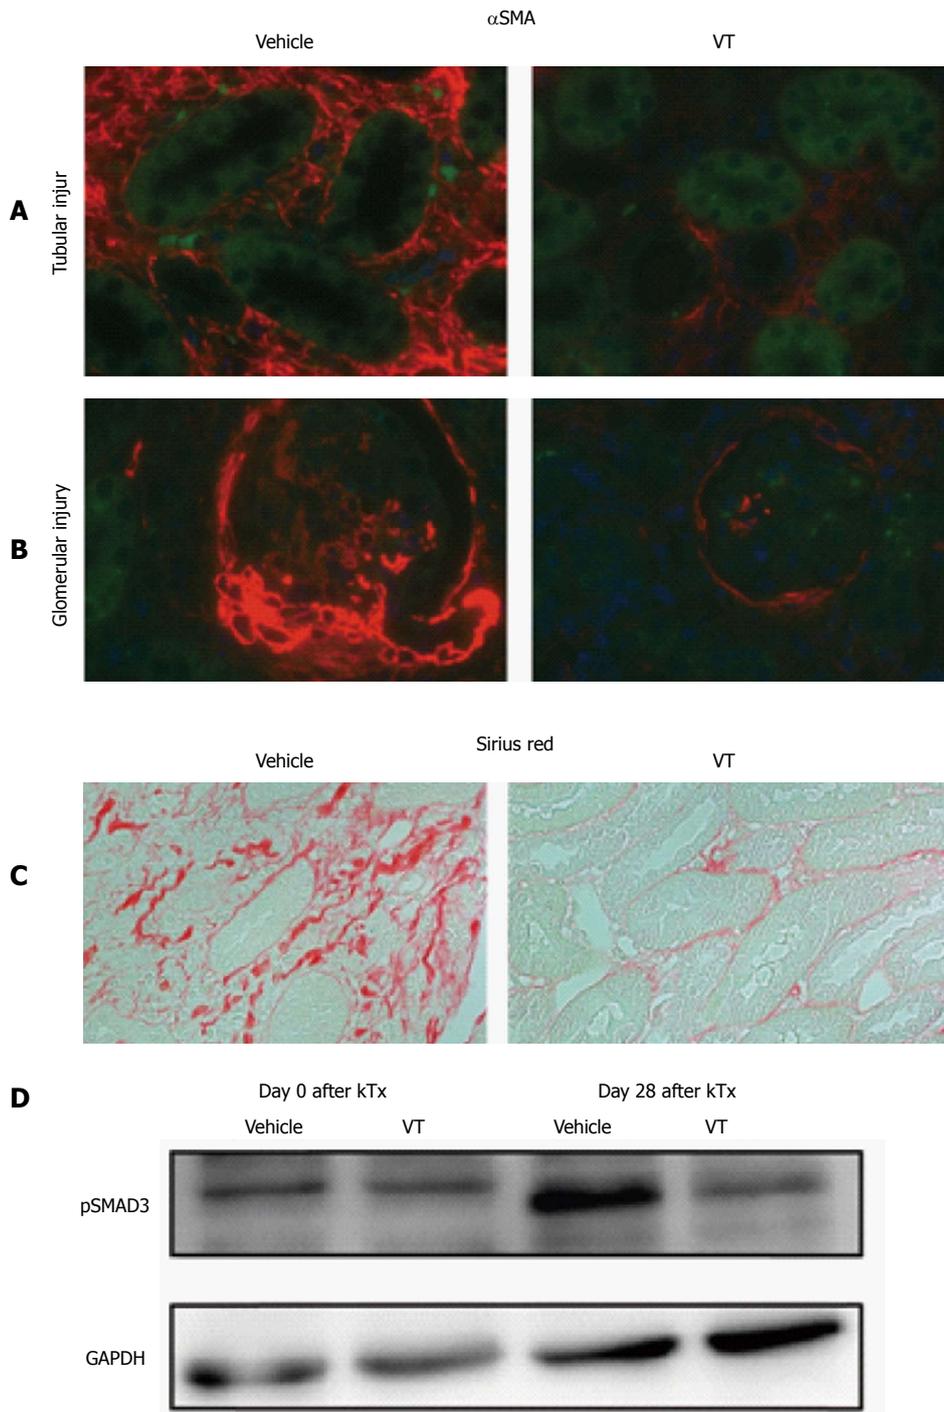

Figure 4 Vasculotide ameliorates fibrogenesis. Autofluorescence is shown in green. Images are exemplary for $n = 5$ /condition; C: Sirius red staining for the same conditions (D) Immunoblot of murine kidney homogenates for pSMAD3 in healthy (day 0) and kidney transplanted mice (day 28) upon vehicle or VT treatment. VT: Vasculotide; α SMA: α -smooth-muscle-actin; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

transcriptional level. Notably, we detected a dramatic upregulation of these markers in vehicle- and VT-treated animals on day 28 after transplantation compared to explanted donor kidneys on day 0. Despite the differences on protein level demonstrating that VT-treatment indeed reduces inflammation in a murine renal transplant model, differences on the transcriptional are not present on day 28 after transplantation (Figure 5 analyzed using Mann-Whitney test, $n = 3-5$).

DISCUSSION

The endothelium plays an important role in maintaining organ function and homeostasis in health and disease. As part of the rejection process of solid organ transplants, the endothelium is characterized by a highly activated proinflammatory phenotype. In routine kidney transplant pathology this has nowadays been implicated in the grading of rejection by using a so-called C4d

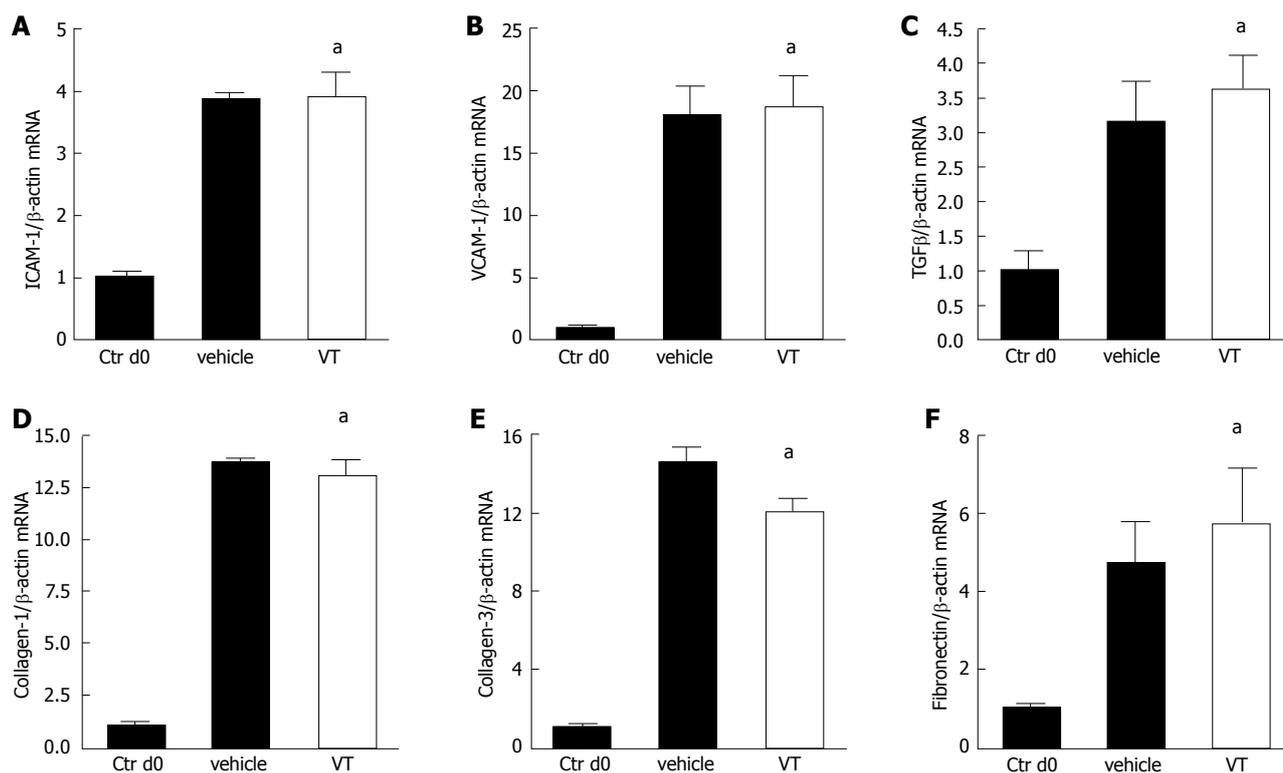

Figure 5 Anti-inflammatory properties of vasculotide are not regulated on the transcriptional level. A-F: Mice were treated with vehicle ($n = 3$) or VT ($n = 5$) and underwent kidney transplantation. Transplanted kidneys were harvested on day 28 after transplantation. Explanted donor kidneys from day 0 served as control ($n = 3$). Expression levels of Intercellular adhesion molecule (ICAM-1), Vascular cell adhesion protein 1 (VCAM-1), Transforming growth factor β (TGF β), collagen-1, collagen-3 and fibronectin in kidney homogenates were determined *via* RT-qPCR and analyzed using Mann-Whitney test ($^*P < 0.05$). VT: Vasculotide.

staining that does reflect complement activation in the endothelium^[23]. We therefore hypothesized that pharmacological stabilization of the vasculature might be beneficial.

Our approach demonstrated that exogenous activation of the endothelium-stabilizing Tie2 receptor with the drug-like compound, termed VT, might prevent graft dysfunction and inflammation. Administration of VT showed trends toward improved organ function and survival in a renal transplant model. One beneficial effect of VT in kidney transplantation could be attributed to phosphorylation of the Tie2 receptor thereby activating the PI3K/Akt pathway and suppressing NF κ B signaling. This assumed canonical mechanisms of action of VT resulted in reduced tissue infiltration of immune cells and expression of endothelial adhesion molecules. Furthermore, early VT administration was sufficient to ameliorate classical fibrogenic signaling (*e.g.*, SMAD3/TGF β) thereby reducing collagen formation and the development of fibrosis. Interestingly, we could not detect any transcriptional regulation of neither adhesion molecules nor inflammatory mediators. How VT regulates endothelial inflammation has to be thoroughly investigated in future projects.

Additionally, organ function in VT treated mice was slightly better at early time points exclusively. Due to the fact, that animals were treated at day 0 and 3 after transplantation, the beneficial effect of VT would be expected to decrease over time. Re-dosing could

further ameliorate outcome after kidney transplantation. To investigate and improve the beneficial effects of VT in kidney transplantation, pharmacokinetics of this Tie2 agonist need to be further investigated. Most experimental data on VT that showed improved outcome are derived from acute short-term injury models, such as sepsis and influenza^[19,21]. These data confirm however that the endothelium indeed plays an important role in the pathogenesis of various medical conditions and that maintaining endothelial homeostasis early in the pathogenesis might provide protection. Some work on slow-progressing disease models, such as diabetes and tumor growth used extensive re-dosing of VT to maintain beneficial effects at the highest possible level^[17,24].

Due to the small number of animals that survived until day 28, we were not able to include more animals into our studies. Nevertheless, our VT-treated mice show a clear trend towards improvement after kidney transplantation indicating a potential type II error in our statistical analysis.

Another aspect that we did not investigate but that is - at least theoretically - of high relevance is the putative long-term effect of an early short-term VT treatment. It might very well be that an improved early graft function has relevant implications for long term graft performance, as our histological data at day 28 suggest and as it has been demonstrated for delayed graft function^[25].

In summary, our study demonstrated that early VT treatment slightly improves graft function in an MHC-mismatched kidney transplant model potentially *via* regulation of endothelial activation and transmigration of harmful inflammatory cells into the transplant's interstitium. The Tie2 agonistic strategy might hold promise as a potential therapeutic in transplant medicine and future examination of long-term results are highly desirable.

We thank Yvonne Nicolai for technical assistance.

COMMENTS

Background

Early graft dysfunction as well as acute rejection after solid organ transplantation are characterized by a proinflammatory microvascular endothelium. The Angiopoietin/Tie2 system plays an important role in maintenance of baseline endothelial barrier function and its response to injury. Activation (*i.e.*, phosphorylation) of the Tie2 receptor promotes endothelial homeostasis as well as anti-inflammatory properties. The authors therefore analyzed the potential of the Tie2 activating drug-like compound "vasculotide" (VT), as a novel therapeutic strategy in an MHC-mismatched renal transplant model.

Research frontiers

As long as the mystery of tolerance remains unsolved pharmacotherapy for transplanted patients is obligatory based on immunosuppressive regimens that come with a high burden of adverse events. Novel approaches aim to find therapeutic strategies that do not weaken the host or graft function. Here, the authors present a putative approach that promotes vascular stability/quiescence thereby preventing graft dysfunction and loss.

Innovations and breakthroughs

Targeting the endothelium as a direct interface between self and non-self offers the opportunity to interfere with graft specifically at the site of rejection.

Applications

The synthetic Tie2 agonist VT promotes vascular quiescence and improves graft function after allogenic solid organ transplantation. The potency of VT has recently been demonstrated in different models of vascular diseases underlining its potential therapeutic relevance. In the future, toxicity studies and first clinical trials are planned, specifically for the treatment of acute kidney injury.

Terminology

Angpt: Angiopoietin; α SMA: α -smooth muscle actin; EC: Endothelial cell; ICAM-1: Intercellular adhesion molecule; LDH: Lactate dehydrogenase; VT: Vasculotide.

Peer-review

This is an interesting study in which authors show that VT - a synthetic Tie2 agonist- may improved renal transplant outcome.

Abstract

AIM

To describe the thromboelastography (TEG) "reference" values within a population of liver transplant (LT) candidates that underline the differences from healthy patients.

METHODS

Between 2000 and 2013, 261 liver transplant patients with a model for end-stage liver disease (MELD) score between 15 and 40 were studied. In particular the adult patients (aged 18-70 years) underwent to a first LT with a MELD score between 15 and 40 were included, while

all patients with acute liver failure, congenital bleeding disorders, and anticoagulant and/or antiplatelet drug use were excluded. In this population of cirrhotic patients, preoperative haematological and coagulation laboratory tests were collected, and the pretransplant thromboelastographic parameters were studied and compared with the parameters measured in a previously studied population of 40 healthy subjects. The basal TEG parameters analysed in the cirrhotic population of liver candidates were as follows: Reaction time (r), coagulation time (k), Angle-Rate of polymerization of clot (α Angle), Maximum strength of clot (MA), Amplitudes of the TEG tracing at 30 min and 60 min after MA is measured ($A30$ and $A60$), and Fibrinolysis at 30 and 60 min after MA ($Ly30$ and $Ly60$). The possible correlation between the distribution of the reference range and the gender, age, MELD score (higher or lower than 20) and indications for transplantation (liver pathology) were also investigated. In particular, a MELD cut-off value of 20 was chosen to verify the possible correlation between the thromboelastographic reference range and MELD score.

RESULTS

Most of the TEG reference values from patients with end-stage liver disease were significantly different from those measured in the healthy population and were outside the suggested normal ranges in up to 79.3% of subjects. Wide differences were found among all TEG variables, including r (41.5% of the values), k (48.6%), α (43.7%), MA (79.3%), $A30$ (74.4%) and $A60$ (80.9%), indicating a prevailing trend to hypocoagulability. The differences between the mean TEG values obtained from healthy subjects and the cirrhotic population were statistically significant for r ($P = 0.039$), k ($P < 0.001$), MA ($P < 0.001$), $A30$ ($P < 0.001$), $A60$ ($P < 0.001$) and $Ly60$ ($P = 0.038$), indicating slower and less stable clot formation in the cirrhotic patients. In the cirrhotic population, 9.5% of patients had an r value shorter than normal, indicating a tendency for faster clot formation. Within the cirrhotic patient population, gender, age and the presence of hepatocellular carcinoma or alcoholic cirrhosis were not significantly associated with greater clot firmness or enhanced whole blood clot formation, whereas greater clot strength was associated with a MELD score < 20 , hepatitis C virus and cholestatic-related cirrhosis ($P < 0.001$; $P = 0.013$; $P < 0.001$).

CONCLUSION

The range and distribution of TEG values in cirrhotic patients differ from those of healthy subjects, suggesting that a specific thromboelastographic reference range is required for liver transplant candidates.

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Thromboelastography provides a more comprehensive coagulation assessment than routine tests in cirrhotic patients. We evaluated the baseline thromboelastography (TEG) tracing and preoperative laboratory tests of cirrhotic patients undergoing liver transplant (LT) to generate a reliable picture of their coagulation profile. We also studied how TEG value distribution in cirrhotic patients could be modified by gender, age, model for end-stage liver disease score and liver disease characteristics. End-stage liver disease is associated with considerable changes in TEG variables, which should be allowed for when interpreting TEG traces in cirrhotic patients. TEG reference values derived from a healthy population could be misleading in the management of cirrhotic patients during LT.

Thromboelastographic reference ranges for a cirrhotic patient population undergoing liver transplantation. *World J Transplant* 2016; 6(3): 583-593 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i3/583.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i3.583>

INTRODUCTION

Laboratory evaluations of bleeding disorders have been conducted with standard clotting assays such as prothrombin time (PT) and activated partial thromboplastin time (PTT) for a long time. However, standard laboratory tests fail to give comprehensive information about the bleeding tendency of cirrhotic patients. Tripodi *et al*^[1] showed that patients suffering from chronic liver disease as well as healthy subjects have the ability to generate the same amount of thrombin in stable liver disease conditions.

PT International Normalized Ratio (INR) tests performed in the absence of thrombomodulin are of little use in representing the real state of coagulation in cirrhotic patients. Furthermore, such tests are not standardized across centres when they are used for patients with liver disease^[2,3].

Because of these limits, the interest in assays performed with thromboelastography (TEG), which offers a more targeted approach to assess the overall outcome of the interactions of clotting factors beyond the initiation of clot formation, has progressively increased. However, even though thromboelastography is a useful tool for measuring global haemostasis during hepatic surgery and liver transplant, allowing the optimization of blood product selection and usage, its methodology is not standardized. Normal TEG values, as reported by manufacturers and in the literature, are determined from the average clotting time of healthy volunteers^[4]. Although investigators have tested the correlation between TEG values and the risk of bleeding in various surgical populations^[5,6], it is possible that standard TEG

cut-off values derived from a healthy population have a different and misleading meaning in the management of cirrhotic patients during liver transplantation (LT). Addressing the issue of the reference values, the TEG analyzer manufacturer suggests that each new user should test 20 healthy volunteers to generate normal values to be used locally as reference values at each institution, prior to clinical use^[7]. The consequence is that TEG suffers from a lack of proven reliability^[8,9], also motivated by the large range of normal values. However, this wide normal range defined for healthy people, is unreliable when applied to patients with liver disease, making it necessary to define thromboelastographic "reference ranges" for cirrhotic patients.

Under physiological conditions, the haemostatic system of these patients reaches a new equilibrium determined by a parallel decline of the pro- and anticoagulant drivers, which is represented by specific thromboelastographic values^[10]. The main aim of the present study was to describe the thromboelastographic preoperative coagulation condition of cirrhotic patients undergoing liver transplant to generate a more reliable picture of their common coagulation profile. A further aim of the study was to compare the TEG range distribution of cirrhotic patients with a population of healthy subjects, verifying that the range corrected for cirrhotic patients could be modified by gender, age and model for end-stage liver disease (MELD) score as well as liver disease characteristics.

MATERIALS AND METHODS

Between 2000 and 2013, 473 patients underwent LT in Liver Transplant Center of Policlinico di Modena (Italy). After the approval of the local Ethical Authority and the receipt of written informed consent, the thromboelastographic parameter distribution of a selected population of cirrhotic patients was studied according to the following inclusion and exclusion criteria: adult patients (aged 18-70 years), first LT, and MELD score between 15 and 40. The exclusion criteria were as follows: acute liver failure, congenital bleeding disorders (*i.e.*, haemophilia A and B), and anticoagulant and/or antiplatelet drug use. Therefore, the analysis was performed in 261 (55%) patients who underwent LT. A MELD score between 15 and 40 was chosen because it is the most frequently used in the literature, and the AISF (Italian Association for Liver Study) also recommends it for listing a patient for LT^[11]. In this population of cirrhotic patients, preoperative haematological and coagulation laboratory tests were collected, and thromboelastographic traces were studied and compared with those obtained from a previously studied population of 40 healthy subjects. The study protocol approved by the Institutional Review Board of Azienda Ospedaliera-Universitaria, Modena (N°:139/14 TRIGGER) was conducted in accordance with the provisions of the Declaration of Helsinki and Good Clinical Practice guidelines.

Blood samples were collected with the double-syringe technique from a clean venipuncture. The first 6 mL of each sample was discarded. All the healthy subjects (20 males and 20 females), selected from among residents, students and nurses, had not taken drugs known to affect coagulation parameters or platelet aggregation for at least 1 wk before the collection of blood samples.

Distribution ranges of the basal TEG parameters (r , k , α , MA , $A30$, $A60$, $Ly30$ and $Ly60$) in the cirrhotic population of patients were analysed. The possible correlation of the distribution of reference ranges with gender, age, MELD score (higher and lower than 20) and indications for transplantation (liver pathology) were also investigated. In particular, a MELD cut-off value of 20 was chosen to verify the possible correlation between thromboelastographic reference range and MELD score. This cut-off is the most frequently used parameter in the literature for predicting mortality risk after LT^[12,13]. Two TEG[®] 5000 Hemostasis Analyzers (Haemoscope Inc., Skokie, Illinois, United States) were used. The strength of clot formation is graphically represented over time as the tracing shown in Figure 1.

Maintenance and quality controls were performed daily in accordance with manufacturer recommendations. Native arterial blood samples were collected from a radial artery cannulated before induction of anaesthesia and were analysed without adding anticoagulant or activator. We routinely use heparinase TEG, only after reperfusion in all cases and from the baseline only in patients with fulminant liver failure.

Blood samples were always handled by the same three anaesthesiologists. TEG tracings were started within 4 min after sampling. Clot formation was triggered by contact activation. TEG tracings were displayed before the surgical procedure in the operating room. Parameters normally used to assess the process of coagulation are as follows^[8,14]: r (*coagulation time*) is the time from the start of the TEG tracing until the TEG trace amplitude reaches 2 mm. This represents the rate of initial fibrin formation and is functionally related to plasma clotting factors and circulating inhibitor activity. Prolongation of the r time may be a result of coagulation factor deficiencies or severe hypofibrinogenemia; k (*Clot Formation time*) is measured from r to the point where the amplitude of the tracing reaches 20 mm. This is the time taken to reach a standard clot firmness and is affected by the activity of the intrinsic clotting factors, fibrinogen and platelet; α *Angle* (Angle-Rate of polymerization of clot) is the angle formed by the slope of the TEG tracing from the r to the k value. This represents the rate of clot growth and describes the polymerization of the structural elements involved in clotting^[15]; MA (Maximum Clot Firmness) is the maximum amplitude of the TEG tracing. This reflects the strength of the clot and is a direct result of the function of platelets and plasma factors and their interaction; the $A30$ and $A60$ parameters are the amplitudes of the TEG tracing at 30 min and 60 min after MA is measured; the

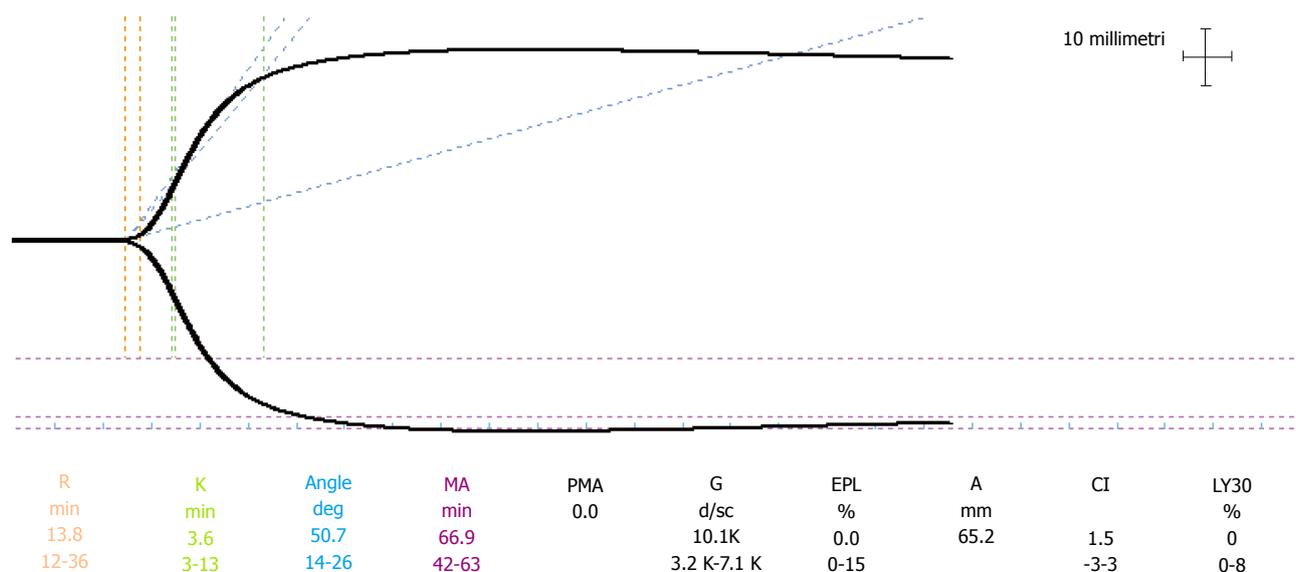

Figure 1 Normal trace. The reference ranges are those defined by manufacturer thromboelastography® 5000 Hemostasis Analyzers (Haemoscope Inc., United States). PMA: Projected MA.

Study group (n = 261)	
Males/females (n/n), %	(193/68) 73.9%/26.1%
Age (yr)	53.5 ± 9.4
Body mass index (kg/m ²)	26.18 ± 6.40
MELD score	24 ± 6.5
Indication for liver transplantation (n, %)	
Alcoholism	40 (15.3 %)
Viral	189 (72.4%)
Colectatic	15 (5.7%)
Other	17 (6.5 %)
HCC	107 (41 %)
Laboratory data	
Hb (g/dL)	11.3 ± 2.2 (nv:12-16)
Hct (%)	3.4 ± 6.2 (nv: 36-46)
PLT (10 ³ /μL)	83.2 ± 66.7 (nv: 150-450)
PT (%)	53.6 ± 22.4 (nv: 70-100)
INR	1.7 ± 0.7 (nv: 0.84-1.24)
aPTT ratio	2.0 ± 9.3 (nv: 0.82-1.24)
Fibrinogen (mg/dL)	190 ± 120 (nv: 200-400)
ATIII (%)	50 ± 27(nv: 80-120)

Data are expressed as the median ± SD. MELD: Model for end stage liver disease; HCC: Hepatocellular carcinoma; PLT: Platelets; PT: Prothrombin time; INR: International normalized ratio; nv: Normal values.

Ly30 and *Ly60* (Fibrinolysis at 30 and 60 min after MA) parameters measure percent lysis at 30 and 60 min after MA is reached. The *Ly30* and *Ly60* measurements are based on the reduction of the area under the TEG tracing from the time MA is measured until 30 (or 60) min after the MA.

Statistical analysis

Continuous data are reported as the mean ± SD (range) and/or median (reference ranges) and were compared using the two-sided Student’s *t* test for normally distributed parameters. Continuous non-

normally distributed data were compared using the Wilcoxon-Mann-Whitney test. Comparisons between groups for categorical variables were performed using the χ^2 test with Yates’ correction or Fisher’s exact test when appropriate. Descriptive methods were used to calculate the 2.5% and 97.5% percentiles according to the NCCLS guidelines to establish reference ranges^[16]. Reference ranges were not calculable for groups of less than 40 cases. Statistical significance was set at *P* < 0.05. Statistical analyses were performed using IBM SPSS Statistics for Windows, Version 19.0., IBM Corp., Armonk, NY. The statistical review of the study was performed by a biomedical statistician.

RESULTS

The demographic profiles and laboratory data of the patient population and their indication for LT are shown in Table 1.

Reference value distribution in the whole population

Median, minimum and maximum value and reference ranges, for the whole population of cirrhotic patients undergoing LT and comparison with healthy subjects, are presented for *r*, *k*, α , MA, A30, A60, *Ly30* and *Ly60* in Table 2.

Most TEG reference values from patients with end-stage liver disease (ESLD) were found to be outside the suggested normal ranges and were abnormal in up to 79.3% of subjects. Wide differences were found for all TEG variables, including *r* (41.5% of the values), *k* (48.6%), α (43.7%), MA (79.3%), A30 (74.4%) and A60 (80.9%), indicating a prevailing trend to hypocoagulability. The differences between mean TEG values obtained from healthy subjects and the cirrhotic population were statistically significant for *r* (*P* = 0.039), *k* (*P* < 0.001), MA (*P* < 0.001), A30 (*P* < 0.001), A60

Number of test results outside the normal reference range proposed by the manufacturer. *r*: Time to initial fibrin formation; *k*: Time to clot formation; α : Alpha angle, rate of clot formation; MA: Maximum amplitude, absolute clot strength; A30: Maximum amplitude at 30 min after MA; Ly30: Fibrinolysis at 30 min after MA; Ly60: Fibrinolysis at 60 min after MA; ¹*P* value expresses the significant differences between the mean values obtained from the study population and from the healthy population.

($P < 0.001$) and Ly60 ($P = 0.038$), indicating slower and less stable clot formation in cirrhotic patients (Table 2). In the cirrhotic population 25 (9.5%), patients had *r* values shorter than normal, indicating a tendency to faster clot formation.

Reference values distribution according to patient gender, age and liver disease characteristics

A comparison of the average values of TEG parameters in the cirrhotic patient population did not show any statistically significant difference for gender and age (Table 3). Gender and age were not significantly associated with greater clot firmness or with enhanced whole blood clot formation (Table 3).

Patients with a MELD score less than 20 showed greater clot firmness (higher MA, A30 and A60) compared with patients with a MELD score above 20, with MA ($P < 0.001$), A30 ($P < 0.001$) and A60 (Table 3, $P < 0.001$).

As shown in Table 3, the presence of hepatocellular carcinoma (HCC) or alcoholic cirrhosis did not result in faster coagulation activation (shorter *r* and *k*) or greater clot firmness (higher MA, A30, or A60). Patients with a MELD score under 20 showed no thromboelastographic difference based on the presence of HCC. Patients with HCV-related cirrhosis did not show faster activation of the coagulation process but showed significantly greater clot firmness compared with the other patients enrolled in the study because of end stage liver disease, according to MA ($P = 0.013$), A30 ($P = 0.021$) and A60 values ($P = 0.023$). Instead, hepatitis B virus-related cirrhosis did not appear to have any significant influence on clot activation or strength.

The clot strength of patients transplanted for cholestatic disease was enhanced (higher MA, A30, and A60; all with $P < 0.001$) compared with patients without cholestatic liver disease, and activation of the coagulation process did not result in faster activation

(Table 3).

DISCUSSION

Several authors have found a relatively poor correlation between bleeding and laboratory indices of coagulation in patients with chronic liver disease^[17,18]. INR and PTT explore only the first 5% of whole thrombin formation^[19,20] and are performed without adding thrombomodulin, making these techniques less optimal for exploring the physiological mechanisms regulating thrombin formation. The inadequacy of laboratory methods and the production of technologies applied to blood coagulation analysis have increased interest in thromboelastography for the management of acute peri-operative bleeding^[21-24]. TEG offers a rapid and global view of the coagulation processes^[15,25-27], but in spite of these advantages, users should keep in mind the poor reproducibility, the wide boundaries of normality, the lack of standardization^[8,28] and the need to define local normal ranges^[28].

Although TEG is a useful viscoelastic test for haemostatic monitoring, interpretation of its results requires care. In particular, the normal ranges of TEG variables may not apply under different operating and patient conditions such as in the cirrhotic patient population.

In the present study, we determined the range of distribution for TEG variables in a population of patients receiving a first liver graft for ESLD or HCC, with a MELD score between 15 and 40. We also underlined the differences in TEG values obtained from cirrhotic patients from those recorded in the normal, healthy population. In the cirrhotic population the *r* and *k* values were above the upper limit of normality in 32% and 47.9% of the population, respectively, indicating significant reduced activation of clot formation. In our population, the mean plasma fibrinogen concentration, PT, INR, aPTT and platelet number were outside

MELD: Model for End-stage Liver Disease; HCV: Hepatitis C virus; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; *r*: Time to initial fibrin formation; *k*: Time to clot formation; α : Alpha angle, rate of clot formation; *MA*: Maximum amplitude, absolute clot strength; *A*30: Maximum amplitude at 30 min after *MA*; *Ly*30: Fibrinolysis at 30 min after *MA*; *Ly*60: Fibrinolysis at 60 min after *MA*.

the normal laboratory reference range, indicating a reduction in clotting factors and platelet number, which are typical features of ESLD and could be a possible explanation for prolonged *r* and *k* values. The heparin-like effect (HLE) may also be another possible explanation for the longer *r* time recorded in the baseline tracings. This effect is not often represented in the first basal tracing (before the beginning of the surgical operation) and is usually less pronounced than that observed after reperfusion or in patients with acute liver failure^[29]. Because only 6% of patients undergoing LT have a severe HLE at baseline, which does not seem to correlate with an increase in blood requirements^[30], we do not usually perform this test at baseline, and we can only argue that a basal prolongation of the *r* time may more often be related to coagulation factor deficiencies or hypofibrinogenemia than to HLE, as shown in the laboratory data.

If a large percentage of *r* and *k* values were abnormally prolonged, then in 58.5% and 51.4% of cases, the same parameters were within the range of normality, expressing normal clot activation and firmness. This observation is in line with Stravitz' study^[31] that showed that the mean and median TEG parameters were within normal limits in a cohort of 273 patients with stable cirrhosis. Nevertheless, we studied a population of patients with decompensated cirrhosis, and we observed normal coagulation parameters in half of the cases and a shorter than normal *r* value in 9.5% of cases, indicating a tendency to faster clot activation.

These observations are in line with the new concept of rebalanced haemostasis, which better describes the coagulation condition of cirrhotic patients and is usually not represented in conventional laboratory tests^[10]. However, the haemostatic balance in a patient with liver disease is relatively unstable as evidenced by the occurrence of both bleeding and thrombotic complications^[27]. The shorter *r* values observed in 9.5% of patients could indicate cirrhotic patients' tendency to develop thromboembolic complications at appreciable rates (between 0.5% and 1.9%)^[32,33]. Another observation derived from the comparison of the two studied groups was the reduced clot firmness observed in the cirrhotic patient group. *MA*, *A*30 and *A*60 values were below the lower limit of normality for healthy people in up to 77%, 74% and 79% of patients, respectively. Thrombocytopenia, a typical feature of chronic liver disease^[34,35], may justify the high number of patients with lower values of *MA*, *A*30 and *A*60 compared with the normal population. Thrombocytopenia, *i.e.*, platelet counts between 30 and 100 × 10⁹/L^[36], is usually a sign of advanced liver atrophy^[37] and is frequently observed in cirrhotic patients arriving in the operating room for LT. Because of increased levels of von Willebrand factor and low levels of ADAMTS 13 metalloproteinase, cirrhotic patients can compensate for platelet abnormalities^[38]. Another possible explanation for these deteriorating TEG parameters may be the hypo- and dysfibrinogenemia associated with liver disease^[39,40]. In our patient population, the mean pre-

operative platelet number was $83.2 \pm 66.7 \times 10^9/L$, which has been shown in experimental observations to be sufficient to secure *in vitro* thrombin generation^[41], whereas the mean plasma fibrinogen concentration was 190 ± 122 mg/dL, a value that can require correction in cases of severe bleeding^[24]. So, a possible explanation for the reduced MA amplitude observed in the study could be a reduction in plasma fibrinogen concentration or fibrinogen function. Specific thromboelastographic tests^[42,43] may be helpful for determining the combined effects of thrombocytopenia and hypofibrinogenemia. Unfortunately, we have only been using TEG functional fibrinogen assays to detect signs of functional fibrinogen deficit in our intraoperative management since 2013, and we did not have enough data to identify the role of platelets and fibrinogen in determining MA amplitude.

Ly30 and *Ly60*, unlike the other parameters studied, have been shown to differentiate between the values recorded in healthy patients in a smaller number of subjects. *Ly30* and *Ly60* reference ranges were different from the healthy population in 0.76% and 10.7% of samples that were above the upper limit of normality. Cirrhosis has been variably associated with an increased tendency to fibrinolysis; however, hypofibrinolysis can also be the result of reduced levels of plasminogen and increased levels of plasminogen activator inhibitor^[34].

Therefore, although contrasting results have been reported, the balance of fibrinolytic processes is most likely restored in patients with liver disease by the parallel changes in the circulating levels of pro-fibrinolytic and anti-fibrinolytic agents^[18]. This phenomenon could explain the low number of patients who showed abnormal *Ly30* and *Ly60* values. During liver transplant, primary hyperfibrinolysis may occur in up to 60% of cases but is usually confined to the phase of hepatectomy and reperfusion^[44,45].

Because of the unique haemostatic behaviour of cirrhotic patients, specific thromboelastographic ranges have to be considered when managing liver transplant patients. Even if it was not the point of the study to demonstrate the clinical advantage of interpreting the TEG traces, taking into account the "reference ranges" for cirrhotic patients in term of blood products usage, we think that when managing bleeding during surgery, it would most likely be useful to correct TEG values while keeping in mind the reference ranges for this category of patients and not for healthy patients.

Realizing the wide variation in patient characteristics and in the causes of ESLD, we divided our cirrhotic population into subgroups of patients based on gender, age, MELD score and liver disease characteristics. For the potential effect of gender on TEG values, our analysis did not find any difference in coagulation activation and in clot firmness between females and males. Our results do not support the findings of Gorton *et al.*^[46] who showed enhanced coagulation activity in females with non-activated thromboelastography. Chronic liver disease induces a severe dysfunction of sex hormone metabolism, causing feminization in men

and infertility and amenorrhoea in women^[47]. This may explain the absence of difference in coagulation activation between males and females observed in our study. Lang *et al.*^[48] showed small differences in ROTEM variables between males and females that were not always statistically significant and argued that a sex-related definition of reference ranges in thromboelastometry is not necessary.

For age, we were not able to find any thromboelastographic signs of increased coagulability related to advanced age as otherwise described by Ng *et al.*^[49] who showed that hypercoagulability increases progressively beyond age sixty. In our study, *r*, *k*, α and *MA* were not dependent on age. The variables are functionally related to levels of plasma clotting factors, fibrinogen, platelets and activity of circulating inhibitors. It is possible that hypercoagulability, which is usually associated with advancing age due to increased plasma concentrations of fibrinogen, factor VII and factor IX, has not been observed in aged patients because of ESLD and coagulation factor synthesis impairment^[49,50].

In accordance with another study^[15], we found significantly higher clot firmness in cholestatic patients compared with cirrhotic patients undergoing liver transplant for other causes. Usually, patients with cholestatic cirrhosis show higher fibrinogen levels as well as stable or even increased platelet function^[51], which can justify the significantly higher clot firmness observed in the group of patients transplanted for cholestatic disease.

Patients with HCV-related cirrhosis showed a significant tendency towards higher clot firmness (higher *MA*, *A30* and *A60*), which was not observed in patients without HCV infection. In HCV liver diseases, Panasiuk *et al.*^[52] showed evidence of *in vivo* platelet activation, as suggested by the increased concentrations of b-thromboglobulin and platelet factor 4 in serum. Furthermore, plasma-soluble P-selectin levels have been shown to be markedly elevated in chronic hepatitis C^[53], and this infection might be directly responsible for *in vivo* platelet activation and for the higher *MA* values observed in patients suffering from this disease.

The presence of HCC nodules has been associated by Samonakis *et al.*^[54] and by Krzanicki *et al.*^[55], even if with a very low prevalence of hypercoagulability, with a thrombophilic tendency and with thrombotic complications. For this reason, we would have expected to see faster coagulation activation (shorter *r*) and/or greater clot firmness (higher *MA*), but we did not observe any signs of hypercoagulation. HCC did not appear to be responsible for a higher thrombophilic tendency in the study population, even in subgroups of patients with a low MELD score (15-20) and a minor coagulation impairment.

Patients affected by alcoholic or hepatitis B cirrhosis did not show any significant difference in clot formation or strength.

Cirrhotic patients with a MELD score under 20 had significantly better *MA*, *A30*, and *A60* values than

patients with a score above 20 ($P < 0.001$), which could be an expression of greater stability of the clot related to less severe liver disease and better coagulation function^[56,57]. In particular, r , k , and α were within normal limits, although the maximum amplitude was decreased. As previously showed by Stravitz *et al.*^[31] in patients with stable cirrhosis, global haemostasis is maintained, while the mean maximum amplitude of clot formation can be below normal limits. Our cohort of patients with a MELD score less than 20 represents a lower grade of liver disease severity and, for this reason, is more similar to the results described by Stravitz.

Our study showed how TEG value distribution in patients with ESLD is very different from that obtained from a healthy population. The coagulation system in healthy patients is characterized by a greater functional reserve of both procoagulants and anticoagulants, and it is unlikely that the thromboelastographic reference ranges of a healthy population are also representative of patients with ESLD. In healthy people, "normal" range also means normal coagulation balance. Patients with liver disease may show a satisfactory coagulation balance without spontaneous bleeding, even if their TEG values are outside the normal ranges observed in healthy people. However, this was a descriptive and not an outcome study, and we think that this study's findings should always be kept in mind when TEG data are interpreted in patients with ESLD. It was not possible to directly demonstrate the clinical effect of interpreting the TEG in cirrhotic patients with or without taking these "normal" variations into account. Thromboelastographic ranges in liver transplant candidates are so different from normal subjects that specific ranges for cirrhotic patients have to be defined. Because of the unique coagulation condition of cirrhotic, TEG ranges representative of this category of patients, have probably to be considered in all bleeding conditions avoiding to correct these parameters to normal TEG ranges for healthy patients. In the last few years, several transfusion algorithms have been proposed, aiming at developing a better treatment for haemostasis in patients with coagulopathy and bleeding, but none of these algorithms have been built using values typically obtained from cirrhotic patient candidates. For this reason, our group has already shown how specific thromboelastographic cut off values, adapted for cirrhotic patients, can be used to guide blood product infusions before invasive procedures, ensuring patient safety and avoiding bleeding episodes^[58]. Similarly, Wang *et al.*^[21] showed that TEG values higher than normal in transplant recipients may not have a reliable predictive value of increased blood loss during surgery. In their study, the authors adopted a TEG-guided transfusion protocol using higher threshold values to initiate transfusions, without observing any negative consequences. Therefore, standard TEG values obtained from healthy volunteers may be misleading for patients with liver disease.

This study presents the following possible limitations: TEG suffers from a lack of proven standardization^[8,9],

and pre-analytical factors such as sampling and sample handling could play a significant role in coagulation testing. Due to the manual steps, such as placement of pin and cup or pipetting a sample, operator-to-operator variability had to be considered. Another possible limitation is that the range of distribution described in this population could most likely only be applied to our reality and is not necessarily representative of other liver transplant centres.

In conclusion, the comparison between thromboelastographic parameters of cirrhotic patients and those of healthy subjects have shown many differences that are the ultimate expression of the different coagulation balance typical of cirrhotic subjects. The analysis of the cirrhotic population has also demonstrated how a MELD score greater than 20 and HCV infection-related cirrhosis may be related to the formation of a less stable clot, and patient candidates for LT due to cholestatic liver diseases are capable of forming more stable and durable clots. The TEG values described in this population of candidates for liver transplantation, although very different from those of a healthy population, are however an expression of a new haemostatic balance that cirrhotic patients reach and, in conditions of stability, does not result in spontaneous bleeding. The observation of a shorter than normal r value in 10% of cirrhotic patients should make the reader remember that such a population of patients can face thrombotic as well as haemorrhagic problems during surgery because of their unstable haemostatic balance. Determining a range of distribution for TEG values in a very specific population of cirrhotic patients could be important for the implementation of a transfusion protocol based on a point-of-care device that could help in properly guiding coagulation therapy. If the imperative is the correction of the thromboelastographic parameters only in the presence of active bleeding, aiming to restore TEG values to those suggested as "normal" could lead to an over-correction of the coagulation abnormalities typical of cirrhotic patients. This hypothesis needs to be confirmed by detailed clinical trials on the medical utility of new TEG reference ranges for the management of perioperative haemostasis in cirrhotic patient clinical settings.

COMMENTS

Background

Standard laboratory tests (international normalized ratio, activated partial thromboplastin time) fail to give comprehensive information about the bleeding tendency and coagulation status of cirrhotic patients because they are not standardized across centres when used for patients with liver disease and are performed in the absence of thrombomodulin. All of these limits have progressively increased the interest in thromboelastography (TEG), which assesses the overall coagulation process beyond the initiation of clot formation. However, this methodology is not standardized, and when defining reference values, the TEG analyzer manufacturer suggests that each new user should test 20 healthy volunteers to generate "his own" normal values to be used locally as reference values. The normal TEG values reported by manufacturers and the literature are determined from the average clotting time of healthy volunteers, making them unreliable and potentially misleading in the

management of patients with liver disease. It is very important to try to generate a more reliable picture of a common cirrhotic patient coagulation profile to properly manage these patients during liver transplant (LT).

Research frontiers

Many publications have shown that TEG-based transfusion algorithms are useful in the management of blood products during LT, but the proposed cut-off value for transfusion is subject to great variability. The values proposed as indices of transfusion are often detected in patients with cirrhosis without being associated with bleeding. In this study, similar to reference values obtained from healthy people, the authors tried to study TEG value distribution in a group of patient candidates for LT. Stravitz, in a cohort of 273 patients with stable cirrhosis, found that the mean and median TEG parameters were within normal limits, although the maximum amplitude was decreased in proportion to the severity of thrombocytopenia due to hypersplenism. In contrast with this author, the authors studied patients with decompensated cirrhosis who arrived in the operating theatre with rebalanced haemostasis, which differs considerably from healthy people but can be "normal" for cirrhotic patients.

Innovations and breakthroughs

Stable cirrhotic patients do not have inherent bleeding diathesis but rather a reduced reserve that can be readily tipped towards a bleeding or thrombotic tendency. In the last few years, several transfusion algorithms have been proposed, aiming to develop a better treatment for haemostasis in patients with coagulopathy and bleeding, but none of these algorithms have been built using values typically obtained from cirrhotic patient candidates. In contrast with Stravitz, the authors studied a population of patients with decompensated cirrhosis, with candidates for liver transplant having normal coagulation parameters in almost half of cases and more rapid clot formation in a small percentage of patients. The authors could show which reference range distributions in a population of patient candidates for LT should be taken into account when administering blood products during LT. However, this is a descriptive and not an outcome study, and the authors think that these findings should always be kept in mind when TEG data are interpreted in patients with end-stage liver disease.

Application

Stable cirrhotic patients do not have an inherent bleeding diathesis but rather a reduced reserve that can be readily tipped towards a bleeding or thrombotic tendency. The liver disease patient has a new balanced haemostatic profile that corresponds with TEG values that are very different from those observed in healthy people but that are within the range of normality in almost half of the liver transplant candidates studied. Even if it was not possible to directly demonstrate the clinical effect of interpreting the TEG traces, taking into account the "reference ranges" for cirrhotic patients, the authors think that in cases of bleeding episodes or intraoperative haemorrhage, it would most likely be useful to correct TEG values while keeping in mind the reference ranges for this category of patients to avoid unnecessary blood product transfusions.

Terminology

TEG offers a more targeted approach for assessing the overall outcome of the interactions of clotting factors beyond the initiation of clot formation. Although TEG is a useful viscoelastic test for haemostatic monitoring, interpretation of its results requires care, especially in cirrhotic patients in whom they have already shown that specific cut off values are necessary to guide blood products infusion. Liver transplantation is the only therapeutic approach for end-stage liver disease. It is a surgical procedure characterized by deep haemodynamic, coagulation and biochemical repercussions that are different depending on the surgical stage (laparotomy, pre-anhepatic, anhepatic, or reperfusion phase) observed.

Peer-review

This is a very interesting observational study and the manuscript has been well written.

Abstract

AIM

To evaluate use of palliative care services in patients with end-stage liver disease who do not have access to liver transplant.

METHODS

Evaluated were end-stage liver disease patients who were removed from the liver transplant wait-list or died prior to transplant at a single transplant center over a 2-year period. Those who were removed due to noncompliance or ultimately transplanted elsewhere were excluded from this study. Patient characteristics associated with palliative care consultation were assessed using logistic regression analysis.

RESULTS

Six hundred and eighty-three patients were listed for liver transplant in 2013-2014 with 107 (16%) dying ($n = 62$) or removed for clinical decompensation prior to liver transplant ($n = 45$): Median age was 58 years, and the majority were male (66%), Caucasian (53%), had Child C cirrhosis (61%) or hepatocellular carcinoma (52%). The palliative care team was consulted in only 18 of the 107 patients (17%) who died or were removed, 89% of which occurred as inpatients. Half of these consultations occurred within 72 h of death. In univariable analysis, patients of younger age, white race, and higher end-stage liver disease scores at time of listing and delisting were more likely to receive palliative care services. Only younger age [Odds ratio (OR) = 0.92; $P = 0.02$] and Caucasian race (OR = 4.90; $P = 0.02$) were still associated with integration of palliative care services through multivariable analysis.

CONCLUSION

Palliative care services are grossly underutilized in older, non-white patients with cirrhosis on the liver transplant wait-list. We encourage early integration of these ser-

vices into clinical decision-making in the transplant population, with further studies aimed at understanding barriers to consultation.

Core tip: Without liver transplant, patients with cirrhosis have 50% mortality at 5 years; these patients represent a population that would benefit from palliative care services. Palliative care services are grossly underutilized in older, non-white patients with cirrhosis on the liver transplant wait-list. We encourage early integration of these services into clinical decision-making in the transplant population, with further studies aimed at understanding barriers to consultation.

Kathpalia P, Smith A, Lai JC. Underutilization of palliative care services in the liver transplant population. *World J Transplant* 2016; 6(3): 594-598 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i3/594.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i3.594>

INTRODUCTION

Decompensated cirrhosis is characterized by ascites, hepatic encephalopathy, and variceal bleeding. Mortality is high with 50% death rate due to complications of cirrhosis within five years^[1,2]. In addition to these medical complications, patients with decompensated cirrhosis experience a large symptomatic burden including debilitating fatigue, muscle wasting, anorexia, and intractable pruritus. Self-reported quality of life is poor in cirrhotics; in one study, 38% of elderly patients with cirrhosis had difficulty in independently completing at least one daily living activity including dressing, walking few steps, or bathing while 10% had impaired integral activities of daily living (*i.e.*, managing money, cooking, grocery shopping)^[3-5]. Their physical symptoms, inability to independently care for themselves, and knowledge of their terminal disease often erodes their emotional and psychological well-being.

While it is clear that liver transplantation is essentially the only known cure for complications of end-stage liver disease, the ability to receive a transplant can be unpredictable: One in five individuals awaiting liver transplantation will die on the waitlist^[6]. While the process of listing individuals for liver transplantation is highly structured through formal medical, surgical, social, and psychological evaluations, there is no standard of care for the process to transition those who are deemed too sick for liver transplantation to comfort care. We aimed to evaluate current utilization of palliative care services in liver transplant candidates who

did not survive to liver transplant and understand which patient characteristics are associated with palliative care consultation in this population.

MATERIALS AND METHODS

All adult cirrhotic patients who were newly listed for liver transplant at a single, large volume United States liver transplant center from January 1, 2013 to December 31, 2014 and died prior to transplant or were delisted for being too ill for transplant were included in this study. We excluded patients delisted due to inadequate social support, medical non-adherence, active substance abuse, or those who were transplanted at another center.

Patient demographics (age, gender, ethnicity, language spoken), etiology of liver disease, Model for End-Stage Liver Disease (MELD) score at time of transplant listing, and education level were received from the United Network for Organ Sharing and Organ Procurement and Transplantation Network registries. Patients' MELD at delisting or death, Child Pugh Score at time of removal, presence of hepatocellular cancer (HCC), and insurance type were collected through review of the electronic health record. Details on the palliative care consultations were also manually reviewed from the electronic medical records.

Descriptive statistics were computed for all continuous variables (age at listing, candidate MELD lab score when being listed for transplant) including means, medians, and interquartile ranges. The rank sum test was used for these continuous variables. Pearson's χ^2 testing was used for the categorical values (candidate gender, ethnicity, highest education level, and diagnosis) to further compare the baseline characteristics of patients removed from the waiting list vs those who remained active. We employed univariable logistic regression to identify factors associated with palliative care consultation with a *P* value cut-off of 0.10. These factors were then evaluated for inclusion in the final multivariable logistic regression model using backwards stepwise elimination, using a *P* value cut-off of 0.05.

This study was approved by the Institutional Review Board of UCSF. Stata, version 12 (Stata Corp., College Station, TX) was used for statistical analyses.

RESULTS

There were 683 patients placed on the liver transplant list in 2013-2014, of which 107 (16%) ultimately dying (*n* = 62) or removed for clinical decompensation prior to liver transplant (*n* = 45). Median age was 58 years and majority (66%) was male. Majority of the patients who died or were de-listed were white (53.3%), followed by Hispanic (22.4%), Asian (12.1%), Black (9.3%), and other (2.8%). The etiology of cirrhosis was alcohol (11%), hepatitis C (41%), alcohol and hepatitis C (20%), and various other etiologies (30%). Majority of these patients had Child-Pugh Class C cirrhosis (60.7%)

Table 1 Baseline characteristics of 107 patients who died or were delisted for being too sick for transplant

	<i>n</i> = 107
Age at listing, yr	58 (53-63)
Male sex	71 (66%)
Ethnicity	
White	57 (53.3%)
Hispanic	24 (22.4%)
Asian	13 (12.1%)
Black	10 (9.3%)
Other	3 (2.8%)
MELD at time of listing	16 (12-23)
Etiology of cirrhosis	
Alcohol related	12 (11%)
Hepatitis C	44 (41%)
Alcohol + hepatitis C	21 (20%)
Other	30 (28%)
Child-pugh score at de-listing	
A	16 (15%)
B	26 (24.3%)
C	65 (60.7%)
HCC	56 (52%)
Education level	
College degree or less	100 (93.5%)
Graduate level degree	7 (6.5%)

MELD: Model for end-stage liver disease; HCC: Hepatocellular cancer.

while 52% of these patients had HCC. In terms of education level, 93.5% had a college degree or less (Table 1).

Of these 107 patients who were delisted or died while awaiting transplant, 18 (17%) received a palliative care consult in the 2-year period, of which 89% occurred as inpatients. The median number of days (interquartile range) from palliative care consultation to death was 4 (1-11) d; half of these consultations occurred within 72 h of death and 17% on the same day as death (Figure 1). Reasons for palliative care consultation included aiding in transitioning to hospice in 78% of patients, goals of care without transition to comfort care in 11%, and symptom management including refractory ascites, pruritus, and pain in the remaining 11%. Even from the 26 patients with ESLD who were delisted for advanced HCC, just 12% had palliative care consultation.

Patient characteristics associated with palliative care consultation in univariate analysis included younger age (OR = 0.92; *P* < 0.01), white race (OR = 3.74; *P* = 0.03), and higher MELD at listing (OR = 1.06; *P* = 0.02) and at delisting (OR = 1.05; *P* = 0.01). Subsequent multivariable analysis revealed only younger age (OR = 0.92; *P* = 0.02) and white race (OR = 4.90; *P* = 0.02) remained associated with utilization of palliative care services (Table 2).

DISCUSSION

According to the World Health Organization, palliative care “improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable

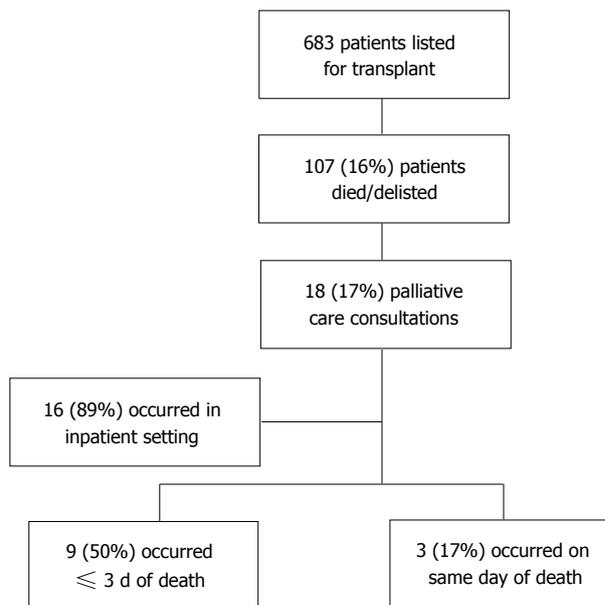

Figure 1 Palliative care consultations in patients who died or were delisted over a 24-mo period.

assessment and treatment of pain and other problems, physical, psychosocial, and spiritual⁽⁷⁾. For patients with end-stage liver disease, early integration of palliative care into their routine medical care is particularly crucial to understanding patients’ preferences for the end of life, as progressive hepatic encephalopathy often leads to impaired decision-making. Those on the liver transplant list, however, represent a unique sub-group of patients with a “terminal” condition - by virtue of having end-stage liver disease - but await the promise of a cure through liver transplantation. In this setting, palliative care, which traditionally has been considered only for those “at the end of life”, may be perceived - by both the patient and providers alike - as unnecessary and unwelcome⁽⁸⁻¹¹⁾.

Indeed, we observed very low utilization of palliative care services among liver transplant candidates who ultimately died or were delisted for being too sick for liver transplant. Among the 17% of these patients who received palliative care services, half of the consultations occurred within 72 h of death and one in five occurred on the day of death, hardly enough time to develop rapport and aid both patients and their caregivers in the transition to supportive care at the end of life^(12,13). Importantly, we identified two factors - younger age and non-Hispanic white race - that were associated with palliative care consultation. This finding confirms a prior study evaluating barriers to palliative care among older adults that demonstrated that a terminal diagnosis in an elderly patient often is considered an “expectation” rather than a shock compared to that in a younger patient; it is also possible that younger patients at the end of life have more support networks/caretakers at this stage that advocate for improved quality of life^(14,15). Cultural and language barriers likely contribute to underutilization of palliative care services in the non-white

population.

In addition, we find it interesting that more than three-fourths of palliative care consultations in our population were to assist with transition to comfort care and just 11% were for aid in symptom management. This depicts how transplant clinicians view palliative care, as a mode to help make patients comfortable at the end of life, but not to facilitate goals of care discussions or to help relieve pain and suffering in a patient population with a terminal condition without transplantation. We recognize the need for integration of palliative care and transplant hepatology teams in efforts to provide comprehensive care for our patients to meet their physical and psychosocial needs even when actively listed for liver transplantation.

We acknowledge that this study is limited by a relatively small sample size; however, it represents the *entire* eligible population at our liver transplant center during the study period, so is an unselected group. Another limitation is that we only evaluated those who died or were delisted rather than all patients on the liver transplant list. This was intentional, as we first wanted to evaluate the uptake of palliative care among those for whom death was certain.

Despite these limitations, this study represents one of the largest to date to evaluate palliative care consultation in the liver transplant population. Poonja *et al*^[16] reported their experience in the liver transplant population at the University of Alberta and noted that of the 102 patients removed from the waitlist or declined over a 5 year period, only 10% were referred to palliative care despite high levels of pain, nausea, and depression. As patients with ESLD have high burden of symptoms, we advocate for increased utilization of palliative care services - for both symptom management and discussions regarding goals of care - and integration of such services early in the liver

transplant listing process. Baumann *et al*^[17] confirmed that early palliative care utilization in patients listed for transplantation led to improved symptom management and well-being in this population.

While this study represents a critical first step towards developing interdisciplinary programs directed at providing palliative care to liver transplant candidates, future studies should focus on understanding barriers to early integration of palliative care in the liver transplant population among all ages and ethnicities, in both the inpatient and outpatient setting. In addition, in a prospective study, patient-centered outcomes can be obtained in efforts to show the direct impact of palliative care involvement on the physical and psychosocial well being of these patients. Ultimately the goal should be to facilitate collaboration and, perhaps, even co-management between transplant and palliative care providers for the care of these complex patients - even when the intention to treat is curative - to improve the quality of care and quality of life for patients with cirrhosis awaiting liver transplantation.

COMMENTS

Background

Patients with end stage liver disease have 50% 5-year mortality due to complications of cirrhosis and experience a large symptomatic burden including debilitating fatigue, muscle wasting, anorexia, and intractable pruritus. While it is clear that liver transplantation is essentially the only known cure for complications of end-stage liver disease, the ability to receive a transplant can be unpredictable. In patients who do not have access to liver transplant, palliative care services may aid in quality of life of patients and caretakers alike.

Research frontiers

Though the process of listing individuals for liver transplantation is highly structured, there is no standard of care for the process to transition those who are deemed too sick for liver transplantation to comfort care. Current utilization of palliative care services in liver transplant candidates who did not survive to liver transplant is not largely understood.

Innovations and breakthroughs

Authors aimed to understand the use of palliative care services in patients with end-stage liver disease who do not have access to liver transplant over a 2-year period and a large volume center. Palliative care services were consulted in less than 20% of patients who were died or removed from the transplant list, majority of which occurred while patients were already hospitalized. In univariable analysis, patients of younger age, white race, and higher model for end-stage liver disease (MELD) scores at time of listing and delisting were more likely to receive palliative care services. Only younger age and Caucasian race were still associated with integration of palliative care services through multivariable analysis. The authors recognize that palliative care services are grossly underutilized in patients who are not deemed transplant candidates.

Applications

While this study represents a critical first step towards developing interdisciplinary programs directed at providing palliative care to liver transplant candidates, future studies should focus on understanding barriers to early integration of palliative care in the liver transplant population. In addition, in a prospective study, patient-centered outcomes can be obtained to show the direct impact of palliative care involvement on the physical and psychosocial well being of these patients. Ultimately the goal should be to facilitate collaboration and, perhaps, even co-management between transplant and palliative care providers for the care of these complex patients - even when the intention to treat is curative - to improve the quality of care and quality of life for patients with cirrhosis awaiting liver transplantation.

Terminology

Palliative care services encompass more than aiding in transitioning to comfort care and assisting in goals of care discussions, and can be particularly helpful in symptom management, even in patients who are not terminally ill. The laboratory based MELD score accounts for patients' bilirubin, international normalized ratio (INR), and creatinine levels and was calculated both at time of transplant listing and delisting. The child pugh score entails a combination of laboratory (bilirubin, albumin, INR) and clinical (presence of ascites, encephalopathy) factors; though it was originally used to predict mortality in cirrhotics at the time of surgery, it can also aid in understanding the severity of liver disease.

Peer-review

This is an integral single center retrospective study that aims to shed light on the need for integration of palliative care into the liver transplant population, even when the intent to treat is curative, in efforts to improve their quality of life.

Abstract

AIM

To characterize major determinants of 20-year survival after liver transplantation (LT).

METHODS

This longitudinal single-institution study includes 313 consecutive patients who received a LT between 1988 and 1992. Pretransplant clinical characteristics and laboratory values were assessed and compared between 20-year survivors and non-survivors. Particular attention was paid to the Model for End-Stage Liver Disease (labMELD)-score and the Eurotransplant Donor Risk Index (ET-DRI) to unravel their impact on 20-year survival after LT.

RESULTS

Twenty-year survivors were significantly younger (44 *vs* 50 years, $P = 0.001$), more likely to be female (49% *vs* 36%, $P = 0.03$) and less likely to be obese at the time of LT (19% *vs* 32%, $P = 0.011$). Mean labMELD-score ($P = 0.156$), rate of high-urgency LT ($P = 0.210$), cold-ischemia time ($P = 0.994$), rate of retransplantation ($P = 0.12$) and average donor age (28 *vs* 33 years, $P = 0.099$) were not statistically different. The mean estimated glomerular filtration rate was higher among survivors ($P = 0.007$). ET-DRI > 1.4 ($P = 0.020$) and donor age ≥ 30 years ($P < 0.022$) had significant influence on 20-year survival. The overall survival was not significantly impacted by labMELD-score categories ($P = 0.263$).

CONCLUSION

LT offers excellent long-term results in case of optimal donor and recipient conditions. However, mainly due to the current organ shortage, these ideal circumstances are rarely given; thus algorithms for donor-recipient matching need to be refined, in order to enable a maximum benefit for the recipients of high quality as well as marginal organs.

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: We compare characteristics of 20-year survivors and non-survivors after liver transplantation. The lab model for end-stage liver disease-score seems not to be an adequate tool for predicting long-term (20 years) outcome. The Eurotransplant Donor Risk Index (ET-DRI) has a significant impact on long-term survival. While close to 60% of patients that received a donor organ with an ET-DRI < 1.2 survived for 20 years and longer, only less than 40% of the patients with an ET-DRI > 1.4 survived the same number of years. Only about 20% survivors had overweight before transplantation, compared to about 33% non-survivors. The mean estimated glomerular filtration rate was higher among survivors.

INTRODUCTION

Over the last three decades, liver transplantation (LT) has become the standard therapeutic treatment for

patients with terminal liver failure^[1-4]. Short- and long-term results have improved, resulting in dramatic prolongation of recipients' life expectancy^[5]. Surgical techniques, pharmaceutical regimens, and intensive care management were continuously refined^[6,7]. Equally as important, LT centers have gained invaluable experience regarding the long-term management of LT patients^[3,4,8]. Many obstacles resulting in patient and graft loss have been identified, and means to overcome them have been developed. This has led to a broad increase in the number of potential LT recipients^[9].

However, with growing waiting lists and an increasing number of LT-centers, the LT community is now facing the issue of fair organ allocation. The limited amount of donor organs led to the implementation of different liver allocation policies^[10,11] and a more liberal acceptance of extended criteria donor (ECD) organs^[12,13]. The implementation of Model for end-stage liver disease (MELD) allocation in 2006 within the Eurotransplant area has reduced waiting list mortality to about 10%^[14], but has also increased the one-year mortality in many European centers, *e.g.*, at our center from 8.2% to about 17.4%^[15]. Donor-recipient-matching has become crucial to achieving reasonable one year mortality^[16] and acceptable waiting list mortality, especially when allocating marginal organs to progressively sicker recipients.

With this study, we aim to evaluate the influence of pretransplant labMELD and Eurotransplant Donor Risk Index (ET-DRI) on the long-term survival of a cohort of LT-recipients. Furthermore, we compared the pretransplant characteristics of recipients who survived ≥ 20 years after their LT to those who died within the 20-year observation period.

MATERIALS AND METHODS**Study design**

A longitudinal single-institution study was performed to characterize 20-year LT survivors. Institutional Review Board approval was obtained for this study.

Patients

The cohort has been described previously^[17]. Indications for primary transplants are presented in Table 1. Patients were divided into groups with regards to their underlying disease: Cholestatic/autoimmune comprises all patients with primary ($n = 19$) or secondary ($n = 3$) sclerosing cholangitis, primary ($n = 29$) or secondary ($n = 1$) biliary cirrhosis and autoimmune hepatitis ($n = 12$). The group hepatobiliary malignancy includes all cases of hepatocellular carcinomas (HCC, $n = 27$), cholangiocarcinomas ($n = 5$) as well as Klatskin tumors ($n = 4$), while virus-related cirrhosis includes all patients with hepatitis B ($n = 47$), hepatitis C ($n = 32$), hepatitis B and C ($n = 3$) and hepatitis B and D ($n = 10$) virus cirrhosis. Overall, virus-related cirrhosis (29.4%), cholestatic/autoimmune liver disease (20.4%), alcoholic cirrhosis (16.0%), hepatobiliary malignancy (11.5%), cryptogenic cirrhosis (9.3%) and acute liver failure

Table 1 Indications of primary liver transplant

¹ratio of survivors/non-survivors in the respective indication category. HCC: Hepatocellular carcinomas; CCC: Cholangiocellular carcinoma.

(7.3%) were the most common indications for primary LT. Of the twenty-seven HCC patients, seven did not fall under the later defined Milan criteria.

Characteristics of donors and recipients are depicted in Table 2. In summary, the cohort consists of 313 consecutive patients who received a primary LT at the Charité, Campus Virchow-Klinikum, between 1988 and 1992. During the twenty-year follow-up those patients received a total of 365 livers including 54 retransplantations (46 first retransplantations). There were 178 male and 135 female recipients. At the date of primary LT, median patient age was 47 (14-66) years including two patients who were minors at the age of 14 and 16, while median donor age was 30 (9-64) years. Mean labMELD-Score was 18.6 ± 7.6 and mean ET-DRI was 1.35 ± 0.2 .

Patients were observed until their death, loss to follow-up, or graft loss. Data were censored at time of patients' death, loss to follow-up, graft loss or at 20 years after transplantation, respectively. A graft survival analysis was performed in which labMELD-scores, pre-transplant laboratory values (median 0 d before LT, range 0-84 d), clinical characteristics and ET-DRI were evaluated for the primary LT as well as for the primary graft, in order to compare characteristics of 20 year-survivors and non-survivors.

MELD-score calculations

LabMELD-scores were retrospectively calculated using the pretransplant serum bilirubin level, serum creatinine

Table 2 Pretransplant characteristics

level, and INR according to Kamath *et al.*^[18].

Given Quick values were converted into INR with the help of the corresponding batch numbers. Serum bilirubin, INR, or serum creatinine values of less than 1.0 were set to 1.0 to preclude negative scores. Serum creatinine level was capped at 4.0. MELD-scores were capped at 40. We were able to retrieve MELD-scores for 308 patients. For the compilation of Kaplan-Meier curves, recipients were grouped into three different categories: MELD ≤ 15 (*n* = 126), MELD = 16-25 (*n* = 134) and MELD > 25 (*n* = 48).

ET-DRI calculations

The ET-DRI was assessed using the required donor and transplant factors according to Braat *et al.*^[19].

We were able to calculate the corresponding ET-DRI for 179 patients (57%). For the remaining donors the latest GGT level was unknown, which is an essential factor for ET-DRI calculation. Ninety-four of these recipients were 20-year survivors, 85 were non-survivors. For Kaplan-Meier estimates, the grafts were divided into three groups: ET-DRI < 1.21 (*n* = 54), 1.21-1.40 (*n* = 61) and > 1.4 (*n* = 64).

Laboratory parameters

Laboratory parameters were obtained after a fasting period of at least 12 h and included serum levels of total cholesterol, triglycerides, creatinine, Quick-value, total bilirubin (tBili), aspartate aminotransferase, alanine aminotransferase and glucose.

Variables

Overweight (HBMI) was defined as body-mass-index (BMI = weight/height²) above 25. Blood cholesterol levels of more than 200 mg/dL, triglyceride levels above 175 mg/dL, or statin treatment were considered "hyperlipidemia" (HLIP). The MDRD-formula was used to estimate glomerular filtration rate (eGFR). An eGFR < 60 mL/min per 1.73 m² was considered moderately impaired renal function (MIRF), while rates < 30 mL/min per 1.73 m² were defined as severely impaired renal function (SIRF)^[20].

Statistical analysis

Categorical variables were compared by the χ^2 test and summarized as percentages and frequencies. Continuous variables were compared using unpaired *t* test and summarized as median and range, or mean \pm SD. A *P* value of less than 0.05 was interpreted as statistically significant. Kaplan-Meier estimates were used to calculate survival curves. Differences in survival curves were compared using log-rank statistics. All calculations were done using the SPSS software package (version 22.0 for Windows, SPSS Inc., Chicago, IL).

RESULTS

After a median follow-up of 233 mo (0-260), 157 patients were alive (141 with complete sets of data, 16 with incomplete sets of data) and 141 had died (27 patients within 6 mo after LT) while 15 patients were lost to follow-up 99 to 243 mo after LT.

Recipients' characteristics

Table 1 depicts the distribution of primary indication for LT among survivors and non-survivors. The most common indications among survivors were virus-related cirrhosis (29.3%), cholestatic/autoimmune liver disease (24.2%), and alcoholic cirrhosis (14.6%), while among non-survivors virus-related cirrhosis (27.7%), hepatobiliary malignancy (19.9%) and alcoholic cirrhosis were the most frequent. The ratio of survivors/non-survivors was lowest for hepatobiliary malignancies (0.25) and highest for cholestatic/autoimmune liver disease (1.90) and acute liver failure (2.29).

As shown in Table 2, median age of 20-year-survivors and non-survivors was 44 (14-66) and 50 (25-65) years, respectively (*P* = 0.001). Both minors (primary indication PSC and ALF) were alive after twenty years of follow-up. The group of non-survivors includes significantly more LT recipients over the age of 55 (26% compared

to 12% of the survivors, *P* = 0.03) while the group of survivors has a significantly larger amount of female recipients (49% compared to 36% of the non-survivors, *P* = 0.03). Mean BMI for survivors and non-survivors was 22.7 \pm 3.0 and 23.5 \pm 3.7 kg/m², respectively (*P* = 0.037). There were no significant differences for survivors and non-survivors regarding pretransplant labMELD-score (19.4 \pm 8.3 and 18.1 \pm 7.0, *P* = 0.156), rate of high-urgent LT (10% and 6%, *P* = 0.210), cold-ischemia time (10.6 \pm 4 and 10.7 \pm 4 h, *P* = 0.994) and rate of retransplantation (11% and 18%, *P* = 0.12).

Donors' characteristics

Among survivors, median donor age was 28 years (14-64) compared to a median donor age of 33 years (9-60) among non-survivors (*P* = 0.099). Mean ET-DRI for survivors and non-survivors was 1.32 \pm 0.2 and 1.37 \pm 0.2, respectively (*P* = 0.121).

Patient and graft survival

The overall actuarial patient survival rates at 1, 10 and 20 years were 88.4%, 72.7% and 52.5%, respectively. The overall graft survival rates were 83.7%, 64.7% and 46.6% after 1, 10 and 20 years, respectively.

Liver function tests

None of the liver function tests that were compared showed a statistically significant difference between survivors and non-survivors (Table 2). Prior to LT, mean total bilirubin was 9.0 \pm 12.6 mg/dL for survivors and 7.7 \pm 11.6 mg/dL for non-survivors (*P* = 0.363). Mean aspartate aminotransferase was 124 \pm 486 U/L for survivors and 111 \pm 454 U/L for non-survivors (*P* = 0.820). Mean pretransplant alanine aminotransferase was 102 \pm 177 U/L for survivors and 108 \pm 286 U/L for non-survivors (*P* = 0.849).

Clinical and laboratory parameters

Systolic BP and diastolic BP were not significantly different between survivors and non-survivors. 20-year survivors' mean blood glucose was 116 \pm 46 mg/dL compared to 126 \pm 70 mg/dL among non-survivors (*P* = 0.174). Cholesterol (129 \pm 55 and 138 \pm 86, *P* = 0.311) and triglycerides (91 \pm 56 and 100 \pm 80, *P* = 0.326) values did not differ significantly between survivors and non-survivors. Regarding the renal function, mean eGFR of 106 \pm 70 mL/min per 1.73 m² in survivors was significantly higher than mean eGFR of 88 \pm 39 mL/min per 1.73 m² in non-survivors (*P* = 0.007). Detailed data are presented in Table 2, where the percentages relate to the amount of patients with complete data in the specific category.

Nineteen percent of the twenty-year survivors had HBMI before transplantation, while 32% of the non-survivors had HBMI (*P* = 0.016). Comparing survivors and non-survivors, prevalence of HLIP (15% and 19%, *P* = 0.407), MIRF (20% and 21%, *P* = 0.886) and SIRF (5% and 3%, *P* = 0.547) did not show a significant

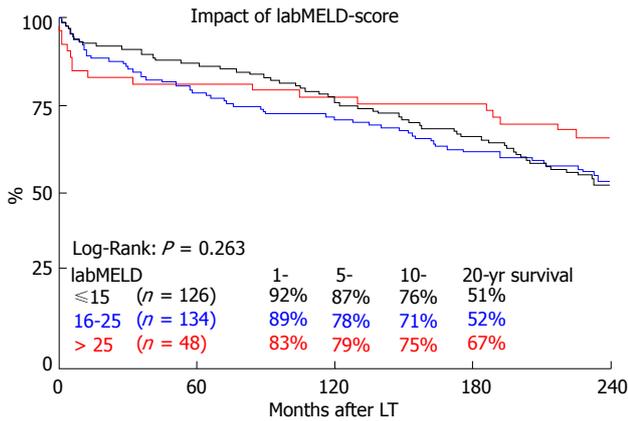

Figure 1 The impact of lab model for end-stage liver disease categories on 20 year survival. MELD: Model for end-stage liver disease; LT: Liver transplantation.

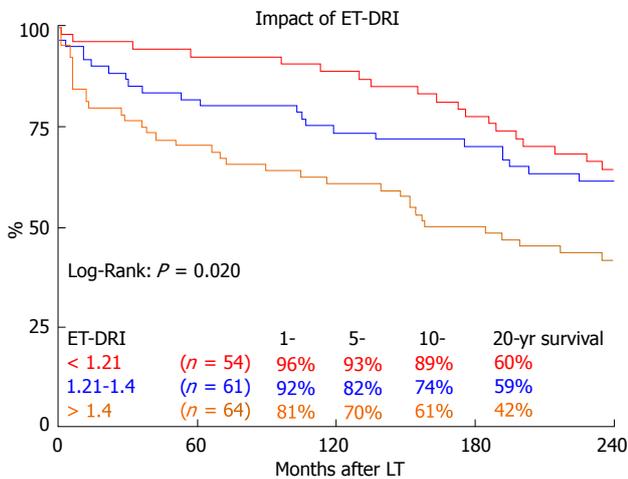

Figure 2 The impact of eurotransplant donor risk index categories on 20 year survival. LT: Liver transplantation; ET-DRI: Eurotransplant donor-risk-index.

difference.

To further analyze the impact of renal function, patients were split up into separate groups, based on their eGFR before transplantation (Table 3). Eighty percent of the survivors and 79% of the non-survivors had an eGFR > 60 ($P = 0.860$), pointing to normal renal function. The groups that comprise eGFR values of 60 to 69 and 70 to 79 contain significantly more non-survivors than survivors (20.0% and 15.7% compared to 6.5% and 6.5%, $P = 0.001$ and $P = 0.011$, respectively), while 30.3% of the survivors had an eGFR > 120 compared to 20.0% of the non-survivors ($P = 0.042$).

A subgroup analysis was performed to assess the underlying diseases among those patients who later developed MIRF and SIRF. The most common indications for primary LT among patients with MIRF at 20 years after LT ($n = 85$) were virus-related cirrhosis ($n = 32$), CD/AIH ($n = 18$) and alcoholic liver disease ($n = 15$). Among patients who later developed SIRF ($n = 10$), the most common primary indications were CD/AIH ($n = 4$), virus-related cirrhosis ($n = 3$) and

Table 3 Pretransplant renal function n (%)

	20-yr survivors n = 155	20-yr non-survivors n = 140	P
eGFR > 60	126 (80%)	112 (79%)	0.860
MIRF	31 (20%)	29 (21%)	0.879

polycystic liver disease ($n = 2$).

Kaplan-Meier estimates

As shown in Figure 1, the overall survival at 1, 5, 10 and 20 years for the three different groups of labMELD-Scores, was 92.1%, 86.5%, 76.2% and 51.3% for group 1 (labMELD ≤ 15), 88.8%, 77.6%, 70.9% and 51.9% for group 2 (labMELD = 16-25) and 83.3%, 79.2%, 75.0% and 66.7% for group 3 (labMELD > 25). The 20-year survival did not differ significantly ($P = 0.263$). This was also true for 0.5- ($P = 0.226$), 1- ($P = 0.293$), 5- ($P = 0.293$), 10- ($P = 0.522$) and 15-year ($P = 0.241$) survival. Survival of recipients with labMELD > 25 was not significantly worse compared to all others at 6 mo after LT, ($P = 0.095$), also not at 1-year ($P = 0.158$), 5-year ($P = 0.704$) and 10-year ($P = 0.726$). At 15-year ($P = 0.143$) and 20-year ($P = 0.107$), recipients with MELD > 25 showed better overall survival, but this difference was not statistically significant.

Long-term survival was significantly influenced by ET-DRI ($P = 0.020$, Figure 2). Comparing only two groups, ET-DRI ≤ 1.4 and >1.4, the survival outcome showed a significant difference as well ($P = 0.011$) (data not shown). Looking at the donor age separately (< vs ≥ 30 years), we also found a significant impact on long-term survival as shown in Figure 3 ($P < 0.014$). A more detailed analysis of donor and recipient age based on a recipient age of < and ≥ 55 years and a donor age of < vs ≥ 30 years revealed a highly significant impact on long term outcome in the comparison of these four categories ($P < 0.0001$, Figure 4).

In a sub-analysis of patients with the best long-term survival^[17] (CD/AIH and ALF) the effect of donor quality (ET-DRI) was even more pronounced: Transplanting an ET-DRI < 1.21 organ resulted in an 20 year survival of 79% compared to 39% for an ET-DRI > 1.4 organ (Figure 5).

Figure 6 shows the impact of the BMI on the long-term outcome after LT. Patients without pretransplant

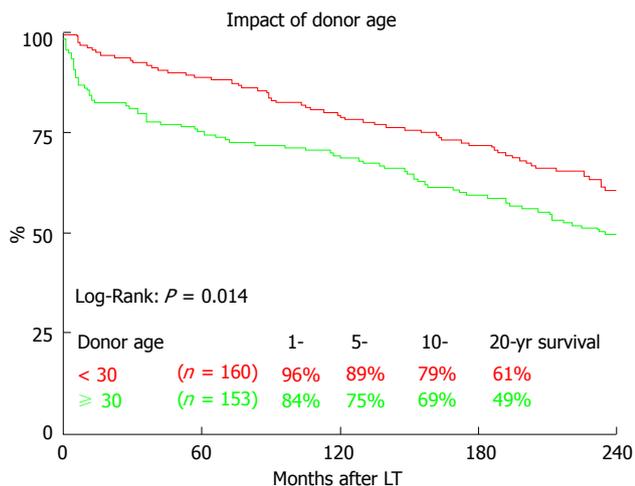

Figure 3 The impact of donor age on 20-year survival. LT: Liver transplantation.

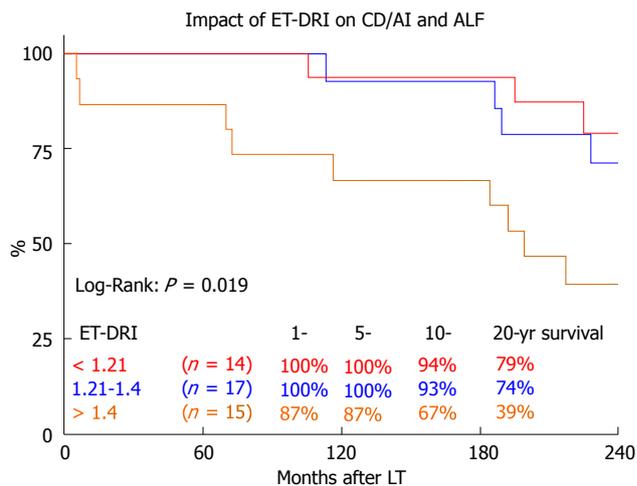

Figure 5 The impact of eurotransplant donor risk index categories on 20-year survival of recipients with cholestatic diseases, autoimmune hepatitis and acute liver failure. LT: Liver transplantation; ET-DRI: Eurotransplant donor-risk-index.

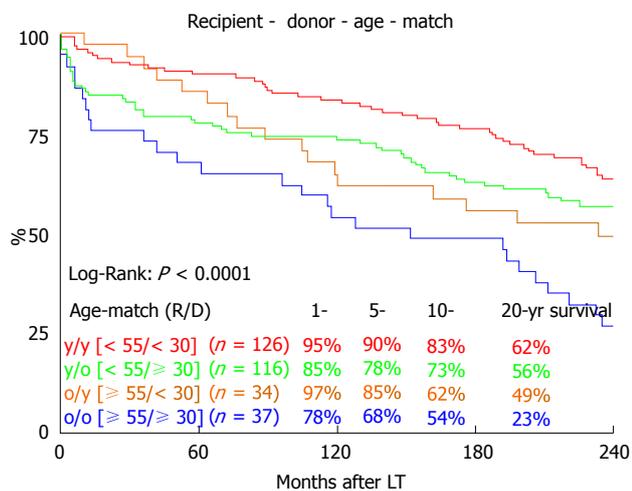

Figure 4 The influence of recipient-donor age match on 20-year survival. LT: Liver transplantation.

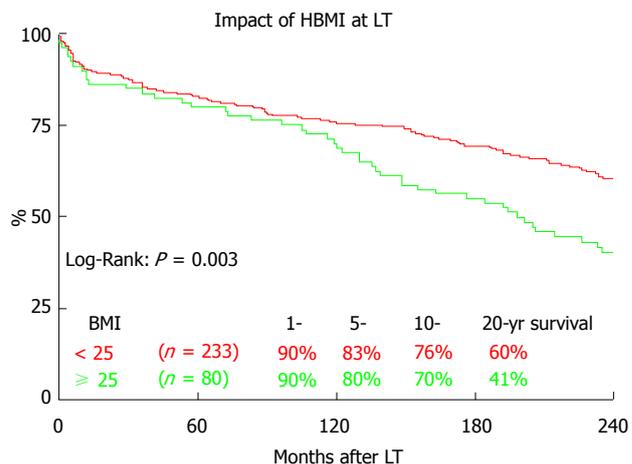

Figure 6 The impact of overweight (overweight, body-mass-index > 25) at time of liver transplantation on 20-year survival. LT: Liver transplantation; HBMI: High body mass index (> 25).

HBMI (< 25) showed significantly better overall 20-year survival (60.4% vs 40.6%, $P = 0.003$). HBMI did not significantly impact 1 year (90.0% vs 90.6%, $P = 0.703$), 5 year (80.0% vs 82.8%, $P = 0.471$) or 10 year (70.0% vs 75.5%, $P = 0.191$) survival.

Presence of MIRF and SIRF before transplantation did not significantly influence the overall 20-year survival ($P = 0.936$ and 0.387 , respectively) (data not shown).

Causes of death

As we have previously published^[17], the most common causes of death overall were recurrence of primary disease (21.3%), infection (20.6%) and *de-novo* malignancy (19.9%). While recurrent disease was most common in the first decade after LT, followed by infection and *de novo* malignancy, *de novo* malignancy was the most common cause of death during the second decade after LT, followed by infection and cardiovascular events. Recurrence of primary disease

was especially common in patients with hepatobiliary malignancy and virus-related cirrhosis. Among the *de-novo* malignancies, squamous-cell carcinomas were most common. Pneumonia and sepsis were the most common infections.

DISCUSSION

Recently, our center published the first European single-institution 20-year survival data and the most promising long-term outcomes worldwide to this point^[17]. More than half of our cohort survived for two decades after LT. With the present study, we aimed to compare the characteristics of 20-year survivors and 20-year non-survivors in order to characterize those patients who achieved outstanding long-term survival.

Not surprisingly, on average 20-year survivors were significantly younger and predominantly female. Pre-

vious studies have also found that survival for female recipients is slightly higher compared to male recipients. The prevalence of cardiovascular risk factors, as well as cardiovascular events, is higher in male long-term survivors, which may explain this finding^[17,21].

The Kaplan-Meier analyses of the long-term survival in this cohort show that the greatest disparity in outcome based on ET-DRI categories (Figure 2) seems to occur within the first year after LT; after this there is little divergence in the Kaplan-Meier curves according to donor risk. Thus, after the short-term post-transplant period has passed, the underlying disease and further recipient characteristics seem to play a more important role than the initial graft quality. Long-term outcome studies, such as this one, are valuable in identifying such recipient characteristics. One example is the fact that in our cohort, presence of HBMI does not become a significant prognostic factor until 10 years after LT.

As far as the distribution of primary indications for LT goes, we found that hepatobiliary malignancies had a particularly low survival rate^[17]. In this cohort, the ratio of survivors/non-survivors for patients with hepatobiliary malignancy was 0.25; several patients in this group presented at an advanced stage. Due to the high prevalence of recurrent disease among patients with HCC far beyond the Milan criteria^[22] and advanced cholangiocellular carcinomas^[23], they are no longer eligible for LT. The European Liver Transplant Registry states 20-year patient survival rates of 27% for primary liver tumors, which make up for 14% of the total indications for LT^[24]. On the other hand, patients with autoimmune and cholestatic liver disease (ratio 1.9) as well as patients with acute liver failure (ratio 2.29), made up a significant part of the 20-year survivors, which is in line with the findings of the European Liver Transplant Registry, which lists 20-year patient survival rates of 44% for cholestatic disease, 55% for autoimmune liver disease and 47% for acute hepatic failure, which make up for a total of 21% of all indications^[24].

Unexpectedly, the labMELD-score did not significantly influence 20-year survival in our cohort. Our study supports the findings of previous studies^[25] showing that the labMELD score is particularly relevant during the first couple years after LT. LabMELD categories showed a strong trend regarding the differences in 1-year survival, even if not statistically significant. After ten years, these differences evened out. Most surprisingly, after 20-years, recipients with labMELD > 25 showed the best overall survival. Even though the labMELD-score is able to predict waiting list mortality, it does not seem to be an adequate tool for predicting long-term outcome and thus survival benefit^[26]. With a mean labMELD-score of 18.6, the patients in our cohort can be considered relatively healthy compared to German patients receiving transplants in the current era, with an average matchMELD of 34^[14]. Also, the mean ET-DRI of 1.35 suggests excellent donor organ quality. In summary excellent overall conditions for transplantation, which

are hardly realized under the current LT conditions. This makes it difficult to interpret the impact of our data on the era of MELD-allocation with ECD organs. The MELD-score has contributed to reduce the waiting list mortality^[27] and decrease the waiting time for LT^[28]. However, there are several weaknesses: Interlaboratory variability of creatinine, bilirubin and INR causes a lack of objectivity^[29,30]. Secondly, the score does not adequately represent the necessity for LT for many indications, making it necessary to assign priority-based extra-points, which have seen a rather arbitrary up- and down-regulation^[31,32]. Most importantly, the MELD score neglects all donor characteristics in the allocation process whatsoever. Therefore, organ allocation according to a MELD-based policy is not true donor-recipient matching at all. Our findings suggest that, depending on the quality of a given donor organ, the underlying disease, the recipients' age and many other factors, a similar MELD value may result in very different long-term outcomes.

Another unexpected finding was the lack of significant impact of an impaired renal function prior to transplantation on long-term survival. The significant difference in mean eGFR between survivors and non-survivors (106 ± 70 mL/min per 1.73 m^2 vs 88 ± 39 mL/min per 1.73 m^2 , respectively, $P = 0.007$) is most likely due to the large amount of survivors with eGFR > 120 mL/min per 1.73 m^2 (30% vs 20%) and the fact that the MDRD-formula does not adequately represent the renal function for patients without impairment^[33]. In our previous publication mentioned above, we showed that a moderately or severely impaired renal function at 6 mo after LT was an independent risk factor for long-term survival in this cohort^[17]. However, in this study, neither patients with pretransplant MIRF nor those with SIRF showed significantly lower overall survival. This is contrary to what other authors have described^[34-36]. What was striking was the high number of non-survivors that had an eGFR that was just above 60, making these patients barely off the limit for an impaired renal function. Possibly, a number of non-survivors were pushed into renal impairment just after their LT. Ojo *et al.*^[36] found that the 5-year incidence of SIRF after LT was 18.1%, resulting in a 4.55-fold increased risk of death and Sanchez *et al.*^[35] described that the lower the initial GFR after LT, the earlier renal failure develops within the next 5 years, emphasizing the importance of a well-controlled post-transplant renal function.

Only about one in five survivors had HBMI before transplantation, compared to every third non-survivor ($P = 0.011$). Obese patients with terminal liver failure are not only at increased risk for perioperative morbidity and mortality^[37], but also for experiencing cardiovascular events^[38], which make up for a major proportion of deaths after LT^[3,17,39].

We found a significant impact of ET-DRI on long-term survival. While close to 60% of patients that received a donor organ with an ET-DRI < 1.2 survived for two

decades and longer, only less than 40% of the patients with an ET-DRI > 1.4 survived for twenty years. In recent years, more than 60% of all LT donor organs in Germany have an ET-DRI of > 1.5^[14], a number that is likely to increase even more with decreasing rates of organ donation. The impact of donor age by itself, which is one of the factors of the ET-DRI, on long-term survival was also significant. Regarding the recipient-donor age match it seems that "older" livers may be suitable for younger recipients, but the benefit of younger organs for elderly recipients evens out 10 years after transplant.

Schaubel *et al.*^[40] described that regardless of the organ quality, higher labMELD recipients have a significant survival benefit from LT, whereas lower labMELD candidates who receive higher ET-DRI organs demonstrate higher mortality and no significant survival benefit. According to that particular study, 2000 life-years could be saved per year if benefit-based allocation was implemented.

Our data suggest that the ideal LT recipient is a young woman with acute liver failure or CD/AIH, who has a BMI < 25, a normal kidney function and no dyslipidemia. Such a patient would benefit the most from a donor organ < 30 years old with an ET-DRI of < 1.2. Since this combination of characteristics may hardly be found in recent years, it is even more important to match a specific donor organ to an adequate recipient, based on benefit-based allocation.

COMMENTS

Background

With major improvements in outcomes after liver transplantation and growing experience regarding transplant management, both the indications for liver transplantation (LT) and donor criteria have been expanded over the years. Shortage of donor organs has led to changes in liver allocation policies and the use of marginal organs.

Research frontiers

Very long-term outcome data (20 years) after LT are scarce. In the presented cohort the best 20-year survival published ever so far was described. This retrospective analysis focuses on donor and recipient characteristics of survivors and non-survivors to elucidate factors that may be predictive of long-term survival.

Innovations and breakthroughs

Several factors influencing long-term survival after liver transplantation could be identified. It seems that "older" livers may be suitable for younger recipients, but the benefit of younger organs for elderly recipients evens out 10 years after transplant. The labMELD score seems not to be an adequate tool in prediction of long term survival. HBMI becomes predictive only ten years after transplant. A high number of non-survivors had an estimated glomerular-filtration-rate that was just above 60, making these recipients barely off the limit for an impaired renal function. Possibly, a number of non-survivors were pushed into renal impairment just after their LT. Immunosuppressive regimens should take this into account and may be adapted accordingly.

Applications

This study gives valuable insights in donor-recipient matching, when trying to achieve excellent long-term outcome, especially when allocating marginal organs to progressively sicker recipients.

Terminology

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; BP: Blood pressure; COD: Cause of death; DCD: Donation after cardiac death; ECD: Extended-criteria donor; ET-DRI: Eurotransplant Donor Risk Index; eGFR: Estimated glomerular-filtration-rate; HBMI: Overweight; HLP: Hyperlipidemia; HCC: Hepatocellular carcinoma; INR: International normalized ratio; LT: Liver transplantation; MELD: Model for end-stage liver disease; MIRF: Moderately impaired renal function; SIRF: Severely impaired renal function; tBili: Total bilirubin.

Peer-review

This retrospective study concerning characteristics of more than 20 years survivors after LT is very interesting and useful.

ABOUT COVER

Editorial Board Member of *World Journal of Transplantation*, Archil Chkhotua, MD, Director, Professor, Department of Urology, National Center of Urology, Tbilisi 0144, Georgia

AIM AND SCOPE

World Journal of Transplantation (*World J Transplant, WJT*, online ISSN 2220-3230, DOI: 10.5500) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJT covers topics concerning organ and tissue donation and preservation; tissue injury, repair, inflammation, and aging; immune recognition, regulation, effector mechanisms, and opportunities for induction of tolerance, thoracic transplantation (heart, lung), abdominal transplantation (kidney, liver, pancreas, islets), transplantation of tissues, cell therapy and islet transplantation, clinical transplantation, experimental transplantation, immunobiology and genomics, and xenotransplantation. The current columns of *WJT* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography.

AIM AND SCOPE

World Journal of Transplantation is now indexed in PubMed, PubMed Central.

Abstract

Chronic graft-*vs*-host disease (cGVHD) is the leading

cause of long-term morbidity and mortality following allogeneic hematopoietic stem cell transplantation. It presents as a chronic inflammatory and sclerotic auto-immune-like condition that most frequently affects the skin, oral mucosa, liver, eyes and gastrointestinal tract. Both clinical and animal studies have shown that multiple T cell subsets including Th1, Th2, Th17, T follicular helper cells and regulatory T-cells play some role in cGVHD development and progression; B cells also play an important role in the disease including the production of antibodies to HY and nuclear antigens that can cause serious tissue damage. An array of cytokines and chemokines produced by different types of immune cells also mediate tissue inflammation and damage of cGVHD target tissues such as the skin and oral cavity. Many of these same immune regulators have been studied as candidate cGVHD biomarkers. Recent studies suggest that some of these biomarkers may be useful for determining disease prognosis and planning long-term clinical follow-up of cGVHD patients.

Key words: Chronic graft-*vs*-host disease; Biomarker; Allogeneic hematopoietic stem cell transplantation; Cytokine

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Chronic graft-*vs*-host disease (cGVHD) is a frequent long-term medical complication of allogeneic hematopoietic stem cell transplantation which can have a devastating impact on overall health and quality of life. This immune-mediated disorder manifests as an inflammatory and autoimmune-like disorder that can affect multiple tissues in an individual patient. Both clinical and animal studies demonstrate that multiple T cell subsets, as well as B cells, and their secreted cytokines play important roles in cGVHD initiation and progression. In the last decade many molecular biomarkers have been identified that correlate with cGVHD onset and/or progression, and some might have applications clinically in the near future.

Presland RB. Biology of chronic graft-vs-host disease: Immune mechanisms and progress in biomarker discovery. *World J Transplant* 2016; 6(4): 608-619 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/608.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.608>

INTRODUCTION

Allogeneic hematopoietic stem cell transplantation (allo-HSCT) is utilized primarily as a curative treatment for both hematological and non-hematological malignancies^[1], although it has been used successfully in small-scale clinical trials as a stem cell therapy for some inherited diseases such as Recessive Dystrophic Epidermolysis Bullosa^[2]. In the case of hematologic malignancies, the graft-vs-leukemia or graft-vs-tumor (GVL or GVT) effect mediated by donor-derived T cells helps to eliminate malignant cells in the transplant recipient^[3]. However, a major long-term complication of allo-HSCT is chronic graft-vs-host disease (cGVHD), which occurs in 30%-70% of patients, with adults more frequently affected than pediatric patients^[4]. Chronic GVHD manifests as an autoimmune-like inflammatory disease that can affect a single organ, but more typically it presents as a multi-organ disease affecting the skin (75% of patients), oral mucosa (51%-63% of patients), liver, eyes and gastrointestinal tract (22%-51% of patients)^[4]. Oral mucosal disease can include salivary gland pathology or sclerosis of the lamina propria or submucosa. Other tissues including the lung, esophagus, joints, muscles and genitalia can also be involved (Table 1). cGVHD is often preceded by acute GVHD, which typically occurs within 100 d after transplantation, although the acute form can persist longer.

In allo-HSCT patients, cGVHD is the most common cause of non-relapse mortality (NRM, which refers to mortality not related to the primary malignancy or disease) among patients surviving more than two years^[5]. Other important contributing factors to patient mortality are viral or bacterial infection and secondary malignancies (Figure 1)^[4,6]. A recent analysis by the Center for International Blood and Marrow Transplant Research (CIBMTR) of more than 26000 allo-HSCT patients demonstrated that the incidence of cGVHD is increasing worldwide, making it imperative that we fully understand the etiology of this disease^[7].

This review will focus on the pathobiology of cGVHD, which has features of both alloimmune and autoimmune disease and involves altered activities and function of various T cell populations [T helper (Th) 1, Th2, Th17, T follicular helper cells and regulatory T-cells] as well as of B cells. Equally important are the various cytokines and chemokines produced by immune cells and their target tissues, which cause inflammation and tissue damage. A second productive area of cGVHD research is biomarker discovery; high-throughput approaches including mass spectrometry have led to the identification of a number

of molecular markers from blood and saliva that correlate with active disease. Not surprisingly, many of these markers are associated with altered host immunity and/or tissue inflammation. This review will not discuss current primary and secondary therapeutic strategies for cGVHD; for an in-depth discussion of this topic, the reader is referred elsewhere^[8-10].

CLINICAL FEATURES

According to the NIH consensus criteria published in 2005, cGVHD can be subclassified into: (1) Classic cGVHD presenting with manifestations that can be ascribed only to cGVHD; and (2) Overlap syndrome that has diagnostic or distinctive cGVHD manifestations together with features typical of acute GVHD^[11]. Acute GVHD occurs in 40%-60% of patients receiving allo-HSCT and is one of the major risk factors for subsequent cGVHD. To improve cGVHD classification, the NIH severity score was developed which documents the number of organs involved and numerically scores the degree of functional impairment. Generally, patients are assessed as having mild, moderate or severe disease on a scale of 1 to 4 for each tissue^[11-13]. However, clinical symptoms of cGVHD often overlap with other autoimmune diseases such as lichen planus and scleroderma and the degree of organ involvement is highly variable, which can make diagnosis challenging^[8,14]. Table 1 lists signs and symptoms that are considered to be diagnostic of cGVHD as well as some of the commonly observed clinical features that are considered to be insufficient for disease diagnosis. As many as three or more tissues can be affected in a single patient, as reflected in the NIH global severity classification of cGVHD^[13]. Skin manifestations that are considered diagnostic include poikiloderma (altered pigmentation with erythema), lichen planus-like lesions, sclerosis and morphea-like features (Table 1). Distinctive features (often observed in skin cGVHD but not sufficient for diagnosis) include depigmentation, papulosquamous lesions, ichthyosis and pruritis. Skin appendages are often targeted as well but these signs are not considered diagnostic: Symptoms can include scalp hair thinning or alopecia, sweat impairment and nail dystrophy or onycholysis (nail loss)^[11,13].

Cutaneous cGVHD can occur in two forms termed lichenoid and sclerodermatous^[15]. Lichenoid lesions usually occur early in the course of the disease, presenting as erythematous papules or plaques, with a squamous surface. Typical affected sites include the face, ears, palms and soles. Sclerodermatous cGVHD, which generally develops as a later complication, appear as sclerotic, shiny, white or yellow plaques with patchy hyperpigmentation or a poikilodermal appearance^[15]. Sclerodermatous cGVHD can be localized or generalized and affect underlying tissues including the fascia, ligaments and peripheral nerves, causing pain and morbidity for the affected patient.

Oral symptoms vary but commonly involve lichenoid changes, xerostomia as a result of salivary gland damage,

Table 1 Signs, symptoms and prevalence of chronic graft-*vs*-host disease in selected organs and tissues

Organ or tissue	Prevalence, % ¹	Diagnostic features ²	Distinctive features ³
Skin	75%	Poikiloderma Lichen planus-like features Sclerosis	Depigmentation Papulosquamous lesions
Mouth	51%-63%	Morphea-like features Lichen planus-like features	Xerostomia Mucocoeles Mucosal atrophy Ulcers Pseudomembranes
Liver	29%-51%	None ⁴	None ⁴
Eye	22%-33%		Dry, gritty or painful eyes Cicatricial conjunctivitis Keratoconjunctivitis-Sicca syndrome
GI tract and esophagus	7%-45%	Esophageal web Strictures or stenosis in upper esophagus	
Lung	4%-19%	Bronchiolitis obliterans	Air trapping and bronchiectasis on chest CT scan
Muscles, fascia and joints	6%	Fasciitis Sclerosis	Myositis or polymyositis
Genitalia	1%	Joint stiffness or contractures Lichen planus-like features Lichen sclerosus-like features	Erosions, Fissures, Ulcers

¹Frequency of tissue involvement at initial cGVHD diagnosis (from Lee *et al*^[4]); ²Clinical symptoms that are sufficient for cGVHD diagnosis. Information adapted from references 8 and 13; ³Clinical symptoms that are frequently seen in cGVHD, but insufficient for cGVHD diagnosis. Information adapted from references 8 and 13; ⁴While no diagnostic or distinctive features have been identified for liver cGVHD, hepatitis is often seen (and also sometimes in acute GVHD) with elevated serum levels of bilirubin, alkaline phosphatase and alanine aminotransferase (ALT)^[13]. cGVHD: Chronic graft-*vs*-host disease; CT: Computed tomography.

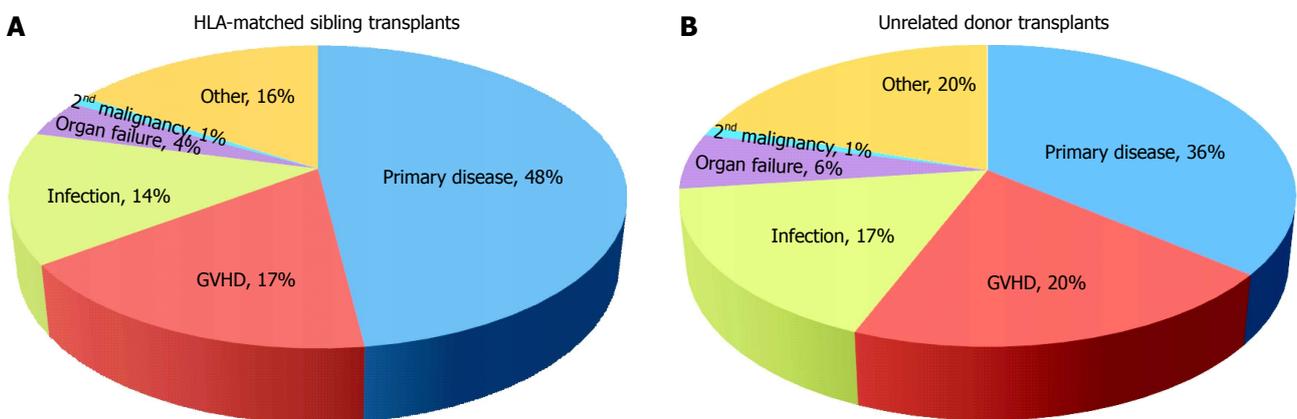

Figure 1 Causes of death among allogeneic hematopoietic stem cell transplantation patients. Pie charts show causes of death among patients who received a cell graft from (A) an HLA-matched sibling or (B) an unrelated donor. Data is from the Center for International Blood and Marrow Transplant Research, for allogeneic hematopoietic stem cell transplants performed in 2012-13^[88] (Available from: URL: <http://www.cibmtr.org/Data/Resources/pages/index.aspx>). GVHD: Graft-*vs*-host disease.

mucositis, erythema, mucocoeles and restricted mouth opening (trismus) due primarily to sclerosis^[16-18]. However, under current guidelines only lichen planus-like features are considered to be diagnostic (Table 1)^[13]. Oral sensitivity and pain are often observed, which in more severe cases manifests as dysphagia (difficulty with swallowing) and weight loss. In one recent study of 210 cGVHD patients, 29% of cases were classified as malnourished by measurement using the Patient-Generated Subjective Global Assessment tool. Malnutrition was correlated with a lower body-mass index and poorer overall survival^[19]. Gingivitis and tooth decay also occur because of xerostomia and altered oral immunity

related to immunosuppression and reduced salivary IgG production^[20].

Clinical symptoms seen in other involved tissues such as the liver, eyes, gastrointestinal tract, lungs, muscles/fascia and genitalia are summarized in Table 1, and have been reviewed extensively elsewhere^[9,13]. Neurological manifestations of cGVHD are rare, but when present can include Myositis and Myasthenia gravis that affect the peripheral nervous system, and less commonly, various complications that affect the central nervous system^[21]. Clinical features of cGVHD do not seem to vary with patient age, graft source (typically either bone marrow or PBSCs) and type of pre-transplant conditioning^[4,9].

Most cases of cGVHD occur 4-6 mo after allo-HSCT, but 5%-10% of patients are diagnosed more than one year following allogeneic transplantation.

RISK FACTORS

The best documented risk factors for cGVHD are a history of acute GVHD (seen in 40%-60% of cGVHD patients), the use of PBSCs for grafting, a female donor-male recipient combination, older patient age and the use of HLA-mismatched or unrelated donors^[13,22,23]. The increasing use of PBSCs (which contain more T cells compared to aspirated bone marrow) is one factor that influences the incidence and severity of cGVHD, since alloreactive T cells are a major player in cGVHD pathobiology^[7]. These risk factors appear to largely explain the increasing incidence of cGVHD worldwide in allo-HSCT; however, additionally, a significant decline in early NRM appears to be contributing to the increased incidence of cGVHD in long-term survivors^[7]. Notably, the frequency of GVHD-associated mortality is similar in HLA-matched sibling transplants compared to transplants performed using an unrelated donor (Figure 1).

A number of studies have also implicated certain genetic polymorphisms in addition to HLA antigen disparity between donor and recipient in the risk of GVHD risk (reviewed in Pidalá *et al*^[24]). For example, polymorphisms in a considerable number of genes that encode cytokines, chemokines or their receptors are associated with increased risk of cGVHD. These include genetic variants in the donor and/or recipient *IL-10* genes^[25-27], donor *IL-1 α* gene^[28], recipient *IL-6* gene^[29], recipient MHC class I-related chain A (*MICA*) gene (Val allele)^[30], and donor and recipient *IL-1* receptor antagonist (*IL-1ra*) genes^[25,28]. For *MICA*, which acts as an activating ligand for the NKG2D receptor on certain types of T-cells, cGVHD incidence was positively correlated with serum *MICA* levels in patients post-HSCT; on the other hand, the presence of *MICA* antibodies prior to transplantation conferred protection against cGVHD^[30]. A smaller number of genetic polymorphisms have been associated with decreased risk of cGVHD^[24].

Baron *et al*^[31] utilized gene expression profiling of donor CD4⁺ and CD8⁺ T cells to develop a "GVHD-predictive signature", demonstrating the central importance of the TGF- β signaling pathway in regulating donor T cell function^[31]. Remarkably, the so-called "dangerous donor" trait derived from T cell gene expression profiling not only predicted early (acute) GVHD, but also cGVHD occurrence in the recipient at one year post-transplantation. These observations reinforces other studies in humans and mice showing that the growth factor TGF- β has pleiotropic effects on T cells, including inhibition of Th1 cell differentiation and promoting expansion of regulatory T cells that are protective against cGVHD^[9,32,33]. It also suggests that the grafted stem cells can have a long-term, dominant influence on the transplant recipient's T cell profile and consequently the overall health of the patient.

PATHOBIOLOGY OF CGVHD: ROLE OF T CELLS, B CELLS AND THEIR CYTOKINES

T cells

While the mechanisms that cause the inflammation and tissue damage of acute GVHD are now quite well understood, the pathobiology of cGVHD is more complex and less well understood. Many investigators believe that the destructive immunological and autoimmune mechanisms that cause cGVHD are distinct from acute GVHD, irrespective of whether or not the cGVHD evolves from acute GVHD^[6,34]. Activated donor T cells are the most important cell population in cGVHD, since T cell depletion from the graft prevents cGVHD in both human and animal studies^[35]. The use of rabbit anti-thymocyte globulin (ATG) in conditioning regimens prior to transplant reduces the risk of subsequent acute and cGVHD, either by depleting donor T cells or by interfering with their activation by recipient alloantigens^[22,36]. The major T cell subsets proposed to be involved in cGVHD include CD4⁺ T cells, CD4⁺ regulatory T cells (Tregs) and CD8⁺ T cells (Table 2).

Th1, Th2 and Th17 cells: Alloreactive CD4⁺ T cells that react to foreign (donor-derived) antigens include several Th cell subsets, primarily Th1, Th2 and Th17 cells. A central role for Th1 cells in acute GVHD is well established^[6]; however, the importance of Th1 (and Th2) cells in cGVHD is still a matter of debate, even though Th1 cytokines such as interferon- γ (IFN- γ) can be found in skin and other tissues of affected patients^[37]. Infusion of murine IFN- γ -null donor T cells reduced cGVHD symptoms in skin and salivary glands, indicating a role for Th1 cells in certain tissues^[38]. A role for Th2 cells has been suggested because of the role of Th2 cytokines such as IL-4 and IL-13 (Table 2) in the production of antibodies to both self and non-self-antigens in patients; murine studies support the involvement of the Th2 cytokines IL-4 and IL-10 in stimulating B cell expansion in cGVHD^[39].

Th17 cells produce several cytokines including IL-17, IL-21 and IL-22, which have potent pro-inflammatory functions in cGVHD^[40]. IL-17A, produced mainly by CD8⁺ T cells, stimulates scleroderma which is an important feature of cutaneous cGVHD; however, current data suggests that co-expressed Th1 cytokines such as tumor necrosis factor- α (TNF- α) contribute to the observed pathology^[41]. Improvement in cGVHD symptoms correlates with a reduction in Th-17 cell numbers in peripheral blood^[42]. In liver cGVHD, there are increased numbers of Th17 cells and an increased Th17/Treg ratio observed in liver biopsies, suggesting that Th17 cells are an important driver of clinical liver disease^[43].

T follicular helper cells: T follicular helper (TFH) cells promote differentiation of naïve B cells into memory B

Table 2 Immune cell types and their function in chronic graft-*vs*-host disease

Cell type	Subtypes	Key cytokines or markers	Brief summary of disease involvement
CD4 ⁺ T cells	Th1	IFN- γ , TNF- α	Pro-inflammatory. Important in acute GVHD, but role in cGVHD unclear
	Th2	IL-4, IL-13	Stimulate antibody production. Role in clinical cGVHD poorly defined
	Th17	IL-17; also IL-21, IL-22, TNF- α	Pro-inflammatory. IL-17 levels correlate with disease severity; IL-17 induces scleroderma of skin and lung
	Tregs	TGF- β , required for Treg proliferation and (differentiation)	Produced mostly in thymus. Suppress autoreactive T cells. Lower levels of Tregs present in cGVHD patients, associated with thymic damage and loss of self-tolerance in cGVHD
	T follicular helper cells ¹	Express CCR5, PD-1 and ICOS	Promote abnormal B cell maturation into long-lived active plasma cells, and IgG secretion
CD8 ⁺ T cells		CXCL9, CXCL10	Mediate graft- <i>vs</i> -tumor effect of transplant. Serum CXCL9 levels elevated in cGVHD patients
B cells (total)		Increased BAFF/B-cell ratio, elevated serum BAFF levels	Decreased in active cGVHD. Remaining B cells are resistant to apoptosis
Naïve and transitional B cells		CD19	Decreased in active cGVHD
Memory B cells (total)		CD19, CD27	Decreased in active cGVHD. Cells essential for a normal immune response to bacterial pathogens or opportunistic infections
Regulatory B cells		IL-10	Decreased in active cGVHD. Function to maintain tolerance and help prevent autoimmune disease
Plasma cells		CD27, CD38	Increased in active cGVHD. Cells secrete immunoglobulins including IgGs and are resistant to apoptosis

¹Mainly classified into Th2 and Th17 subtypes^[44]. cGVHD: Chronic graft-*vs*-host disease; BAFF: B-cell activating factor; CD3: Cluster of Differentiation molecule 13, 19, 27 and 38; CCR5: Chemokine (C-C Motif) receptor 5; CXCL: Chemokine (C-X-C motif) ligand; ICOS: Inducible T-Cell Co-Stimulator; IFN- γ : interferon gamma; IL: Interleukin; PD-1: Programmed cell death 1; Th: T helper cell; TGF- β : Transforming growth factor beta; TNF- α : Tumor necrosis factor alpha.

cells and class switching of *IgG* genes in the germinal center, within secondary lymphoid organs. A recent study showed that TFH cells were unusually active with prolonged survival in cGVHD patients, which correlates with the aberrant survival of B cells and hypersecretion of immunoglobulins^[44]. The increased survival of Th2- and Th17-type TFH cells was correlated with increased cellular expression of the pro-survival marker Bcl-2. Overall, the study by Forcade *et al*^[44] suggests that aberrant B cell activity including production of antibodies is driven, at least in part, by abnormal TFH cell activity. Studies using a murine model have confirmed the importance of TFH cells in cGVHD pathogenesis, particularly for the development of bronchiolitis obliterans syndrome which is a signature feature of lung cGVHD^[45] (Table 1).

Tregs: Tregs, which are CD4⁺ CD25⁺ and also express the transcription factor FOXP3, suppress autoreactive T cells and are important for immune system homeostasis. Specifically, Tregs are essential for the establishment and maintenance of tolerance after allo-HSCT^[46]. Tregs are depleted in both acute and cGVHD, demonstrating their importance as suppressors of inflammation and disease development^[23]. Impaired Treg production and function has been linked to thymic damage as a result of CD4⁺ lymphopenia following allo-HSCT, at least in myeloablative patients^[47]. The presence of Tregs in the skin and oral mucosa of cGVHD patients in a functional (*e.g.*, CXCR3⁺)

state suggests they may play a role in limiting tissue damage by alloreactive T cells^[48]. Pharmacological approaches used to treat steroid-refractory cGVHD that increased Treg cell numbers have shown promise clinically in treating cutaneous cGVHD^[49]. Further, in a study of allo-HSCT patients with acute leukemia, direct infusion of Tregs together with conventional T cells protected against GVHD in almost 90% of engrafted patients, while still maintaining the GVT anti-tumor effect conferred by conventional T cells^[50]. These studies suggest that manipulation of Tregs might be a feasible approach to reducing or preventing GVHD without compromising the anti-tumor surveillance capacity of the patient's immune system.

CD8⁺ T cells: CD8⁺ T cells are another immune cell population present in tissues affected by cGVHD, including the skin and oral mucosa^[17]. Donor CD8⁺ cells mediate the GVT effect of allo-HSCT that typically results in the eradication of malignant cells from the patient. Among the cytokines produced by CD8⁺ cells are CXCL9 and CXCL10; CXCL9 is elevated in the serum of early-stage cGVHD patients, with CXCL9 levels being correlated with disease severity^[51] (Tables 2 and 3).

B cells

In addition to T cells, there is increasing evidence that B cells play a number of important roles in cGVHD pathogenesis^[52]. Patients with active cGVHD consistently have

Table 3 Candidate biomarkers of chronic graft-*vs*-host disease¹

Gene/protein	Function	Biofluid ³	Ref.
BAFF, soluble; BAFF/B cell ratio	Growth factor, promotes B cell expansion and activation	Blood	[59,60,77]
CXCL9 ²	Chemokine produced by activated T cells	Blood	[51,79]
CD-13, soluble	Antigen presentation	Blood	[59]
C-reactive protein ³	Acute phase protein	Blood	[12]
Cystatin B	Inhibitor of cathepsin proteases	Saliva	[80]
IL-1ra	Inhibitor of IL-1 receptor signaling	Saliva	[80]
IL-2R, soluble	IL-2 receptor, marker of activated T cells	Blood	[59,76]
IL-6	Pro-inflammatory Th2 cytokine	Blood	[42,75]
IL-10	Th2 cytokine	Blood	[73]
IL-15	Enhances anti-tumor function of CD8 ⁺ T cells	Blood	[78]
Lactoperoxidase	Anti-microbial enzyme	Saliva	[81]
Lactoferrin	Iron-binding glycoprotein	Saliva	[81]
MICA, soluble	Stimulates T cell activity <i>via</i> NKG2D receptor	Blood	[30]
TGF- β	Anti-inflammatory cytokine; stimulates activity of Tregs	Blood	[33]
TNF- α	Pro-inflammatory Th1 cytokine	Blood	[73-75]

¹This table only includes proteins identified in human biofluids. Antibodies are discussed in the text; ²Blood markers were measured in either plasma or serum isolated from peripheral blood, depending on the study. For saliva, whole unstimulated saliva collected from oral cGVHD patients was used; ³Increased CRP levels were especially associated with joint/fascia and skin involvement, compared to the non-cGVHD control group. cGVHD: Chronic graft-*vs*-host disease; BAFF: B-cell activating factor; CXCL: Chemokine (C-X-C motif) ligand; CD-13: Cluster of Differentiation molecule 13 (or aminopeptidase N); IL-1ra: Interleukin 1 receptor antagonist; IL-2R: Interleukin 2 receptor; MICA: MHC class I-related chain A; TGF- β : Transforming growth factor beta; TNF- α : Tumor necrosis factor alpha; CRP: C-reactive protein.

lower numbers of naïve and transitional B cells as well as total B cells^[53,54] (Table 3). Regulatory B cells that secrete the anti-inflammatory cytokine IL-10 (and form a subpopulation within the transitional and memory B cell compartments) were also less frequent in cGVHD patients and displayed a deficiency in IL-10 production^[55]. Together with Tregs, regulatory B cells play a central role in graft tolerance and the prevention of autoimmune disease and hence represent a topic worthy of further investigation in relation to cGVHD^[56]. CGVHD patients are susceptible to pneumococcal infection which can cause severe or fatal infections in long term transplant survivors^[57]. This susceptibility to infections is associated with the abnormal B cell profile, including decreased numbers of memory B cells that are critical for a normal immune response including IgG production^[53,58]. Like many other autoimmune conditions, cGVHD patients frequently produce allo- and auto-antibodies to DNA and/or other antigens such as male HY antigen, which can correlate with disease onset and severity (see below). Activated B cells secrete an array of Th1 and Th2 cytokines that can regulate the function of T cell populations including Tregs. Levels of B cell activation factor (BAFF), a cytokine that promotes the survival and differentiation of activated B cells, are consistently increased relative to B cell numbers in patients with cGVHD^[59,60]. As discussed above, the increased activity of TFH cells appears to play a significant role in producing the abnormal B cell profile characteristic of cGVHD^[44].

Perhaps the best evidence that B cells are functionally important in human cGVHD are the numerous clinical observations with Rituximab, a humanized monoclonal antibody that targets the membrane protein CD20 of B cells, causing their cell death. Rituximab (and other anti-CD20 drugs) are effective in the treatment of steroid-

refractory cGVHD, resulting in rapid and selective depletion of B cells and diminished activation of cytotoxic T cells; concurrently, the number and activity of Tregs are elevated^[52,61,62]. In one study, the prophylactic use of Rituximab after allo-HSCT significantly reduced the incidence of both acute and cGVHD as well as NRM^[63]. Hence, inhibiting B cell function has profound effects on both B and T cell homeostasis, with significant benefits to cGVHD patients especially in cases where other primary and/or secondary treatments have been unsatisfactory.

ANIMAL MODELS OF CGVHD

Several types of murine models have been utilized for studies of GVHD pathobiology including: (1) a bone marrow transplantation (BMT) model involving lethal radiation (total body irradiation, TBI) and transplantation of syngeneic marrow into treated mice^[64]; (2) a parent-into-F1 model where donor spleen cells are infused into non-irradiated mice^[39]; and (3) a transgenic model utilizing a self-antigen, membrane-associated chick ovalbumin, expressed under the control of the K14 promoter (K14-mOVA), where autoreactive skin disease is promoted by adoptive transfer of CD8 T cells from a second mouse strain, OT-1, that has an engineered T cell receptor specific for an ovalbumin peptide^[65,66]. These animal models each demonstrate one or more manifestations of clinical cGVHD including the presence of anti-DNA antibodies, sclerosis, weight loss and chronic inflammation of skin and mucosal tissues associated with elevated Th1, Th2 and/or Th17 cytokines. The K14-mOVA adoptive transfer model has been used to test the efficacy of novel anti-inflammatory biologics that target the Janus kinase (JAK)^[67] and Histone Deacetylase 6^[68] enzymes, which were shown to be effective at suppressing and/or

reversing cutaneous disease. Tofacitinib, the JAK inhibitor, blocked the expansion and activation of CD8⁺ cells thereby reducing IFN- γ secretion by CD8⁺ cells and keratinocytes as well as preventing the downstream consequences of interferon signaling such as chemokine production and keratinocyte apoptosis^[67]. Another JAK inhibitor, Ruxolitinib (INCB018424), reduced murine GVHD (acute GVHD) symptoms and the levels of pro-inflammatory cytokines by both impairing differentiation of CD4⁺ T cells into IFN- γ and IL-17-producing cells, and by promoting the production of protective Tregs^[69]. Notably this JAK 1/2 inhibitor reduced GVHD symptoms and improved overall animal survival while still maintaining the anti-tumor (GVT) effect^[70].

While these pre-clinical models have been valuable in defining the immune mediators of cGVHD, the animal models do not typically parallel the evolution of the human disease, especially the common clinical presentation of classic cGVHD^[8]. Additionally, in mice receiving intensive conditioning regimens (especially radiation), there is a well characterized scenario of inflammatory cytokine release, T cell activation and homing to target organs where tissue destruction occurs through the action of PBMCs and their associated cytokines. However, in humans the preparative regimen is only one factor involved in GVHD initiation, and its influence may be diminished in patients who now receive reduced-intensity conditioning prior to allo-HSCT^[8]. Some recently described animal models exhibit systemic disease with multi-organ involvement including the lung, which appears to more closely resemble human cGVHD^[71]. Despite some weaknesses, animal models will undoubtedly continue to provide insight into specific aspects of cGVHD pathobiology and will be essential for preclinical testing of new therapies for acute and cGVHD.

CGVHD BIOMARKERS

An emerging area of cGVHD research involves the discovery and validation of biomarkers that might eventually be used in clinical diagnosis or treatment planning. To date, most studies have focused on protein and immune cell biomarkers, even though RNAs (including mRNAs and micro RNAs) might also have utility as disease biomarkers^[54,60]. As defined at the first meeting of the NIH Biomarker Working Group in 2006, cGVHD biomarkers could be used in disease management or clinical trials to: (1) predict response to therapy; (2) measure disease activity; (3) predict the risk of developing cGVHD; (4) diagnose cGVHD or predict prognosis; and (5) serve as a surrogate end point for therapeutic response^[37].

To date, researchers have utilized mass spectrometry-based discovery approaches as well as Luminex and antibody arrays to screen clinical samples for potential serum and saliva protein biomarkers. Biomarkers identified to date can be broadly divided into proteins that function as cytokines and chemokines, immune (*e.g.*, cytokine) receptors and other types of immune or non-immune proteins (Paczesny *et al*^[72] for a recent review).

Identified serum biomarkers that might indicate overall disease (and/or altered immune cell) activity include B cell activation factor (BAFF), MICA and anti-MICA antibodies, TNF- α , IL-15 and Chemokine (C-X-C motif) ligand 9 (CXCL9). Salivary biomarkers, associated mainly with oral cGVHD, include IL-1ra, cystatin B, lactotransferrin and lactoperoxidase (Table 3). Cellular markers primarily comprise immune cell populations that are altered in cGVHD (Table 2).

Serum biomarkers

Chronic cGVHD onset and/or persistence is associated with increased levels of TNF- α , BAFF, IL-6, sIL-2R (soluble IL-2 receptor alpha), and IL-10, and decreased levels of TGF- β and IL-15 (Table 3). Several studies have reported elevated levels of the pro-inflammatory cytokine TNF- α in acute and cGVHD, with measured levels correlating with cGVHD severity^[73-75]. IL-6 shows a similar trend and correlation with cGVHD severity^[42,75]. Soluble IL-2 receptor alpha (sIL-2R α) is another example of a serum marker that is increased in pediatric and adult patients with cGVHD^[59,76]. BAFF, a growth factor that promotes B cell differentiation and immunoglobulin production, is increased in both pediatric and adult patients with cGVHD; levels of this growth factor are often reported relative to the number of B cells in blood samples^[51,59,60,77]. High levels of BAFF protein were present in allo-HSCT patients who subsequently developed cGVHD, confirming its role in alloimmunity^[77]. CXCL9 levels are also elevated in newly diagnosed cGVHD patients and were correlated with disease severity in three different cohorts studied at two transplant centers^[51].

Other markers besides BAFF and CXCL9 have been shown to have potential predictive value in allo-HSCT patients for determining future disease. For example, elevated levels of soluble MICA protein post-allo-HSCT were associated with an increased risk of cGVHD (by contrast, as stated above, the presence of MICA antibodies before transplantation conferred some protection from cGVHD)^[30]. Similarly, Pratt *et al*^[78] have shown that patients with low serum levels of IL-15 at day 7 post-transplant had 3-fold higher risk of developing cGVHD subsequently. IL-15 levels were observed to be inversely correlated with CD8 T cell levels, which are important for the GVT effect but also influence the development of cGVHD (see above).

In addition to intrinsic, host-dependent (*e.g.*, immune) factors, the levels of biomarkers such as BAFF and CXCL9 can be modified by extrinsic factors including immunosuppressive drugs such as corticosteroids^[51,54]. Hence, as recognized by many investigators, independent validation of promising biomarker candidates is essential. CXCL9 was recently validated as a cGVHD biomarker in a multicenter United States study of allo-HSCT patients^[79].

Salivary biomarkers

Two recent studies utilizing mass spectrometry approaches identified a total of 82 and 102 salivary proteins, re-

spectively, that showed altered expression in oral cGVHD^[80,81]. IL-1 receptor antagonist (IL-1ra) exhibited reduced expression in patients with oral cGVHD^[80]. The changes in IL-1ra expression coupled with higher levels of IL-1 family cytokines^[16] in saliva likely enhance oral inflammation and subsequent tissue damage. In particular, IL-6 levels have been shown to correlate with oral cGVHD severity^[16]. Changes in expression of salivary lactoperoxidase and lactotransferrin have also been reported, indicative of impaired innate immunity in oral cGVHD^[81] (Table 3). The alterations in the salivary proteome among proteins involved in innate and acquired immunity are consistent with the clinical features of oral cGVHD, in particular patient susceptibility to bacterial and viral infections^[4,18]. Changes in inorganic salivary components, especially Na⁺ and Cl⁻ ions and inorganic phosphate, also occur in concert with cGVHD onset, correlating with hyposalivation and damage to the salivary glands^[82,83].

Other biofluids

Certain Th2 and Th17 cytokines, in particular IL-6, IL-10, IL-17A and TNF- α are elevated in the tear fluid of cGVHD patients and correlated with systemic cGVHD regardless of ocular symptoms; levels of three of these cytokines (IL-6, IL-10 and TNF- α) also were significantly correlated with ocular cGVHD parameters^[84].

Cellular biomarkers

In addition to protein biomarkers, a large number of immune cell populations have been studied as potential cGVHD biomarkers. Some of the best studied are listed in Table 2. As discussed in the Pathobiology section above, CD4⁺ IL-17⁺ Th17 cells are elevated in active cGVHD while Tregs that express the markers CD4, CD25 and FoxP3 are typically decreased^[42,47]. There are also complex changes in the B cell population of cGVHD patients. Overall, total B cell counts are decreased in cGVHD patients as are the levels of naïve, transitional and regulatory B cells. In contrast, differentiated CD38⁺ CD27⁺ IgG-secreting plasma cells are increased in patients with active cGVHD (Table 2)^[53,54].

Antibodies

Antibodies including autoantibodies are another group of well-studied potential biomarkers that are produced in cGVHD patients by an aberrant B cell population. Up to 80% of allogeneic transplants involving a female donor-male recipient combination produce antibodies against Y-chromosome-encoded HY proteins, and these antibodies appear to predict the development of cGVHD^[8,37]. Antibodies to Platelet-derived Growth Factor (PDGF) Receptor, double stranded DNA and anti-nuclear antibody (ANA) are also common in cGVHD patients^[59]. Anti-PDGF receptor antibodies cause accumulation of reactive oxygen species and stimulate type I collagen expression, suggesting a role for these antibodies in skin and lung fibrosis^[85,86]. Patients with classic cGVHD were found

to have higher levels of ANA and anti-DNA antibodies compared to patients who had a prior history of acute GVHD where B cells have limited involvement^[59].

CONCLUSION

CGVHD is a chronic inflammatory and autoimmune-like condition that involves a complex interplay between the immune systems of the transplant donor and recipient. Despite significant progress in understanding the risk factors, and the development of effective second-line treatments for steroid-refractory cGVHD, the incidence of cGVHD is increasing worldwide^[7]. While donor-derived T cells are still considered to be the preeminent mediators of cGVHD, aberrant B cells clearly play a significant role in promoting autoimmunity and inflammation, and conferring susceptibility to serious, often life-threatening infections. The enhanced activity of T follicular helper cells in cGVHD also appears to play a key role in the aberrant B cell activity and the resulting autoimmune-like features of cGVHD, including the presence of antibodies that target HY and nuclear proteins^[44].

In addition to the significant progress in our understanding of cGVHD immunobiology and pathobiology, guidelines for biomarker development and validation were recently updated. The updated guidelines include recommendations for biomarker identification, verification, qualification, and application with terminology based on Food and Drug Administration and European Medicines Agency guidelines^[72]. Suggested areas of focus for validation include biomarkers that are prognostic, stratify cGVHD risk or are predictive of future disease. Biobank repositories that can serially collect peripheral blood and cell samples from allo-HSCT patients in a standardized format will also be an important tool for pre-clinical biomarker validation^[72]. The French National Cryostem Project is one example of such a national effort^[87,88] which, together with multicenter collaborations^[51,79], should enable protein biomarkers to be added to the clinician's toolkit for cGVHD patient care in the not-too-distant future.

ACKNOWLEDGMENTS

I thank Dr. Thomas Morton for critically reading this manuscript. I also thank the anonymous reviewers for their many helpful comments and suggestions.

Abstract

Patients listed for organ transplant frequently have severe coronary artery disease (CAD), which may be treated with drug eluting stents (DES). Everolimus and zotarolimus eluting stents are commonly used. Newer generation

biolimus and novolimus eluting biodegradable stents are becoming increasingly popular. Patients undergoing transplant surgery soon after the placement of DES are at increased risk of stent thrombosis (ST) in the perioperative period. Dual antiplatelet therapy (DAPT) with aspirin and a P2Y12 inhibitor such as clopidogrel, prasugrel and ticagrelor is instated post stenting to decrease the incident of ST. Cangrelor has recently been approved by Food and Drug Administration and can be used as a bridging antiplatelet drug. The risk of ischemia vs bleeding must be considered when discontinuing or continuing DAPT for surgery. Though living donor transplant surgery is an elective procedure and can be optimally timed, cadaveric organ availability is unpredictable, therefore, discontinuation of antiplatelet medication cannot be optimally timed. The type of stent and timing of transplant surgery can be of utmost importance. Many platelet function point of care tests such as Light Transmittance Aggregometry, Thromboelastography Platelet Mapping, VerifyNow, Multiple Electrode Aggregometry are used to assess bleeding risk and guide perioperative platelet transfusion. Response to allogenic platelet transfusion to control severe intraoperative bleeding may differ with the antiplatelet drug. In stent thrombosis is an emergency where management with either a drug eluting balloon or a DES has shown superior outcomes. Post-transplant complications often involved stenosis of an important vessel that may need revascularization. DES are now used for endovascular interventions for transplant orthotropic heart CAD, hepatic artery stenosis post liver transplantation, transplant renal artery stenosis following kidney transplantation, *etc.* Several antiproliferative drugs used in the DES are inhibitors of mammalian target of rapamycin. Thus they are used for post-transplant immunosuppression to prevent acute rejection in recipients with heart, liver, lung and kidney transplantation. This article describes in detail the various perioperative challenges encountered in organ transplantation surgery and patients with drug eluting stents.

Key words: Drug eluting stents; Cangrelor; Stent thro-

mbosis; Organ transplant; Antiplatelet medication; Platelet function assays; Mammalian target of rapamycin inhibitors; Post-transplant immunosuppression; Post-transplant endovascular inhibition; Ticagrelor; Thromboelastograms platelet mapping; Novolimus; Biolimus A9

INTRODUCTION

Percutaneous coronary intervention (PCI) is presently the most frequent revascularization procedure used for treating coronary artery disease (CAD). It surpasses coronary artery bypass grafting. Balloon angioplasty and coronary stenting are the most common percutaneous coronary interventions.

Angioplasty is complicated by vessel spasm, recoil, and abrupt closure. Coronary stenting with bare metal stents (BMS) may prevent these complications, however, they are associated with restenosis rates of 25%-30%^[1]. Studies on stent thrombosis (ST) with BMS show that clinical consequences of angiographic ST includes a 64.4% incidence of death or myocardial infarction at the time of ST and a six-month mortality of 8.9%^[2]. For clinically defined ST events, the associated six-month mortality is as high as 20.8%. Due to such high risk of death following ST, it must be prevented at all costs. The angiographic outcome yielded by primary percutaneous intervention (PPCI) by drug eluting balloons (DEB)-only in selected patients was comparable to those stented by BMS alone and when DEB insertion was followed by stenting with BMS. If the patient has potential contraindications to DES, then DEB-only is a good alternative^[3].

When the stented coronary artery is narrowed due

to the development of neo-intimal hyperplasia within the stent, it is termed as restenosis. An inflammatory reaction, both acute and chronic, results when there is arterial trauma and a foreign body response. Smooth muscle migration and proliferation result in scar tissue formation within the stent, thus narrowing the vessel lumen. This process generally begins to occur in first six to eight weeks after stenting, but can be seen beyond one year after stent placement.

DES was introduced to reduce the rate of restenosis. The antiproliferative drug eluted inhibits smooth muscle and endothelial cell proliferation^[4], thus delaying the inflammatory response. The layering of endothelial cells over the stent is slower paced than with BMS. When the stent is endothelialized, it becomes incorporated into the artery. Complete healing of first generation DES may take upto two years^[5]. The drug is held and released by a biocompatible polymer coating^[6]. However, endothelialization of the stent may also be delayed. This increases the risk of subacute ST. Risk of after DES implantation is related to stent length, stenting across branch ostia, disruption of adjacent vulnerable plaques, and plaque prolapse^[7]. Failure to form a complete neo-intimal layer over stent struts or impaired healing makes the stent more susceptible to thrombosis^[8]. Premature interruption of DAPT, renal failure, cardiac compromise with low ejection fraction (EF), bifurcation stenting and diabetes contribute to the risk of thrombotic events in DES^[9].

DES

The type of stent can have significant implications on the perioperative management of a transplant recipient (Table 1).

First generation DES

Coronary first generation drug eluting stents were coated with antiproliferative drugs sirolimus and paclitaxel. First generation stents used were Paclitaxel eluting TAXUS (Boston Scientific, Natick, MA) stent (PES) and sirolimus eluting CYPHER (Cordis, Miami, FL) stent (SES). Paclitaxel, which is derived from a Pacific Yew Tree (*Taxus Brevifolia*), is a cytotoxic anti-neoplastic drug which causes cell-cycle arrest in the G2/M phase transition^[10,11]. PES, have a bimodal release that is completed in approximately two weeks^[12]. Sirolimus is a macrolide antibiotic with potent antifungal, immunosuppressive, and anti-mitotic activities, and is produced by the fungus *Streptomyces hygroscopicus*^[11]. Sirolimus is cytostatic, and produces cell-cycle arrest in the G1/S phase transition. Sirolimus eluting stents (SES) slowly elute over a time frame of four to six weeks.

Second generation stents

Everolimus and zotarolimus are drugs used in second generation durable polymer stents. Second generation stents commonly used are zotarolimus eluting stent

Table 1 Types of stents

Generation of DES	Drug eluted	Some commercially available products	Features
First generation	Sirolimus, Paclitaxel	TAXUS, CYPHER	High Incidence of stent thrombosis, subacute as well as late thrombosis
Second generation	Zotarolimus, Everolimus	ENDEAVOR, XIENCE V	Safer and more efficacious as compared to first generation stents
Third generation	Novolimus, Biolimus A9	SYNERGY, BIOMATRIX, NOBORI, DESyne	Newer generation biodegradable stents which have shown superior outcomes

DES: Drug eluting stents.

(ZES) ENDEAVOR (Medtronic Inc. NJ) and everolimus eluting stent (EES), XIENCE V (Guidant Corporation, IN). Everolimus is a derived from sirolimus. Everolimus has a shorter half-life, and a greater bioavailability. It also has different blood metabolite patterns, as compared to sirolimus^[13].

Third generation stents

Newer generation biodegradable drug-eluting stents are designed to manage the longer side effects of residual durable polymer which persist after the drug has been completely eluted. The biodegradable polymer is applied to the abluminal side or outside surface only. Thus the inner or luminal side is free from the drug. After 3-4 mo of implantation, this stent loses most of its coating, acquiring a profile which is similar to that of a BMS^[14,15]. Novolimus and Biolimus A9 have been used in the third generation biodegradable stents. Biolimus A9 is a highly lipophilic analogue of sirolimus. The uptake by the coronary vessel wall is much better, thus the risk of systemic immunosuppression and toxicity is reduced^[16]. Novolimus is an active metabolite of sirolimus. It provides efficacy at lower dose (85 mcg of novolimus vs 140 mcg of sirolimus) and a lower polymer load^[17]. Recent ones introduced are the SYNERGY, BioMatrix, Nobori and DESyne stents^[18]. The NOBORI is a biodegradable biolimus eluting stent. Third generation stents with bioresorbable scaffolds such as the Abbott's BVS[®], an everolimus-eluting device with a poly-L-lactic acid (PLLA)-base, is now seeing increasing clinical use. Elixir's DESolve[®], a PLLA-based novolimus-eluting device is another device used clinically. Biotronik's DREAMS[®], a metallic magnesium-based paclitaxel-eluting device, is a third device that has been deployed^[19]. The drug attaches directly, without polymer to the textured stent surfaces, in stents such as the BioFreedom stents and Yukon Choice stents^[18]. Coatings which are non-pharmacological, such as carbon, silicon carbide and titanium-nitride-oxide provide better outcomes than BMS. Gene eluting stents such as the Genous stent, function by promoting the attachment of endothelial progenitor cells^[18].

A meta-analysis of 51 trials that included a total of 52158 randomized patients concluded that all DES have demonstrated superior efficacy when compared with BMS^[20]. First generation stents have a high incidence of stent thrombosis, both subacute as well as late thrombosis^[9]. Among DES, second-generation devices are

substantially safer and more efficacious when compared with first-generation devices^[20]. These second generation stents are now being used to revascularize blocked left main coronary artery and are clearly superior to CABG. RESOLUTE all-comers (Randomized Comparison of a Zotarolimus-Eluting Stent with an Everolimus-Eluting Stent for Percutaneous Coronary Intervention) trial showed that ZES was noninferior to EES at 12-mo for the primary end point of target lesion failure^[21]. The NOBLE (Coronary Artery Bypass Grafting vs Drug Eluting Stent Percutaneous Coronary Angioplasty in the Treatment of Unprotected Left Main Stenosis) and EXCEL (Evaluation of XIENCE Everolimus Eluting Stent vs Coronary Artery Bypass Surgery for Effectiveness of Left Main Revascularization) trials were conducted to compare PCI vs CABG. The EXCEL trial concluded that there was an equipoise for long-term mortality between CABG and PCI in subjects with unprotected left main coronary artery (ULMCA) disease up to an intermediate anatomical complexity. The anatomical and clinical characteristics impacted the decision making between CABG and PCI, and also in prediction of the long term mortality^[22]. Clinical characteristics which shifted long-term mortality predictions in favor of PCI was COPD, male gender and old age. Reduced left ventricular ejection fraction, lower creatinine clearance, younger age and female gender favored CABG^[22]. Thus PCI of the ULMCA with drug-eluting stents is safe and effective when performed in high volume centers with expertise^[23]. The SYNERGY bioresorbable polymer everolimus-eluting stent was noninferior to the PROMUS Element Plus everolimus-eluting stent with respect to 1-year target lesion failure^[24]. In a large meta-analysis, bioresorbable polymer based biolimus eluting stents (BP-DES) were associated with superior clinical outcomes compared with BMS and first generation DES and similar rates of death/MI, MI and target vessel revascularization (TVR) compared with second generation durable polymer DES. However, there were higher rates of ST compared with cobalt chromium EES^[25]. The novolimus eluting coronary stent DeSyne was found to be superior to ZES at a five year follow up^[26].

Various strategies have been employed to reduce the adverse effects associated with the drug eluting stents. A novel curcumin loaded nanoparticles (Cur-NP) preparation administered intravenously after stent implantation recovered endothelium function by accelerating endothelial cells restoration^[27].

Combretastatin CA4 inhibits the SMC cycle more

effectively than paclitaxel and sirolimus. It may be a newer antiproliferative drug which can be used for drug-eluting stents^[28]. Another drug called MiR-21 modulates the post stenting inflammatory response. This may have a therapeutic potential to clinical efficacy of stenting^[29].

ANTIPLATELET MEDICATION

Antiplatelet medications prevent thrombus formation till the stent is completely endothelialized. Intraluminal thrombus formation may lead to vascular occlusion, transient ischemia, or infarction^[27]. Antiplatelet drugs interfere with platelet adhesion, release and/or aggregation^[30].

Aspirin

Aspirin binds to enzyme cyclo-oxygenase preventing conversion of arachidonic acid to thromboxane, thus interfering with platelet action. Aspirin alone has little or no effect on angiographic or clinical restenosis. Lower doses of aspirin, 75-100 mg, are used in combination with other antiplatelet agents. Higher dose of aspirin is associated with increased risk of bleeding when used along with clopidogrel without any added benefit^[31].

Aspirin irreversibly inhibits platelets. Therefore, its action lasts until a significant number of platelets have been synthesized. By day 3, complete recovery of platelet aggregation may occur in 50% of cases. By day 4, complete recovery occurs in approximately 80% of cases^[32]. Reduced aspirin responsiveness can be measured by impedance platelet aggregometry^[33]. Some of the potential causes of reduced aspirin responsiveness include non-compliant intake, genetic polymorphisms of COX-1, increased platelet turnover and drug interactions^[34].

Clopidogrel

Clopidogrel has an active metabolite which irreversibly inhibits the acts on the ADP P2Y₁₂ receptor. The P2Y₁₂ receptor plays a vital role in the formation of a thrombus since it amplifies and completes the ADP response to thromboxane, thrombin and collagen^[35], and completes the activation of GP IIb/IIIa and GP I a/IIa for further stabilization of platelet aggregates^[36,37]. At steady state, the average inhibition level observed with a dose of 75 mg of clopidogrel per day is between 40%-60%. The prevalence of reduced clopidogrel response in patients is evaluated between 5% and 44%^[38] and is termed as high on treatment platelet reactivity (HTPR). Some of the causes of clopidogrel HTPR include genetic polymorphisms of the P2Y₁₂ receptor and of CYP3As, accrued release of adenosine phosphate, and up-regulation of other platelet activation pathways^[35].

Ticagrelor

It is a direct-acting, oral, newer reversible P2Y₁₂ receptor antagonist, and has a faster onset, and is more predictable and potent than clopidogrel. It binds allosterically to the

platelet ADP P2Y₁₂ receptor, thus, the binding does not cause a conformational change in the P2Y₁₂ receptor. It has a short offset time. It does need metabolic activation. It has a superior safety profile as compared to clopidogrel or prasugrel as seen in the PLATO (Platelet Inhibition and Patient Outcomes) study^[39]. It has been proven superior than clopidogrel in patients with chronic kidney disease. However, it should be avoided in patients with moderate-to-severe hepatic impairment and high bleeding risk^[40]. Complications include lung injury and dyspnea due to endogenous adenosine release^[41].

Prasugrel

Prasugrel is an oral irreversible inhibitor of the P2Y₁₂ receptor. Current European Society of Cardiology guidelines recommend prasugrel or ticagrelor over clopidogrel in patients with acute coronary syndromes (ACS) after PCI^[42]. If clopidogrel is used as a first line antiplatelet agent, then a platelet function assay should be performed, and a switch to prasugrel or ticagrelor is recommended for those with HTPR^[43]. The advantage of prasugrel is that it has a 5%-6% or low percentage of non-responders^[43].

Cangrelor

Cangrelor is an intravenous short-acting (half-life 3-6 min) P2Y₁₂ inhibitor, which is directly reversible. It does not require metabolic conversion. Intravenous cangrelor can produce rapid platelet aggregation with almost full recovery of platelet activity within 60-90 min of withdrawal^[44]. When cangrelor is administered intravenously to patients with CAD, the risk of MACE and stent thrombosis is reduced. There are however, increased events of minor bleeding^[44]. Additionally, cangrelor plays an important role in cases where cardiologist is not comfortable preloading a patient with antiplatelet therapy before an angiography, when it is uncertain that the patient may need urgent surgery. It has been recently approved by the FDA in June 2015^[45].

It is useful as a "bridging therapy" in patients with stents or acute coronary syndrome who need surgery, since they are increased risk for stent thrombosis when oral P2Y₁₂ therapy is temporarily stopped^[46].

The optimal duration of dual antiplatelet therapy has been a topic of debate. Most trials which compare antiplatelet strategies after PCI in a population state that the risk of bleeding and ischemia are average. Unfortunately, the information to recommend choices based on individual patient risks is scarce, especially beyond 1 year of DES placement and DAPT. There are many common risk factors associated with individual patient risks of ischemia and bleeding^[47].

A trial compared 6 wk of clopidogrel, aspirin and oral anticoagulation medications with 6 mo of clopidogrel therapy. However, there were no superior outcomes with the 6 wk triple therapy^[48]. Another study determined when permanent DAPT is discontinued before 30 d post cobalt chromium everolimus-eluting stent implantation, there was a strong association with ST. If the DAPT was discontinued after 90 d, it was safer^[49]. A large multicenter

study determined that the safety and efficacy of a 6-mo DAPT post implantation of new-generation DES was noninferior to that of a 12-mo DAPT^[50].

There is a lot of debate regarding short term dual antiplatelet therapy vs extended dual antiplatelet therapy. A study concluded that extended DAPT is associated with 8 fewer myocardial infarctions per 1000 treated patients per year. But unfortunately, there were 6 more major bleeding events than shorter-duration DAPT. Thus the duration of the DAPT should ideally be optimized taking into account the patient's values and preferences^[51]. A meta-analysis concluded that among selected patients undergoing DES implantation, a short duration (3-6 mo) of DAPT appears as the safest strategy. An extended duration (24-36 mo) of DAPT reduces thrombotic complications but with an excess in major bleeding complications^[52-54]. The duration of DAPT is challenging to adjust in those patients with an increased bleeding or thrombotic risk. These patients need a personalized DAPT duration, which is tailored to patients's, not stent's, characteristics^[55].

Two large studies, the Patient Related Outcomes With Endeavor vs Cypher Stenting Trial (PROTECT), and PROTECT US, determined that at a median follow-up of 4.1 years, major bleeding occurred in 2.8% subjects and ischemic events in 6.3%^[47]. There was no difference in mortality or stroke^[56].

The SECURITY trial which studied 6 mo vs 12 mo dual antiplatelet therapy following second generation DES implantation concluded that in a low-risk population, the 6 mo of DAPT following second-generation DES implantation was acceptable for the incidence of death, MI and stroke^[57]. The OPTIMIZE trial results stated that in patients with stable coronary artery disease or low-risk ACS treated with zotarolimus-eluting stents, 3 mo of DAPT was noninferior to 12 mo for NACCE, (NACCE; a composite of all-cause death, myocardial infarction (MI), stroke, or major bleeding) without significantly increasing the risk of stent thrombosis^[58].

The 2014 ACC/AHA current guidelines^[59] recommend 12 mo of DAPT post DES implantation. As the result of several randomized clinical trials showing the safety of a shorter duration of DAPT, the European Heart Society altered their recommendations to 6-12 mo of DAPT post DES implantation^[42].

PERIOPERATIVE MANAGEMENT

Transplant organ recipients usually have end stage organ disease and other comorbidities, and can be assigned the American Society of Anesthesiologists Grade 4 status. Furthermore, all transplant surgery can be classified as high risk. Thus, potential transplant recipients with drug eluting stents require extensive workup and evaluation. It is essential that the transplant anesthesiologist, surgeon and cardiologist be a part of the multidisciplinary team to help determine the optimal management for surgery in these patients. Such patients also need to be

screened carefully by the Transplant Center's Selection Committee prior to UNOS listing as a potential organ recipient. Major considerations would be whether the recipient would tolerate such a high risk associated with the transplant surgery and whether the organ is being optimally allocated (Table 2).

Living donor transplant surgery is an elective procedure and can be optimally timed so that the risk of intraoperative bleeding and ischemia is minimized in a drug eluting stent recipient. On the other hand, cadaveric organ availability is unpredictable, therefore, the discontinuation of antiplatelet therapy cannot be optimally planned. Discontinuation of anti-platelet medication for transplant surgery can pose a significant challenge for perioperative management. Patients undergoing transplant surgery soon after the placement of coronary stents are at increased risk of ST in the perioperative period. The risk of perioperative ischemia is higher if the stent were originally inserted for ACS rather than stable coronary artery disease (SCAD). When antiplatelet therapy is discontinued due to risk of bleeding, the risk of ST is clearly elevated, especially during surgery, which is generally a hypercoagulable state due to increased fibrin formation. If the antiplatelet therapy is continued, there may be bleeding, which in turn leads to hypotension. Hypotension may slow the blood through the stent resulting in ST. Thus risk of ST will be elevated in the perioperative period regardless of whether the antiplatelet therapy is continued or not. If the patient is on top of the Transplant Center's recipient list, one may discontinue oral antiplatelet medication and use a bridging therapy till a cadaveric organ is obtained. However, such a strategy may have inherent risks and would need meticulous monitoring.

ACC/AHA guidelines state in patients undergoing urgent noncardiac surgery during the first 4 to 6 wk after BMS or DES implantation, dual antiplatelet therapy should be continued unless the relative risk of bleeding outweighs the benefit of the prevention of stent thrombosis. In patients who have received coronary stents and must undergo surgical procedures that mandate the discontinuation of P2Y12 platelet receptor-inhibitor therapy, it is recommended that aspirin be continued if possible and the P2Y12 platelet receptor-inhibitor be restarted as soon as possible after surgery. Perioperative management of antiplatelet therapy should be formulated by a team of the surgeon, anesthesiologist, cardiologist, and patient, who should weigh the relative risk of bleeding with that of stent thrombosis^[59].

Aspirin is usually continued throughout the surgical procedure. The 2014 European Society of Cardiology and European Association for Cardiothoracic Surgery guidelines on myocardial revascularization support the 5 d clopidogrel withdrawal period before CABG. These guidelines also add that platelet function testing should be used to guide antiplatelet therapy interruption rather than a specified arbitrary time period^[42]. Recent studies state that patients on aspirin and clopidogrel < 5 d before CABG who had preoperative ADP-induced platelet aggregation \geq

Table 2 Antiplatelet drugs

Drug	Mechanism of action	Duration of action	Platelet responsiveness	Features
Aspirin	Aspirin binds to enzyme cyclo-oxygenase preventing conversion of arachidonic acid to thromboxane	Effect of aspirin lasts until a significant pool of new platelets is synthesized	Reduced aspirin responsiveness can be measured by impedance platelet aggregometry	Aspirin alone has little or no effect on angiographic or clinical restenosis
Clopidogrel	Irreversibly inhibits the ADP P2Y12 receptor	At steady state, the average inhibition level observed with a dose of 75 mg of clopidogrel per day is between 40%-60%	The prevalence of reduced clopidogrel response in patients is evaluated between 5% and 44% and is termed as HTPR	Some of the causes of clopidogrel HTPR include genetic polymorphisms of the P2Y12 receptor and of CYP3As, accrued release of adenosine phosphate, and up-regulation of other platelet activation pathways
Ticagrelor	Direct-acting, oral, newer reversible P2Y12 receptor antagonist	It binds allosterically to the platelet ADP P2Y12 receptor, thus, the binding does not cause a conformational change in the P2Y12 receptor. It has a short offset time	More predictable and potent than clopidogrel	Should be avoided in patients with moderate-to-severe hepatic impairment and high bleeding risk. Complications include lung injury and dyspnea due to endogenous adenosine release
Prasugrel	Oral irreversible inhibitor of the P2Y12 receptor	Effect of prasugrel lasts until a significant pool of new platelets is synthesized	Better inhibition for those with high HTPR	A 5%-6% or low percentage of non-responders
Cangrelor	Intravenous directly reversible P2Y12 inhibitor	Half-life 3-6 min	Rapid platelet aggregation with almost full recovery of platelet activity within 60-90 min of withdrawal	Useful to preload with antiplatelet therapy before the angiography should the patient's anatomy require urgent surgery

HTPR: High on treatment platelet reactivity.

50% have bleeding risk similar to those receiving aspirin monotherapy, thus a 5 d clopidogrel discontinuation period may not always be necessary^[60]. Guidelines also recommend the discontinuation of ticagrelor 5 d prior to surgery and recommencing therapy as soon as it is safe to do so. Since prasugrel has more prolonged and effective platelet inhibition than clopidogrel, it should be stopped 7 d prior to surgery^[42].

The risk of stent thrombosis is associated with stent type and time from stenting to surgery. It will be highest if BMS or DES is inserted within 30 d of the transplant surgery. The risk is high when the surgery is carried out < 1 mo after BMS and < 6 mo after DES, is intermediate if performed between 1-6 mo after BMS and 6-12 mo after DES, and low if performed > 6 mo after BMS and > 12 mo after DES^[61].

A study involving over 12000 patients with previous coronary stenting who underwent over 17000 surgical procedures stated that cardiac death occurred in 2.5%, myocardial infarction in 1.5%, and serious bleeding event in 6.4%. Surgery increased 1.58 × the risk of cardiac death during follow-up. Older generation stents were associated with higher risk of adverse events as compared to BMS > 12 mo before surgery. Newer DES showed similar safety as BMS > 12 mo and between 6 and 12 mo. They also trended to be safer between 0 and 6 mo^[61].

European Guidelines state that most surgical procedures can be performed on DAPT or ASA alone with acceptable rates of bleeding^[42]. The timing of surgery mattered most during the first 6 mo after PCI, with

respect to MACE events. There was no association of the stent type (BMS vs DES) with MACE after surgery. The guidelines further state that whenever possible, the elective non cardiac surgery should be postponed till the completion of the full course of DAPT ideally, 6 mo in SCAD and 1 year in acute coronary artery syndrome (ACS) patients, and that surgery be performed without discontinuation of aspirin^[42]. Shorter duration of DAPT may be justifiable if surgery cannot be delayed. In very high risk patients, 5 d prior to surgery, patient maybe switched from clopidogrel to a reversible antiplatelet agent with a short half-life such as IV tirofiban or eptifibatid, and stop the infusion 4 h prior to surgery^[42]. The substitution of DAPT with LMWH or UFH is ineffective. In surgical procedures with low-to-moderate bleeding risk, surgeons should be encouraged to operate while maintaining DAPT^[42].

Various Platelet Function Assays for P2Y12 Receptor Antagonisms are Light Transmittance Aggregometry, (LTA), vasodilator stimulated phosphoprotein (VASP), VerifyNow, TEG Plateletmapping and Multiple Electrode Aggregometry (MEA)^[62]. The LTA uses plasma and optically measures platelet aggregation, and is considered the gold standard. The VASP uses whole blood and flow cytometry to specifically measure P2Y12 activity, as it is the only assay which is not affected by the ADP's effect on the P2Y1 receptor, and thus is specific for P2Y12 inhibition. The VerifyNow P2Y12 assay uses whole blood, and optically measures platelet aggregation. Advantages of VerifyNow is that it is readily available in clinical settings and is a point of care assay^[62]. The Assessment

of Dual Antiplatelet Therapy with Drug-Eluting Stents (ADAPT-DES) trial is a very large observational platelet function study. It stated that upto 50% of 30-d post-PCI ST could be attributed to HTPR, which was defined as a P2Y12 reaction unit value of > 208 with VerifyNow® test^[63]. Point of care platelet function testing can also be done with TEG Plateletmapping (TEG-PM). It measures the degree of platelet inhibition resulting from aspirin or ADP receptor antagonists and correlates well with light transmission aggregometry^[64]. TEG-PM can measure the percentage adenosine 5'-diphosphate platelet receptor inhibition (ADP-PRI) by clopidogrel prior to urgent transplant surgery. An ADP PRI of 30% or more can be classified as high bleeding risk. Another study was conducted to predicted risk of bleeding and adverse outcomes by TEM-PM in patients taking clopidogrel within 7 d of non-cardiac surgery. Interestingly, there was no correlation between duration of clopidogrel omission and percentage ADP-PRI^[65].

Excessive bleeding can be treated by allogenic platelet transfusions (PT) in patients on P2Y12 receptor inhibitors. Though the American Association of Blood Banks 2015 clinical practice guidelines suggests prophylactic platelet transfusion for patients having major elective nonneuraxial surgery with a platelet count less than 50×10^9 cells/L, there is no recommendation for platelet transfusions for patients on dual antiplatelet therapy^[66]. In the APTITUDE-Coronary Artery Bypass Graft (APTITUDE-CABG) study, VASP reactivity index, was assessed before and after *in vivo* PT administered for excessive bleeding in patients undergoing cardiac surgery while on a maintenance dose of aspirin and clopidogrel ($n = 45$), prasugrel ($n = 6$), or ticagrelor ($n = 3$). When compared with baseline, there was a significant relative increase of 23.1% in platelet activation after PT transfusion. PT restores platelet reactivity in patients with ACS/PCI and in patients undergoing cardiac surgery on P2Y12 RI while bleeding with a less effect with increasing potency of P2Y12 inhibition^[67]. A recent study stated that clopidogrel had no effect on donor PLT function. Prasugrel has mild effect on donor platelet function. Ticagrelor completely abolished ADP mediated PLT activation in all assays tested. The observed effects were due to Ticagrelor and not elevated adenosine concentrations in the patient's plasma. A modified multiple electrode aggregometry (MEA) assay can be used to determine whether the patient would be likely to benefit from platelet (PLT) transfusions^[68].

The BRIDGE trial was a pharmacodynamic study evaluating platelet reactivity of cangrelor vs placebo in ACS and/or patients with a stent who were at increased risk of thrombotic events because of discontinuation of an oral P2Y12 inhibitor before cardiac surgery^[46]. The primary efficacy end point [percentage of patients with all samples during the infusion achieving platelet reactivity unit (PRU) < 240 as determined by VerifyNow P2Y12 assay, Accumetrics, San Diego, CA] was met in 98.8% of cangrelor- treated patients compared to 19.0%

of placebo-treated patients. After discontinuation of cangrelor, platelet reactivity was similar for both cangrelor and placebo groups^[55]. Cangrelor has been approved by the FDA in June 2015^[45]. When cangrelor occupies the P2 Y12 receptor, the active metabolite of clopidogrel is unable to bind to it. However, this reaction is avoided when clopidogrel is given at the end of the cangrelor infusion. Earlier administration increases the recovery of platelet function. Antiplatelet effects of prasugrel were apparent when prasugrel was administered 0.5 h before cangrelor was stopped^[69,70].

In the Drug Eluting Stent Event Registry of Thrombosis (DESERT)^[71], the largest case- control registry of late/very late thrombosis after DES, 75% of ST events occurred after 1 year, similar to the 60% rate observed in a study^[71]. Furthermore, the clinical presentation of late/very late ST events in DESERT was mainly ST-segment-elevation myocardial infarction (67%). More than half of all ST-related MIs were Q-wave MIs, and subsequent mortality was increased 8-fold after an ST-related MI, the greatest hazard of any MI type^[71].

In stent restenosis can be managed with BMS, brachytherapy, rotational atherectomy and cutting balloons, DEB and DES. A meta-analysis concludes that for treatment of any type of coronary in-stent restenosis (ISR), PCI with everolimus-eluting stents is optimal, because of the best angiographic and clinical outcomes. Use of drug coated balloons (DCB) is also favored, because of its ability to provide favorable results without adding a new stent layer^[73]. Additionally, when DES are implanted to treat BMS restenosis, at 6 mo, struts coverage is more complete when compared with DES implanted in atherosclerotic lesions^[74]. In patients with DES-ISR, EES were superior, both clinically, as well as angiographically, when compared with DEB^[75].

POST TRANSPLANT

IMMUNOSUPPRESSION

The drugs sirolimus, everolimus, biolimus and novolimus are inhibitors of the mammalian target of rapamycin (mTOR). After organ organ transplantation, the mTORs are used along with calcineurin inhibitors (CNIs) to provide immunosuppression. They are also used as proliferation signal inhibitors coated on DES. Their use in cancer therapy bears the same mechanism. Everolimus antagonizes the negative effects of CNIs kidney cell and neuronal metabolism and stimulates mitochondrial oxidation, thus reducing the vascular inflammation^[13]. In transplantation, everolimus has been used post-transplant in heart, liver, lung and kidney transplant recipients to prevent acute rejection. In kidney transplant patients, everolimus may minimize or remove calcineurin inhibitors^[76]. Interestingly, renal transplant patients with DES had a low rate of ST, probably related to the immunosuppressants given to prevent kidney rejection^[77]. Everolimus has also been approved by the FDA for use in liver transplantation (LT), and is safe for use with tacrolimus within the first month

after LT^[78].

POST TRANSPLANT ENDOVASCULAR INTERVENTION WITH DES

DES has been successfully used to stent stenotic lesions post-transplant surgery. Transplant coronary artery disease (TCAD) is a major cause of morbidity and mortality after the first year after orthotopic heart transplantation (OHT). OHT patients with ISR have poor long-term prognosis^[79]. EES used on OHT patients with TCAD is associated with a low incidence of target vessel revascularization (TVR) and target lesion revascularization (TLR)^[80]. Unfortunately, long-term mortality remains high in orthotopic heart transplantation (OHT) recipients after PCI with either DES or BMS^[81].

Transplant renal artery stenosis (TRAS) following kidney transplantation has an incidence rate ranging from 6% to 23%. Endovascular intervention with DES improves blood pressure control and allograft function^[82]. ISR occurs in as many as 13% of patients after PTA and stent insertion. A case report describes three such patients, of which, in two patients, the transplant renal artery remained patent after insertion of PES, and one patient required balloon angioplasty 7 mo after the DES was inserted^[83]. BMS have been used to treat lung transplant related pulmonary artery stenosis^[84]. DES have been placed into the pulmonary veins as a bridge to heart lung transplantation in a patient with extensive and recurrent congenital pulmonary vein stenosis^[85]. DES have been safely used and may prevent ISR in patients who undergo intracoronary bone marrow mononuclear cell transplantation post coronary stenting^[86]. Orthotopic liver transplantation (OLT) is commonly complicated by hepatic artery stenosis (HAS). It can lead to hepatic artery thrombosis, with subsequent liver failure in 30% of the patients. Though traditionally this was managed with either surgical revascularization or retransplantation, use of DES has resulted in high technical success and provided for excellent patency. Avoidance of hepatic artery thrombosis is possible in > 95% of patients with endovascular treatment and close follow-up^[87]. Paclitaxel eluting balloon has been employed successfully to treat biliary anastomotic strictures after liver transplantation^[88]. Stents have also been used to manage stenosis in the hepatic veins and/or inferior vena cava above hepatic venous anastomosis to relieve an outflow venous block following living donor liver transplantation^[89].

CONCLUSION

Though several perioperative challenges encountered in organ transplantation surgery and patients with drug eluting stents, these can be optimally managed with proper planning and teamwork, ensuring patient safety.

Abstract

The recurrence of renal disease after renal transplantation is becoming one of the main causes of graft loss after

kidney transplantation. This principally concerns some of the original diseases as the atypical hemolytic uremic syndrome (HUS), the membranoproliferative glomerulonephritis (MPGN), in particular the MPGN now called C3 glomerulopathy. Both this groups of renal diseases are characterized by congenital (genetic) or acquired (auto-antibodies) modifications of the alternative pathway of complement. These abnormalities often remain after transplantation because they are constitutional and poorly influenced by the immunosuppression. This fact justifies the high recurrence rate of these diseases. Early diagnosis of recurrence is essential for an optimal therapeutically approach, whenever possible. Patients affected by end stage renal disease due to C3 glomerulopathies or to atypical HUS, may be transplanted with extreme caution. Living donor donation from relatives is not recommended because members of the same family may be affected by the same gene mutation. Different therapeutically approaches have been attempted either for recurrence prevention and treatment. The most promising approach is represented by complement inhibitors. Eculizumab, a monoclonal antibody against C5 convertase is the most promising drug, even if to date is not known how long the therapy should be continued and which are the best dosing. These facts face the high costs of the treatment. Eculizumab resistant patients have been described. They could benefit by a C3 convertase inhibitor, but this class of drugs is by now the object of randomized controlled trials.

Key words: Kidney disease recurrence; Complement dysregulation; Atypical hemolytic uremic syndrome; C3 glomerulopathies; Dense deposit disease; Plasma therapy; Eculizumab; C3 glomerulonephritis

Core tip: Complement cascade is an important pathway of several kidney diseases. A distinction should be made between kidney diseases with complement overactivation

and those with complement dysregulation. The latter are related to congenital or acquired abnormalities of complement factors. These diseases are linked to constitutional abnormalities of the patients, have high recurrence rate after renal transplantation and represent an important cause of graft loss. Diagnosis and treatment are not easy to be made. Just in the last decade a growing knowledge in the field of genetic and biology allowed the complement inhibitors to be the first class drug in the treatment.

Salvadori M, Bertoni E. Complement related kidney diseases: Recurrence after transplantation. *World J Transplant* 2016; 6(4): 632-645 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/632.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.632>

INTRODUCTION

The aim of this review is to highlight the relevance of recurrent diseases after kidney transplantation and, in particular, to discuss the frequency and severity of recurrence of two groups of renal diseases strictly related to each other: C3 glomerulopathy (C3G) and thrombotic microangiopathy (TMA).

Along with the improved control of acute rejections and infections, the recurrence of primary nephropathy has become the most important cause of graft loss principally for patients who have glomerulonephritis (GN) as the primary disease^[1,2]. In some series, recurrence of the original disease was reported to be the principal cause of graft loss more than one year after transplantation^[2] (Table 1). Some renal diseases have a higher risk of recurrence and recurrence-related graft loss. Hariharan *et al*^[3] observed, in a total of 4913 renal transplants, that the greatest relative risk (RR) for graft failure was related to the recurrence of hemolytic uremic syndrome/thrombotic thrombocytopenic purpura (HUS/TTP) (5.36), membranoproliferative glomerulonephritis (MPGN) (2.77) and focal segmental glomerulosclerosis (FSGS) (2.25). Interestingly, HUS/TTP and many cases of MPGN were related to complement cascade dysregulation and were ascribed to genetic abnormalities or to acquired abnormalities of components of the complement system^[4].

ROLE OF COMPLEMENT IN KIDNEY DISEASES

The complement proteins may be seen in the biopsies of all forms of GN, and all three activation pathways have been documented in different kidney diseases and may be activated by different triggers^[5] (Figure 1). Indeed, the complement system is activated by three pathways (the alternative, classical and lectin pathways) that generate a common terminal pathway. The classical (CP) and lectin pathways (LP) are triggered by the

recognition of pathogens or damaged cell surfaces by antibodies and recognition molecules^[6]. Many glomerular diseases, such as membranous nephropathy, IgA nephropathy and lupus nephropathy, involve these pathways. The activation of the alternative pathway (AP) is relatively complex. The AP undergoes continuous low-grade activation in the fluid phase by spontaneous C3 hydrolysis that is responsible for the deposition of a low amount of C3b onto cell surfaces (Figure 2). Self-surfaces are protected from complement damage by several regulators that are either membrane-anchored or in the fluid phase. Perturbation of the balance between complement activators and regulators provides the basis for aHUS and MPGN/C3G^[7].

As mentioned above, the complement system is involved in the vast majority of kidney diseases. Two broad categories of kidney diseases should be distinguished. The first category is associated with complement over-activation and characterizes diseases such as lupus nephritis, membranous nephropathy, immune complex-associated MPGN and IgA nephropathy. The second category is related to complement dysregulation and characterizes diseases such as aHUS and C3G. In the former category, complement is activated by other factors, including immune-complex formation and deposition. After transplantation, the original disease may recur but is also more easily controlled by the immunosuppression needed to support the transplanted kidney. In the latter disease, complement activation may occur spontaneously and is often related to abnormalities of complement regulating factors. These nephropathies often recur after renal transplantation because the diseases are related to a constitutional and often genetically determined abnormality of the complement proteins. These abnormalities are not corrected either by the transplant itself or by the immunosuppressive therapy.

Tremendous advances are being made in our understanding of both aHUS/TMA and C3G. With the improvement of our understanding of genetics and biology, it has become increasingly clear that different disease mechanisms may cause the disease formerly called TTP/HUS. Furthermore, these mechanisms may deeply influence the recurrence rate after transplantation^[8].

Similarly, the role of complement in C3G has been better defined^[9], thus allowing us to move from a histologically based classification of the MPGNs to a new classification based on pathophysiology^[10,11].

To date, the term aHUS applies to a heterogeneous group of diseases that have in common a TMA associated with some degree of renal failure. Frequently, aHUS patients have a complement abnormality (a genetic mutation or an autoantibody to complement factors) as the primary etiology. As a consequence, they are affected by a complement mediated TMA (Figure 3)^[8].

Similarly, after reclassification, the MPGNs are distinguished into immune-complex-mediated MPGNs and C3Gs. The latter have clear signs of C3 staining with little

EPIDEMIOLOGY

GNs that occur in the transplanted kidney may be caused either by recurrent or *de novo* disease. In clinical and in the epidemiological studies is necessary to distinguish between these conditions. True recurrence occurs when: (1) post-transplant proteinuria or hematuria or elevated serum creatinine is found after transplantation; (2) biopsy-proven kidney disease is diagnosed in the native kidneys; or (3) the same disease is proven by biopsy in the transplanted kidney^[12]. Challenges to the diagnosis of recurrent diseases are manifold. They include: (1)

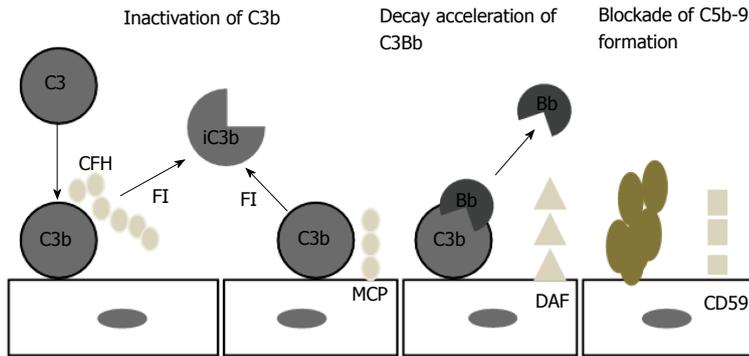

Figure 4 Regulation of complement on surfaces. CFH: Complement factor H; FI: Complement factor I; iC3b: Inactivated C3b; MCP: Membrane cofactor protein; DAF: Decay accelerating factor; CD59: MAC inhibitor protein.

misdiagnosis or mislabeling of native kidney disease; (2) lack of a unified approach to using diagnostic tools for the diagnosis of recurrent disease; and (3) difficulties in differentiating recurrent disease from other causes of renal damage such as drug toxicity and chronic rejection^[3,13].

There are still other potential biases occurring among registries dealing with recurrences of renal diseases mediated by complement dysregulation. For example Shiga toxin-related HUS combined with aHUS in many registries. Additionally, the vast majority of registries or networks report data by using the classification of MPGNs, which precedes the results of the consensus report on C3G^[14] and the recent consensus report and reclassification of GNs^[10,11].

Because of the above-mentioned factors, the data reported by different registries as the North American Pediatric Renal Transplant Collaborative Study (NAPRTCS), the Australia New Zealand Dialysis Transplant Data System (ANZDATA), the Renal Allograft Disease Registry (RADR) and the United States Renal Data System (USRDS) differ significantly in reporting the prevalence of recurrent GNs after transplantation^[3,12,15-18]. A study by Shimmura *et al.*^[2] on 266 living kidney transplants clearly documents that recurrence of the original disease is the third leading cause of graft loss after one year from transplantation (Table 1). The aforementioned study by Hariharan^[3] documents the highest RR for graft failure for HUS/TTP and MPGN.

Two other studies on pediatric patients^[19,20] report high rates of recurrence for aHUS and type I and II MPGN according to the old classification, although there is a wide range of rates among the studies.

Series related to the early 2000s indicated that the risk of post-transplant recurrence for aHUS was 20% in pediatric patients and 50% in adult patients^[21]. Recently, in 280 patients with aHUS screened for CFH, IF or MCP mutations, post-transplant aHUS recurrence was reported in 33%^[22], 37%^[23] and 60%^[24], respectively.

Fewer data are available regarding the epidemiology of MPGN recurrence according to the new classification. Indeed, many registries are still using the old classification. According to these data, MPGN type I recurs in 20%-30% of patients, whereas MPGN type II recurs in 80%-100% of patients^[25].

More recently, Kasiske *et al.*^[26], observing 1574 MP

GNs in 140109 transplant patients recorded in the USRDS an observation that the true recurrence rate of MPGN increased over time, with the most frequent recurrences of GN between 1995 and 2003.

After the reclassification^[10,11], the most interesting and recent data on C3G recurrence are those reported by Zand *et al.*^[27]. According to these data, the recurrence rate of C3GN is 66.7%, and graft failure occurs in 50% of patients with recurrence.

PATHOPHYSIOLOGY OF TMA AND ITS RECURRENCE

As mentioned above, the complement AP is constitutively active. After the generation of C3b, it binds either to either pathogens or the host cells. This necessitates the prompt and tight control of its activity. In turn, C3b may generate new C3 convertases (C3bBb) that act as an auto-amplifier by creating new C3b molecules. The same enzymes may also generate the C5 convertases that activate C5, the anaphylatoxins C5a and C5b and activate the membrane attack complex (MAC) C5b-C9^[28]. In normal conditions, the AP may be spontaneously activated by the process called tick over. Cell surfaces are protected from auto-activation by several factors both in the fluid phase and anchored to the cell membranes.

The principal inhibiting factor is complement factor H (CFH), which acts both in the fluid phase and on cell surfaces. Factor H also act as a co-factor to complement factor I (CFI)^[29-31]. Cell surfaces are also protected by at least 4 specific membrane regulators: (1) complement receptor 1 (CR1/CD 35); (2) membrane cofactor protein (MCP/CD46); (3) decay accelerating factor (DAF/CD55); and (4) protectin (CD59), which blocks MAC formation (Figure 4)^[32,33].

The loss of this complex regulation results in complement activation, with consequent cell damage^[34,35]. The role of complement dysregulation is increasingly recognized as the principal cause of TMAs. It may be caused by genetic mutations or by autoantibodies. Additionally, a triggering factor, often from the environment, is needed.

Figure 5 represents the whole spectrum of TMAs. In this figure, three different conditions are possible: (1) complement-driven TMA (*i.e.*, aHUS), where there is an underlying complement defect; (2) complement-

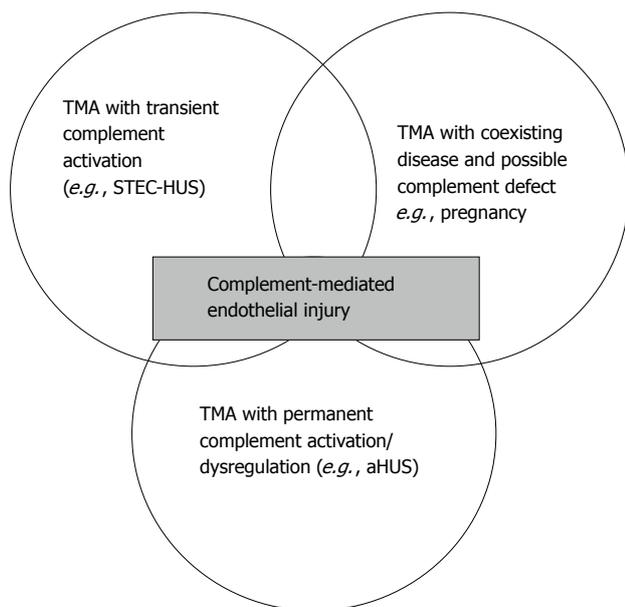

Figure 5 Spectrum of thrombotic microangiopathies. TMA: Thrombotic microangiopathies; STEC-HUS: Shiga toxin-producing *Escherichia coli*-hemolytic uremic syndrome.

enhanced TMA, as in Shiga-toxin-producing *Escherichia coli*-HUS (STEC-HUS); and (3) TMA with coexisting disease (e.g., pregnancy, lupus). The most frequently mutated gene in aHUS is *CFH*. Mutations have been identified in 25% of sporadic cases and 40% of familial cases^[6,36,37]. In addition to *CFH*, the *CFH* gene family includes five other complement factor H-related genes (*CFHR1-5*). Deletion, duplications and hybrid proteins occur^[38]. As a result, the loss of cell surface protection may occur and aHUS may develop^[36,39].

The *CFHR3-CFHR1* deletion is the most frequent deletion associated with aHUS. Recently a new role for the FHR protein was identified by Goicochea de Jorge *et al.*^[40]. According to these findings, FHRs could act as competitive antagonists to FH. *MCP* (CD46) mutations are found in 5%-9% of aHUS patients^[36]. The protein is membrane-anchored and serves as a co-factor of FI. *FI* mutations lead to a lack of complement control accounting for 4%-8% of aHUS^[36,37].

In addition to mutations in regulatory genes, gain of function mutations of effector proteins (C3 and factor B) has been reported. Factor B mutations are reported in < 4% cases of aHUS^[41-43]. Factor B mutations enhance the C3bB formation. Gain of function mutations in C3 are reported in 2%-8% of aHUS^[36,37]. These mutations impair MCP and confer resistance to cleavage by CFI^[44,45].

Mutations in the thrombomodulin gene (*THBD*) have been reported in up to 5% of aHUS patients^[36]. Few data have been reported on this mutation. It is probable that the *THBD* mutation may influence disease severity in association with other mutations^[46].

Autoantibodies against different complement factors, independent of genetic mutations or in association with genetic abnormalities, may cause aHUS. Antibodies to anti-complement factor H (FHAA) account for 3%-8%

of aHUS and are often found in association with *FHR1* deficiency or deletion^[36]. Recently, in India, an association of FHAA and aHUS was reported in approximately 60% of the pediatric population^[47]. Auto antibodies to anti-factor I have been reported only in three patients^[48]. Their role is not yet clear.

In many cases, the development of aHUS in patients who are affected by complement abnormalities needs a triggering factor. Among these well-known factors are pregnancy, drugs, and autoimmune disorders. Complement abnormalities were identified in 83% of patients with pregnancy associated aHUS^[49]. *CFH* mutations have been reported in 4 patients with aHUS associated with ticlopidine^[50]. Further 4% of patients affected by lupus disease documented an aHUS related to complement abnormalities^[51,52]. Complement abnormalities strongly influence aHUS recurrence after renal transplantation. Indeed, aHUS recurrence was reported at rates from 20% to 50% in the era when genetic analysis of complement proteins was not available^[53-56]. Recently, several studies have highlighted the risk of aHUS recurrence according to different genes abnormalities^[53] (Table 2). Complement abnormalities have also been found in conditions that should not be affected by recurrence.

STEC-HUS of the native kidneys should be protected from recurrence. However, two patients with a history of STEC-HUS were recently diagnosed with post-transplant recurrence^[57]. Both patients were recognized to be affected by complement abnormalities; one had a heterozygous *CFI* mutation, and the other had a heterozygous *MCP* mutation.

Patients affected by *MCP* mutations rarely have aHUS recurrence after transplantation^[58]. Recently, however, transplant failures due to aHUS recurrence have been observed in patients affected by *MCP* mutations^[59]. Almost all of these patients were affected by combined *MCP* and *CFH* or *CFI* mutations.

Patients affected by *CFH* mutations are at a high risk of recurrence. In two French case series, recurrences were observed in 80% of children^[22] and 75% of adults^[60]. The graft failure rates in the case of recurrence are approximately 86%.

Interestingly, the location of *CFH* mutation impacts the recurrence risk^[61]. Indeed, mutations involving the C-terminal domain of *CFH* confer higher risk and have a worse prognosis^[49]. This finding is consistent with the critical role of the *CFH* C-terminal domain in binding to the endothelium and exerting the protective role of the endothelial cells^[62].

The majority of FHAA is directed against the C-terminal domain of factor H. As a consequence, a higher risk of recurrence should be expected due to FHAA. However, this does not seem to be the case, because aHUS recurrence due to FHAA is uncommon^[63].

Nonetheless, the recurrence risk due to FHAA is not easily understood because 40% of patients with FHAA are also affected by mutations in the complement genes^[64]. Additionally, a reduction of FHAA is achievable with the immunosuppressant therapy, thereby reducing

Table 2 Risk of atypical hemolytic uremic syndrome recurrence according to the implicated genetic abnormality

Gene	Protein location	Functional impact	Mutation frequency in aHUS (%)	Recurrence frequency after transplantation (%)
Mutation				
<i>CFH</i>	Plasma	Loss	20-30	75-90
<i>CFI</i>	Plasma	Loss	2-12	45-80
<i>CFB</i>	Plasma	Gain	1-2	100
<i>C3</i>	Plasma	Gain	5-10	40-70
<i>MCP</i>	Membrane	Loss	10-15	15-20
<i>THBD</i>	Membrane	Loss	5	1 case
Genetic polymorphism (frequency in control population)				
Homozygous <i>CFHR1del</i> (3%-8%)	Circulating	Undetermined	14-23 (> 90% in patients with anti-CFH antibodies)	NA

aHUS: Atypical hemolytic uremic syndrome; C3: Complement C3; CFH: Complement factor H; CFI: Complement factor I; CFB: Complement factor B; MCP: Membrane cofactor protein; THBD: Thrombomodulin; CFHR1: Complement factor H receptor 1; NA: Not available.

the risk of aHUS recurrence.

In summary, the risk of recurrence is 4 times higher in patients with mutations in the *CFH* gene or carriers of the hybrid gene between *CFH/CFHR1*. In a recent study by Le Quintrec^[65], patients with the hybrid gene lost their grafts due to early recurrence.

The relevance of *CFI* mutations on aHUS recurrence has discordant results and interpretations. The first studies to *CFI* mutations reported a high recurrence rate and graft loss^[10,31,53,58,66,67]. A study by Bienaimé *et al*^[68] in 2010 reported that patients with *CFI* mutations do not seem to carry a higher risk of recurrence. These data were more recently confirmed by the study mentioned above by Le Quintrec *et al*^[65].

MCP mutations rarely affect aHUS recurrence because the endothelial cell surfaces of the transplanted kidney normally express MCP. Only three recurrences have been reported in the literature^[69,70]. In these patients, recurrence might be ascribed to combined complement gene mutations^[59] or microchimerism from the recipient endothelial cells^[70].

Data on the role of THBD are scarce. aHUS recurrence due to *THBD* mutations should not occur because the molecule is membrane-anchored as MCP. Additionally, a small proportion of THBD is present in soluble form. Nonetheless, sporadic cases of recurrence due to THBD have been reported^[71,72]. In one patient the recurrence occurred early post-transplantation during the ischemia-reperfusion phase. During this phase, the soluble form of THBD might be not adequate to protect from recurrence.

Patients affected by gain of function mutations (*CFB*, *C3*) are also exposed to the risk of recurrence. To date, four patient carriers of the *CFB* mutation have been reported to have aHUS recurrences and consequent graft loss^[73,74]. Data on recurrence in patients affected by *C3* mutations are discordant. Le Quintrec^[65] reported a high recurrence rate, with 4 recurrences in 5 grafts. Previously, Noris *et al*^[75] reported only two recurrences in 7 transplanted patients. In an attempt to explain the difference, Zuber *et al*^[53] speculated that for some patients, the intra-graft production of normal C3 might occur and might be protective.

Several environmental triggers might act to damage the graft endothelium and to facilitate aHUS recurrence on already damaged cells in patients with genetic abnormalities.

Anti-HLA antibodies^[76], ischemia-reperfusion events^[77], immunosuppressant drugs^[78] and viral infections^[79], either isolated or in association, might play a relevant role and favor aHUS recurrence in genetically predisposed patients.

Le Quintrec *et al*^[65] attempted to identify the risk factors for aHUS recurrence. Low C3 levels and the presence of a mutation were significant in the univariate analysis. In a multivariate analysis of mutations, a mammalian target of rapamycin (mTOR) inhibitor regimen and recipient age were significantly associated with increased aHUS recurrence rates.

PATHOPHYSIOLOGY AND RECURRENCE OF C3G

After the reclassification of MPGNs, as mentioned above^[10,14], C3Gs included the MPGNs caused by complement dysregulation rather than the MPGN immune-complex-related disorders^[80]. As a consequence, C3Gs include the GNs for which immunofluorescence microscopy is C3-positive and immunoglobulin-negative.

C3Gs may be sub-divided into DDD and C3GN based on electron microscopy, even if, in some cases the distinction is challenging^[14,81]. Recently, advances toward an improved understanding of the characteristics of C3 deposits have been made through proteomic analysis and laser microdissection (LMD)^[82]. Laser dissection and mass spectrometry of glomeruli from patients with C3G documented an accumulation of the AP and the terminal complement complex proteins, thus confirming that C3G results from abnormalities of the AP, which lead to glomerular damage^[81].

The pathophysiology of AP pathway activation in C3GN and DDD is very similar, with fluid phase dysregulation due to gene mutations or autoantibodies occurring in both disorders. Indeed, as for aHUS, the complement abnormalities in C3Gs may occur on a genetic basis or as acquired factors as autoantibodies.

The most common acquired complement defect is represented by the presence of an antibody called the C3 nephritic factor (C3NeF), which blocks CFH-mediated decay and stabilizes C3 convertase^[81,83]. In particular, C3NeF binds to C3 convertase and inhibits the action of factor H, CR1 and DAF, blocking the dissociation of the convertase. C3NeF enhances C3 convertase activity 10 fold^[9,84,85]. The frequency of C3NeF is high in C3G, ranging from 50% to 80% of patients^[83]. C3NeF may also be associated with genetic mutations. Recently, other auto antibodies have been found in C3Gs. These auto antibodies are directed against C3 convertase, factor B^[86] or anti-factor H^[87,88]. AP dysregulation in DDD is more frequently autoantibody-induced with respect to TMA. Genetic abnormalities also have been encountered. Few patients have been identified with genetic mutations of factor I, MCP, C3, factor B and factor H^[83,89]. In an extensive study by Servais *et al.*^[83], only 5.3% of the patients affected by C3GN had *CFI* mutations, and 1.8% had *MCP* mutations.

In 2010, Martinez-Barricarte *et al.*^[90] identified a mutant C3 protein resistant to factor H inactivation in a patient affected by DDD. More recently, a different C3 mutation has been identified.

Mutations in factor H have been reported more frequently among patients affected by C3Gs. Mutations may result in a defective protein or a complete lack of protein H. Mutations may occur in a homozygous or heterozygous manner^[91,92] and may be associated with C3NeF, thus documenting the association of different risk factors.

In recent years genetic mutations of the *CFHR* gene cluster have been reported among patients with C3G^[93]. *CFHR* family gene mutations^[94], deletions^[95], duplication^[96] and hybrid genes^[97] have been reported in patients with C3Gs either in either isolated patients or family groups.

For example, Gale *et al.*^[96] reported two Cypriot families whose members were affected by a *CFHR5* mutation. The protein produced by the mutated gene was poorly effective in binding to C3b on cell surfaces and thus led to the deregulation of the fluid phase of the AP. The disease was called *CFHR5* nephropathy.

Recently, Malik *et al.*^[98] reported patients from the same family affected by C3G due to abnormal copies in the *CFHR3* and *CFHR1* loci. The finding of familial cases of C3G highlights the genetic origin of several C3Gs and the related complement AP dysregulation.

In summary the specific cause of C3G is inadequate regulation of the complement system. The causes of complement dysregulation may be divided into genetic and acquired factors. Among the former are changes in many of the complement genes: Among the latter are specific antibodies called C3 nephritic factors or C3NeFs that impair normal regulation of the complement system. It appears that patients with DDD are more likely to have C3NeFs, while patients with C3GN are more likely to have abnormalities in a group of proteins called the "Complement Factor H-Related" proteins.

Additionally, genetic defects may represent the basis of either C3G or aHUS (Table 3). Indeed, in recent years, a large number of genetic studies have established a strong association between the factor H-related proteins and different diseases involving complement dysregulation. This association, together with the recent functional data on factor H-related proteins such as FH competitors and complement deregulators, has gained the attention of the complement scientific community^[99].

From the pathophysiological point of view, many cases of C3Gs and TMA are associated with defective control of the AP. The inevitable questions are whether C3G and TMA are the other sides of the same coin and which factors determine whether a patient develops one disease instead of the other^[5].

Animal models highlight that C3G may be the consequence of prevalent dysregulation of fluid phase complement activation, whereas TMA is principally related to complement activation on the capillary wall. The same studies determined that an absolute deficiency of factor H favors fluid phase complement activation and C3G, whereas the absence or abnormality of the binding region of factor H favors TMA^[100]. It has also been hypothesized that *CFH* and *CFH/CFHR* mutations induce aHUS to inhibit the CFH binding to most cell surfaces, whereas C3G-associated mutant *CFHRs* do not inhibit CFH binding to endothelial cell surfaces^[6].

Concerning C3G recurrence after transplantation, the finding of familial cases of C3GN highlights the genetic origin and the related complement AP dysregulation of the vast majority of C3GN. These data form the basis of its recurrence after transplantation. However, fewer data are available on C3G recurrence compared to TMA. Indeed, C3G is a rare disease and principally, its pathogenesis and its complement-dependent nature have been recognized only recently. More data are available on DDD recurrence. Indeed, this disease was identified a long time ago based on its characteristic microscopic aspects. This finding occurred long before our understanding of its pathogenesis. In a retrospective analysis of 75 children, the 5-year graft survival rate was only 50%^[101]. Almost all adult patients had recurrences after transplantation and up to 25% lost their graft^[19].

In a large, retrospective cohort study of 80 adults and children affected by C3G, Medjeral-Thomas *et al.*^[102] reported a histological recurrence following renal transplantation in all 6 DDD patients. Recurrence was associated with graft loss in 50% of patients. Similarly, four of seven C3GN patients transplanted had histological recurrences. Graft loss occurred in 3 patients. A UNOS review reported a 10-year graft survival rate of 57.5% for patients affected by DDD recurrence^[103]. In different studies, the reported rate of DDD recurrence is variable ranging from 18% to 100%^[104,105].

Considering only those patients whose diagnosis was made by renal biopsy, the recurrence rate was over 70%^[106,107]. Disease recurrence may occur suddenly after transplantation. However, cases of recurrence many years later are also described^[107]. The risk factors for

Table 3 Overview of mutations in complement factor H related protein genes

Genetic defect	Phenotypical expression
Duplication in the <i>CFHR5</i> gene	C3 glomerulopathy (CFHR5 nephropathy)

Hybrid <i>CFH/CFHR3</i> gene	aHUS

CFHR: Complement factor H related; aHUS: Atypical hemolytic uremic syndrome.

recurrence and graft loss for DDD are not well defined. No relationship with preTx disease presentation or C3 serum levels has been found. Additionally, the C3NeF levels do not correlate with the risk of recurrence^[108]. The presence of heavy proteinuria seems to be the only risk factor related to recurrence.

The different genetic variants responsible of C3GN have been already described. Overall, C3GN recurs in two-thirds of transplanted patients and graft loss is common^[27,81,83]. Histologically, it recurs with a membranoproliferative pattern. Risk factors for recurrence are still now debated. According to some studies^[25], they include the severity of histological lesions in the native kidneys, HLA-B8 DR3, living related donors and previous graft loss for recurrence^[109]. To date, our understanding of C3GN recurrence is only based on case reports. Furthermore, the broadest study on C3GN outcomes after recurrence by Zand *et al.*^[27] was unable to find any risk factor for recurrence. The multiple defects in complement regulatory proteins causing C3GN likely impair the establishment of any well-defined recurrence risk.

Eleven patients affected by CFHR5 nephropathy were successfully transplanted^[110]; however protocol biopsies have documented recurrence^[111]. The recurrence may be early after transplantation and demonstrates that renal-derived CFHR5 protein cannot prevent the development of CFHR5 graft nephropathy. Very recently Wong *et al.*^[112] described a high recurrence rate in 5 patients affected by hybrid *CFHR3 1* gene-associated C3GN.

DIAGNOSIS OF RECURRENCE

Diagnosis of recurrence may be easy if the clinical history of the recipient is known and the diagnosis of C3G/aHUS of the native kidneys has been made after an etiological workup and a kidney biopsy. Unfortunately, the clinical history of the recipient and a renal biopsy of the native kidneys are often not available.

In such patients, if the graft is not doing well, a renal biopsy should be promptly performed and examined by light microscopy, immunofluorescence and electron microscopy. When the diagnosis of C3G/aHUS is suspected, a complete workup should be undertaken. The diagnostic approach should include a comprehensive biochemical,

genetic and pathologic analysis of the complement AP. This approach should include complement factors and complement regulatory protein levels, measurement of MCP on peripheral blood leukocytes as well as screening for anti-CFH antibodies and C3NeFs. Additionally, the genetic investigation should include mutation screening of CFH, CFI, MCP, C3 and CFB. The screening requires an extensive sequencing of all coding exons. Additionally, a study of recombination in the CFHR region should be made^[113]. The genetic studies are not easy to perform because the spectrum of genes currently known to be involved is rapidly expanding^[114]. Nonetheless, such studies are vital because the importance of genetic mutation screening to determine the outcome of retransplantation following a failed kidney allograft from a patient with recurrent aHUS has recently been documented^[115]. In other words, not all mutations have the similar detrimental effects. The absence of a more severe genotype could facilitate the successful treatment of the recurrence.

RECOMMENDATIONS, PREVENTION AND TREATMENT OF POST-TRANSPLANT aHUS AND C3Gs RECURRENCE

The vast majority of data are available for aHUS because C3G has been only recently defined and data on prevention and treatment rely more on case reports than on evidence-based medicine.

Recommendations

Patients with aHUS as a primary disease and patients with suspected aHUS and with STEC-HUS should be screened for all complement factors and regulating proteins. Additionally, a genotyping for *CFH*, *CFHR*, *CFI*, *MCP*, *CFB* and *C3* should be performed^[114].

Patients with a suspected diagnosis of C3G should also be screened for C3NeF and for other autoantibodies that are known to be involved in this disease.

Living donor renal transplantation, even in the eculizumab era, is not indicated for patients with mutations in *CFH*, *CFI*, *C3* and *CFB*. In patients with aHUS due to a mutation in *MCP*, donation may be safe after exclusion of other mutations often associated with *MCP* mutation. However, increased evidence for a polygenic pattern for aHUS and C3G and the still-unknown polymorphisms should always consider a living donation with extreme caution^[53].

Patients affected by aHUS but with no identified mutations should be recommended to proceed with transplantation combined with intensive plasma exchange (PE)^[21].

Prevention

To date, there is limited evidence for preventing C3G recurrence after transplantation. The more validated experience refers to the use of eculizumab to prevent aHUS recurrence^[80]. Whether these strategies may be

recommended to prevent C3G will be subject to future research.

More data are available concerning aHUS prevention. The avoidance of any possible endothelial insult has been highlighted^[113]. Post-transplant conditions that may cause endothelial insult include ischemia-reperfusion injury, infections, and immunosuppressive drugs. All of these factors could act as triggers to activate the AP in predisposed patients.

An association between calcineurin inhibitors (CNIs) and aHUS recurrence has been hypothesized^[7]. Other studies do not confirm this association and note that mTOR inhibitors are frequently used to avoid CNIs and may, *per se*, induce aHUS^[116,117]. PE has been used to prevent aHUS recurrence^[53]. However, PE has several drawbacks.

First, in some cases, PE fails to prevent aHUS^[118]. Second, there is a risk of recurrence when PE is interrupted. Third, the evidence of subclinical recurrent aHUS in patients still under treatment indicates that in some cases, PE does not control complement activation^[118].

Pre-transplant rituximab administration has been effective for patients with anti-CFH antibodies^[40,119,120]. In these patients, the association of PE may improve the treatment efficacy. The anti-C5 monoclonal antibody (eculizumab) has been used to prevent post-transplant aHUS in several patients. Among the reported patients, nine had either *CFH* mutations or a *CFH/CFHR1* hybrid gene. Another patient had a *C3* mutation^[118,121-124]. All of these patients had a complement genetic abnormality with a risk of aHUS recurrence greater than 80%. Only one patient lost the graft due to an arterial thrombosis. All other patients had a successful recurrence-free post-transplant course, even if, to our knowledge, they are still undergoing eculizumab treatment^[116].

Treatment

In a retrospective study, Zand *et al.*^[27] reviewed the outcomes of 14 patients diagnosed with a C3G recurrence after transplantation. Ten patients did not receive any additional treatment. Three patients received rituximab treatment, but the overall outcome was poor.

Another study reported the beneficial effect of plasma infusions (PI) in patients with a genetic mutation in factor H^[125]. Case reports documented the efficacy of eculizumab in patients with DDD recurrence^[106] and patients with C3GN recurrence^[126], although the patient with C3GN repeat allograft biopsies showed progression of the disease. Other studies^[127,128] reported eculizumab efficacy for the treatment of recurrent DDD and C3GN. A randomized clinical trial to evaluate the efficacy of eculizumab in patients with C3G is ongoing^[129].

An exciting new approach to C3G treatment is the soluble complement receptor 1 (CR1), which promotes the breakdown of active C3b. The infusion of soluble CR1 was reported to improve C3 and serum MAC levels in a patient with DDD recurrence^[97].

Before the eculizumab era, patients affected by aHUS

recurrence were extensively treated with PE. In the French survey, the outcomes of aHUS recurrence were not different among patients, regardless of treatment with PE^[116]. PE combined with belatacept was effective for one patient, as reported by Midvedt *et al.*^[130]. Eculizumab has been reported to be effective in a recent study by Matar *et al.*^[131], regardless of concomitant PE treatment. The largest experience in treating recurrent aHUS with eculizumab was reported by Zuber *et al.*^[118].

According to their findings, eculizumab was efficient in treating aHUS recurrence after transplantation. The treatment should be started as early as possible, and the treatment tolerance is excellent. Interestingly, two patients who received a single dose regimen experienced a delayed relapse^[132]. Two attempts of eculizumab discontinuation were followed by new relapses^[133].

Overall, these experiences suggest that a high risk of relapse may persist after a first recurrence. This fact suggests caution in withdrawing eculizumab in this setting.

Additionally, active HUS lesions have been observed in patients with a documented C5 blockade receiving eculizumab regularly^[118]. Whether a C3 convertase blocker could more efficiently treat these patients is currently unknown.

Two additional studies have documented eculizumab efficacy in plasma therapy resistant or dependent patients with recurrent aHUS^[134,135]. More than 80% of the patients achieved TMA-free status.

The efficacy of eculizumab has changed our approach to aHUS and C3G recurrence after transplantation. However several questions remain to be answered, including: (1) Do complement investigations impact therapeutic decisions? (2) For how long should patients with recurrent aHUS or C3G be given eculizumab? and (3) Does eculizumab change our indications for renal transplant for patients on dialysis for aHUS or C3G?^[136].

It is crucial to explore the most appropriate dose, dosing intervals and duration of treatment to reduce the enormous financial burden of eculizumab therapy^[137].

CONCLUSION

Recurrence of primary disease after renal transplantation is currently one of the most important causes of graft loss.

Recurrence is principally common for those diseases, often glomerulonephritis, caused by constitutional abnormalities of the patient, not kidney related. Among these abnormalities are diseases caused by complement dysregulation such as aHUS and C3Gs. To date, aHUS and C3Gs often represent a contraindication to renal transplantation due to the frequency and severity of recurrent disease. The clinical use of the anti-C5 inhibitor, eculizumab, seems to overcome the limitations to kidney transplantation for selected patients. However, we have highlighted the drawbacks of this therapy, principally represented by the high costs of lifelong therapy. The main perspectives in the field of renal transplantation

of avoiding or treating recurrences are either diagnostic and therapeutic. An improved understanding of genetics and biology will allow an improved knowledge of gene mutations and the possibility of opening new methods in the field of living donor transplantation; Future therapeutic approaches are represented by the availability of purified deficient gene products and the availability of C3 convertase inhibitors. In addition to CR1 as mentioned above, the current targets of research include the compstatin analog Cp40, which can block C3b^[138]. Similarly, another research target is a monoclonal antibody able to inhibit the C3 convertase induced by C3NeF^[139].

Abstract

Face transplantation is a complex vascular composite allotransplantation (VCA) surgery. It involves multiple types of tissue, such as bone, muscles, blood vessels, nerves to be transferred from the donor to the recipient as one unit. VCAs were added to the definition of organs covered by the Organ Procurement and Transplantation Network

Final Rule and National Organ Transplant Act. Prior to harvest of the face from the donor, a tracheostomy is usually performed. The osteotomies and dissection of the midface bony skeleton may involve severe hemorrhagic blood loss often requiring transfusion of blood products. A silicon face mask created from the facial impression is used to reconstruct the face and preserve the donor's dignity. The recipient airway management most commonly used is primary intubation of an existing tracheostoma with a flexometallic endotracheal tube. The recipient surgery usually averages to 19-20 h. Since the face is a very vascular organ, there is usually massive bleeding, both in the dissection phase as well as in the reperfusion phase. Prior to reperfusion, often, after one sided anastomosis of the graft, the contralateral side is allowed to bleed to get rid of the preservation solution and other additives. Intraoperative product replacement should be guided by laboratory values and point of care testing for coagulation and hemostasis. In face transplantation, bolus doses of pressors or pressor infusions have been used intraoperatively in several patients to manage hypotension. This article reviews the anesthetic considerations for management for face transplantation, and some of the perioperative challenges faced.

INTRODUCTION

Face transplantation is a complex vascular composite allotransplantation (VCA) surgery. VCA involves multiple types of tissue, such as bone, muscles, blood vessels, nerves to be transferred from the donor to the recipient as one unit^[1]. It is a rapidly evolving field which has benefited tremendously from the advances in microsurgery, transplantation, and immunologic techniques. Complex facial defects can be corrected, both functionally and cosmetically. Restoration involves availability of sufficient blood supply, esthetic unit match, nerve function, and integration into the recipients surrounding structures.

The first face transplant was performed in France in 2005^[1] and the first near total face transplant was performed in the United States by the Cleveland Clinic Foundation in 2008^[2]. Till date (Jan 2016) there have been 37 (20 partial and 17 full face) transplants done in the world. In Europe, face transplants have been done in France, Spain, Belgium, Turkey and Poland. China has been the only Asian Country to venture in this field^[3-5]. There have been five patient deaths reported so far^[5].

VCAs were added to the definition of organs covered by federal regulation [the Organ Procurement and Transplantation Network (OPTN) Final Rule] and legislation (the National Organ Transplant Act). The designation went into effect on July 3, 2014^[6]. The United Network of Organ Sharing (UNOS) was assigned to oversee all face and hand transplants and take responsibility for developing all relevant policies and byelaws in this field. Thus a special VCA Transplantation committee was formed by UNOS in 2014, to develop aspects of VCA policies such as refining allocation policy, defining criteria for VCAs to be covered in OPTN policy, OPTN membership requirement for VCA transplant programs, data requirements, data collection procedures, etc.^[7].

Face transplantation is a relatively new and rapidly developing field, and experience and expertise in this field is still limited. The American Society of Anesthesiologists (ASA) has not yet developed any guidelines to manage face transplantation procedures. This article reviews the anesthetic considerations for management for face transplantation, and some of the perioperative challenges faced.

ANESTHETIC CONSIDERATIONS

Donor

The ASA Physical Status Classification System typically

classifies a declared brain dead patient whose organs are being removed for donor purposes as ASA VI. Prior to harvest of the face, a tracheostomy is usually performed because endotracheal intubation may hamper the surgical procedure^[8]. The donor operation involves removal of the facial segment which varies as per the recipient's requirements^[9]. The donor graft may contain skin, multiple vessels, nerves, muscles, and facial bones. The dissection can be very prolonged and may take 12-15 h, even up to 22 h^[9,10]. The osteotomies and dissection of the midface bony skeleton may involve severe hemorrhagic blood loss needing transfusion of blood products. Explantation is done after systemic heparinization. The vascular pedicle consisting of carotid and internal jugular vessels is also dissected and used to flush the graft with cold preservative solution such as University of Wisconsin solution^[9]. Though the total ischemia time tolerated by facial grafts is unknown, approximately 4 h should be well tolerated^[11-13]. A silicon face mask created from the facial impression is used to reconstruct the face and preserve the donor's dignity^[8,14].

If the donor is a multiorgan donor, co-ordination with other solid organ teams is vital. If there is elevated blood loss and hemodynamic instability, then the solid organ team should ideally be prepared to harvest the other organs immediately. Otherwise, solid organ retrieval could be delayed till just prior to the face explantation. The solid organs should ideally be given priority over the VCAs^[8].

Recipient

The common indications for face transplantation have been devastating facial injuries which not only produce subsequent disfigurement but also compromise key facial functions, such as breathing, eating, facial expressions, vision etc.^[3]. Though face allotransplantation may not be life saving, it certainly has a significant impact on an individual whose face has been severely injured, and constitutes a major reconstructive procedure^[15,16]. It is essential for both, physical and social survival, and optimal social survival makes physical life worth living^[15].

The ASA Physical Status Classification System typically classifies patient with end organ stage disease undergoing a transplant surgery as ASA IV, *i.e.*, a patient with systemic disease that is a constant threat to life. However, since a face transplant is not theoretically life saving, the patient may fall into category ASA III, *i.e.*, a patient with a severe systemic disease, with substantive functional limitations. However, the patient may have several other comorbidities which may increase the ASA Grade. Reports published so far have cited damage to other organs as well, due to thermal burns, animal attacks, radiation injury, ballistic trauma, electrical burns, lye burns etc.^[1,3,16].

The airway management most commonly used in facial transplantations has been *via* a primary intubation of an existing tracheostoma with a flexometallic endotracheal tube^[17,18]. Primary orotracheal intubation may be challenging in cases of restricted mouth opening,

with facial skin contractures as commonly seen in burns, chemical trauma, etc. In such cases, fiberoptic intubation, awake or asleep, depending on the patient airway and the risks of aspiration, can be performed. Prior to commencement of surgery, a tracheostomy is done and a soft flexometallic endotracheal tube is inserted into the trachea. This is then sutured rather than tied, in order to prevent compression to venous outflow from the face by pressure exerted by the circumferential tie^[17,18].

Face transplantation surgery has a very long duration, usually averaging to approximately 19-20 h^[17,18]. One case has been reported to have a surgical time of 36 h^[19]. Venous access and hemodynamic monitoring would depend on the patient and existing comorbidities. An arterial line allows accurate monitoring of hypotension especially during massive blood loss, and also sampling for hematocrits, blood gases and coagulation profiles. Radial or femoral arterial lines can be placed, depending on accessibility.

A central line is usually preferred to administer fluids and pressors. The internal jugular and subclavian veins may be at risk of thrombosis, or maybe inaccessible. Though femoral venous access is associated with a higher degree of infection^[20], it has been used in several cases^[17,18]. Whenever feasible, a subclavian central venous line is preferable, to reduce risk of infections in this group of patients receiving immunosuppressive therapy postoperatively. A slight reverse Trendelenburg position (15 degrees) can be used to facilitate venous drainage and reduce blood loss.

Patients are usually induced using an induction agent such as propofol or etomidate, an opioid such as fentanyl or sufentanil, and a muscle relaxant. Muscle relaxants are usually avoided during the course of the procedure during dissection and reconstruction phases involving neural repair. Anesthesia is usually maintained using propofol, opioid, e.g., remifentanyl and inhalationals eg. sevoflurane. No particular anesthetic technique has been proven more superior than the other in face transplantation or free flap surgery. Normothermia is usually maintained by appropriate surface warming and by warming intravenous fluids and blood products administered to the patient. A mean arterial pressure of 65 mmHg ensures adequate perfusion and oxygen deliver to the vital organs including the graft. Urine output of 0.5-1 mL/kg per hour is usually adequate. In cases of severe hypotension, apical and subcostal views in transthoracic echocardiography maybe useful in assessing cardiac function. Antibiotics, timely redosing of antibiotics and immunosuppressants are crucial to the success of this surgery.

Since the face is a very vascular organ, there is usually massive bleeding, both in the dissection phase as well as in the reperfusion phase. Moreover, osteotomy sites can bleed excessively. Anesthesiologists involved in this surgery have reported that quantification of the bleeding is often difficult due to diffuse bleeding into the drapes and poor visualization of surgical site. Prior to reperfusion, often, after one sided anastomosis of the

graft, the contralateral side is allowed to bleed to get rid of the preservation solution and other additives which maybe used for allograft preservation, such as heparin or tissue plasminogen activator^[18].

A median of 20 U of packed red blood cells, 13 U of FFP, 2 platelet units, and 13 L of crystalloid administration has been reported^[18]. Though usually, massive transfusion protocols advocate 1:1:1 replacement of red blood cells, FFP and platelets^[21], the amount of plasma and platelets transfused have been on the lower side due to fear of risk of thrombosis of the facial vessels. Intraoperative product replacement should be guided by laboratory values and point of care testing for coagulation and hemostasis such as thromboelastography. Use of colloids such as dextrans^[22] are not preferred, and there is no data currently available on use of albumin for this surgery.

Many surgeons usually discourage use of pressors in microsurgical procedures, and though it is not typically a first line strategy, intraoperative use of pressors should be discussed in advance with the surgical team. It has been observed that there has been no difference in the outcomes when pressors were used or not used, and there is no reliable evidence to support contraindication of pressor use^[23]. Frequency of flap necrosis and postoperative complications and adverse events were similar with or without use of intraoperative pressors^[24]. Norepinephrine has been analysed as the most potential suitable agent for free flap transfer when compared to epinephrine, dobutamine and doxepine. This is because with norepinephrine, control of blood flow depends mostly on low frequency vasomotion or average blood pressure^[22,25]. Though vasoconstriction increased, the blood pressure increased too, resulting in overall increased flap blood flow^[26]. Dobutamine increases flap skin conductance, thereby benefiting flap blood flow^[26]. Epinephrine decreased flap blood flow^[26]. In face transplantation, bolus doses of pressors or pressor infusions have been used intraoperatively in several patients to manage hypotension^[17,18].

Post procedure, the regular flexometallic endotracheal tube maybe replaced by a regular tracheostomy tube, prior to transfer of the patient to the intensive care unit.

CONCLUSION

Face transplantation is a long procedure and involves complex planning for airway management, vascular access, fluid and pressor management. Teamwork between the surgeon, anesthesiologist and intensivist is essential for a successful outcome.

Abstract

The number of older end-stage renal disease patients being referred for kidney transplantation continues to increase. This rise is occurring alongside the continually increasing prevalence of older end-stage renal disease patients. Although older kidney transplant recipients have decreased patient and graft survival compared to younger patients, transplantation in this patient population is pursued due to the survival advantage that it confers over remaining on the deceased donor waiting list. The upper limit of age and the extent of comorbidity and frailty at which transplantation ceases to be advantageous is not known. Transplant physicians are therefore faced with the challenge of determining who among older patients are appropriate candidates for kidney transplantation. This is usually achieved by means of an organ systems-based medical evaluation with particular focus given to cardiovascular health. More recently, global measures of health such as functional status and frailty are increasingly being recognized as potential tools in risk stratifying kidney transplant candidates. For those candidates who are deemed eligible, living donor transplantation should be pursued. This may mean accepting a kidney from an older living donor. In the absence of any living donor, the choice to accept lesser quality kidneys should be made while taking into account the organ shortage and expected waiting times on the deceased donor list. Appropriate counseling of patients should be a cornerstone in the evaluation process and includes a discussion regarding expected outcomes, expected waiting times in the setting of the new Kidney Allocation System, benefits of living donor transplantation and the acceptance of lesser quality kidneys.

Key words: Kidney transplant outcomes; Frailty; Elderly; Expanded criteria donor; Quality of life

Core tip: Transplant physicians must be well-versed in the intricacies of evaluating older kidney transplant candidates. This includes the appropriate selection of candidates which can be challenging due to the extent of comorbidity and frailty in this patient population. For patients who are deemed appropriate for transplant, physicians must be able to counsel them regarding expected outcomes and explain the expected benefit that transplantation confers over remaining on the deceased donor waiting list. Living donor kidney transplantation, even from older donors, should be encouraged. If no living donor is available, the rationale for accepting lesser quality kidneys should be discussed.

Concepcion BP, Forbes RC, Schaefer HM. Older candidates for kidney transplantation: Who to refer and what to expect? *World J Transplant* 2016; 6(4): 650-657 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/650.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.650>

INTRODUCTION

Although the incidence of end stage renal disease (ESRD) in the United States for patients ≥ 65 years old is declining, prevalence continues to increase due to increasing patient survival. Older patients (≥ 65 years) now constitute over 40% of the ESRD population and with an aging general population, this is likely to grow further. Among 116990 incident ESRD patients in 2013, 56977 (48.7%) were ≥ 65 years and the mean age was 62.5 years^[1]. Due to the above trends, the number of older patients referred for kidney transplantation will likely continue to increase as well. As such, transplant physicians must be well versed in the unique issues that arise in the evaluation of older candidates. In this review, we answer key questions that confront both physicians and patients during the evaluation process.

WHO IS AN APPROPRIATE CANDIDATE?

An appropriate candidate is a patient whose survival and quality of life are expected to improve with transplantation as compared to remaining on dialysis. Unfortunately, there are no clinical criteria that accurately and reliably predict this. Older age alone is not a contraindication to transplantation^[2]. Transplant centers, however, may arbitrarily set their own age cut-offs. For candidates who do not have a living donor, this may be influenced by the expected waiting time in an individual center. In choosing the appropriate candidate, it is logical to only consider patients with reasonable long-term prognosis. However, determining who these patients are can be quite complex and there may be an inherent bias to exclude older patients due to perceived poor outcomes. Grams *et al.*^[3] developed a prediction model specific to older patients (≥ 65 years) using United States Renal Data System (USRDS) data of 128850 incident Medicare-

primary older adults with ESRD and United Network for Organ Sharing (UNOS) data of 6988 Medicare-primary first kidney transplant recipients aged ≥ 65 years. They identified 19 variables (15 comorbidities, age, dialysis vintage, sex and transplantation year) that predicted post-transplant outcomes. Based on the model, 11756 (9.1%) were found to be excellent kidney transplant candidates with a predicted 3-year post kidney transplant survival of 87.6% or higher. Of note, 76.3% of these patients were never placed on the waiting list or referred for living donor kidney transplantation. The authors concluded that using a simple risk prediction model may help identify suitable candidates and ultimately improve older candidates' access to transplantation. In another more recent study, Dusseuz *et al.*^[4] developed a simple clinical scoring system using data from the French national prospective registry. By applying this scoring system on incident dialysis patients aged 70 or above, they identified a subgroup of patients that had a 70% probability of survival within 3 years, representing about 20% of the entire cohort. They suggested that this subgroup of patients, despite their older age, were worthy of being referred for kidney transplant evaluation.

Medical evaluation

The primary reason for graft loss in the older patient population is death with a functioning graft hence a great deal of emphasis is usually placed on the medical evaluation to determine suitability for transplant. Transplant centers may have variable selection criteria especially in older patients. Although several guidelines^[2,5,6] exist with regards to the medical evaluation of a kidney transplant candidate, these are not specific for the older population. In general, however, individual organ systems are evaluated by means of history taking, physical examination and ancillary testing. If there is end-stage or severe disease, for example multi-vessel coronary artery disease not amenable to revascularization, then this usually becomes a reason to exclude patients from transplantation. Screening for infection and malignancy is also inherent to the evaluation especially in older patients due to their heightened susceptibility for both^[7].

Particular focus is given to the cardiovascular work-up because cardiovascular causes comprise the leading cause of death among transplant recipients^[1]. Unfortunately, the optimal method of screening for cardiovascular disease, in particular coronary artery disease, is not known^[8,9]. Transplant centers may have variable approaches, usually ranging from cardiac stress testing to more invasive testing such as coronary angiography. Stress testing is relatively easy and inexpensive to perform, but has suboptimal sensitivity and specificity especially in diabetics^[10]. As such, some centers may opt to go straight to a coronary angiogram. For example, at our center patients who are older than 70 years of age are required to undergo coronary angiography and if there is a significant burden of coronary artery disease, then a patient is deemed to be "too high risk" and therefore unsuitable for kidney transplantation. As part of the

cardiovascular work-up, additional attention is also given to imaging the iliac vessels to assess for patency and calcification. The imaging modality of choice at our center is computed tomography ± angiogram but a non-contrast magnetic resonance angiogram may also be a reasonable alternative if calcific burden is the main concern. At our center, not surprisingly, the primary reasons for excluding patients aged 60 years old or above are coronary artery disease, peripheral vascular disease (PVD), or both. It must be noted, however, that there are no studies that specifically compare the survival of these “very high risk” patients with transplantation as opposed to remaining on dialysis. Therefore, the decision to exclude these patients from transplantation remains rather subjective.

Measures of global health

Although a medical evaluation is able to closely scrutinize individual medical conditions, measures of global health and overall burden of disease may be more predictive of an older patient’s prognosis post-transplant. Measures of global health that are increasingly being recognized as important predictors of outcome in kidney transplantation include comorbidity indices and measures of functional status, physical performance, and frailty.

Comorbidity refers to the presence of two or more chronic diseases or conditions. The Charlson Comorbidity Index (CCI) is the most widely used tool to quantify comorbidity. In the kidney transplant population, high CCI scores, indicating increased comorbidity, have been shown to correlate with an increased risk of death^[11,12]. However, in a study by Heldal *et al.*^[13], although increasing CCI scores predicted mortality in younger patients (ages 45-54 and 60-69 years), these were not predictive in those aged 70 years or older. Additionally, the applicability of the CCI, however, has been questioned in kidney transplant candidates^[14]. In a recently published Dutch study, Laging *et al.*^[14] developed the Rotterdam Comorbidity in Kidney Transplantation (RoCKeT) score as an alternative to the CCI. The RoCKeT score is determined by the presence of cardiovascular disease (3 points), cerebrovascular accident (2 points), PVD (2 points), diabetes mellitus (2 points), liver disease (2 points), lung disease (2 points), malignancy (2 points) and human immunodeficiency virus (1 point). Not surprisingly, comorbidity was highest in the oldest age group in that 75% of patients aged 70 to 79 had comorbidity (at least 1 point). When RoCKeT scores were categorized and analyzed for the influence on patient survival, the group with the highest scores (5-9) had a significantly lower survival than those without comorbidity (score of 0). After multivariate analysis, patients with a score of 5-9 had a 2.7 increased risk of death compared to patients with a score of 0. Despite this, 50% of patients in the highest comorbidity category survived more than 10 years. The authors concluded that patients with severe comorbidity should not be excluded from transplantation due to superior patient survival compared with published survival data of hemodialysis patients. Moreover, meticulous selection of high-risk patients for kidney

transplantation can lead to successful outcomes.

Functional status is measured by a patient’s self-report of his or her ability to perform certain tasks. These tasks may include the ability to walk a certain distance, climb stairs, or perform activities of daily living. Functional status measurements are subjective and are obtained *via* questionnaires such as the short form-36 (SF-36) Physical Function (PF) scale, Vulnerable Elderly Survey-13, or Physical Activity Scale for the Elderly. A number of studies have reported an association between functional status and patient survival^[15-19]. In the largest study to date, Reese *et al.*^[19] analyzed 19242 *Fresenius* dialysis patients who had answered the SF-36 PF scale pre-transplant and had linked post-transplant data *via* the UNOS registry. Patient PF scores were divided into PF quartiles and these were correlated with time to kidney transplantation and the net survival benefit of kidney transplantation vs remaining on the waiting list. Patients in the lowest quartile were significantly older than those in the highest quartile (median age 54 years vs 46 years). In terms of survival, patients who were in the lowest PF quartile had the worst 3-year survival rates (84% compared to 92% for the highest quartile). When compared to remaining on the waiting list, patients across all PF quartiles had a survival benefit with transplantation. The lowest PF quartile had a survival benefit evident by 6 mo after transplantation. Another important finding in this study is that patients in the lowest PF quartile were more likely to be inactivated on the waiting list (adjusted hazard ratio vs highest quartile, 1.3) and less likely to be transplanted (adjusted hazard ratio vs higher quartile, 0.64). The authors concluded that functional status measures may be more useful in counseling patients regarding their probability of transplantation. It must be noted however that this study did not examine patients who were excluded from kidney transplant listing and who presumably had poorer baseline functional status, *i.e.*, the study only examined the best patients referred for transplant. Also, only 12% of the cohort were 65 years or older. Therefore, for patients referred for transplant who are older or with potentially worse baseline functional status, the applicability of this study’s findings in regards to the survival benefit of transplant vs remaining on the waiting list remains to be determined.

Physical performance is the measured ability to perform tasks or exercise. Examples include measurements of gait speed or grip strength. The short physical performance battery (SBBP) is a combination of tests with a sub-score assigned. Measures of physical performance are objective and may be superior to reports of functional status in that these avoid reporting bias and overestimation of patients of their health status. Hartman *et al.*^[20] in a study of 26 patients aged ≥ 60 years and referred for kidney transplantation, found that these patients with renal failure had lower SBBP scores, gait speed and grip strength compared to patients with diastolic heart failure (71 patients), chronic obstructive pulmonary disease (176 patients) or those with high cardiovascular risk (294 patients). Interestingly, despite

their inferior physical performance, renal failure patients were less likely to report functional impairment on disability questionnaires. We are not aware of any studies to date that have measured physical performance and correlated these with outcomes in kidney transplant patients. In other solid organ transplant candidates, particularly in lung transplant, the six-minute walk test (6MWT)^[21] has been used routinely in pre-transplant evaluations and has been shown to be a predictor of morbidity and mortality^[22,23]. The 6MWT measures the distance that a patient can quickly walk on a flat, hard surface in a period of 6 min. It would certainly be interesting to see if the 6MWT can be used similarly in older kidney transplant candidates to predict outcomes.

Frailty is a state of decreased physiologic reserve and is defined by the presence of 5 features, namely unintentional weight loss, weakness as measured by decreased grip strength, slow walking speed, low physical activity and self-reported exhaustion. It has been shown by McAdams-DeMarco *et al.*^[24-26] in successive papers that frailty is associated with increased hospital readmission post-transplant, graft loss and mortality. In a prospective study of 537 kidney transplant recipients in a single center^[26], frailty was measured at time of transplantation. Those who were frail, defined as having at least 3 out of the 5 features, were found to have a hazard ratio for death post-transplant of 2.22 (1.03-4.81, $P = 0.042$) compared to patients who were non-frail. In the subgroup of patients who were 65 years or older, 1-year survival was 85.8% in the frail group as opposed to 97.4% and 97.5% in the intermediately frail and non-frail groups, respectively. The authors suggested that frail patients should be identified pre-transplant and that patient survival may improve with appropriate management and closer monitoring of these patients.

A common theme to all the global measures of health discussed above is that it is not clear as to who is "too sick", "too debilitated", "too weak" or "too frail" to undergo kidney transplantation. Although these tools may help risk stratify patients, each candidate should be assessed on an individual basis and all data considered as a whole in determining a patient's suitability for transplant.

WHAT OUTCOMES CAN BE EXPECTED POST-TRANSPLANT?

Older recipients have decreased patient and graft survival compared to younger patients^[27]. Graft loss is commonly due to patient death, the top 3 causes being cardiovascular disease, infection and malignancy^[28]. There is less acute rejection in older patients and if graft loss is censored for death, graft survival actually improves with increasing age^[7,29].

Despite inferior patient survival in older compared to younger patients, kidney transplantation is pursued due to the survival benefit that it confers when compared to remaining on the deceased donor waiting list. In a study by Rao *et al.*^[30], 5667 patients aged ≥ 70 years who

were waitlisted for kidney transplantation were analyzed based on scientific registry of transplant recipients (SRTR) data. Of these patients, 2438 ultimately underwent kidney transplantation and when compared to those who remained on the waiting list, the transplanted patients had a 41% reduction in risk of death (0.59 relative risk of death). The time to equal risk was 125 d and the time to equal survival was 1.8 years from transplant. Of note, the mortality benefit that was seen in this study extended to the subgroup of patients aged ≥ 75 years, those with diabetes and those who received an expanded criteria donor. This study confirmed the findings of an earlier study by Wolfe *et al.*^[31] wherein the subgroup of patients aged 60-74 years was found to have a 61% lower mortality (0.39 relative risk of death 18 mo after transplantation) compared to similar patients on the waiting list. This survival advantage was calculated to translate into a 4-year increase in life expectancy (from 6 to 10 years).

In addition to superior patient survival compared to remaining on the waiting list, kidney transplantation is pursued due to the improvement in quality of life (QOL) that it confers^[32,33]. Transplant patients have superior QOL compared to dialysis patients^[34], though this may not be a fair comparison given that transplanted patients are a highly selected group. Age may have an effect on post-transplant QOL^[35-37]. In a single center study by Weber *et al.*^[36], they compared the post-transplant health-related QOL of patients ≥ 65 years with younger patients and with the general population. They found that physical QOL in older patients was significantly lower compared to younger patients and the general population. However, mental QOL was better than younger patients and similar to the general population. Humar *et al.*^[37] compared QOL of patients ≥ 65 years to younger patients and with national norms for this age group. They found that older transplanted patients scored higher in their general health perception, social functioning and mental health compared to national norms and also scored higher on social functioning and mental health compared to younger transplanted patients. Both these studies, however, did not look at pre-transplant QOL data to determine if there was an actual improvement in QOL before and after transplant. In a study by Laupacis *et al.*^[38] of 166 patients, 22 of whom were ≥ 60 years, they found that mean health-related QOL scores of almost all measures improved from pre-transplant to 6 mo after transplantation.

WHICH TYPE OF KIDNEY IS BEST?

Clearly, living donor (LD) transplantation confers the best outcomes in terms of patient and graft survival^[39]. This eliminates time on the waiting list, reduces dialysis vintage and allows for preemptive transplantation, affords patients better quality kidneys, and reduces the incidence of delayed graft function and a potentially tumultuous immediate post-transplant course. Moreover, due to the

elective and scheduled nature of LD transplant surgery, recipient issues can be addressed in a controlled manner prior to surgery thereby reducing perioperative risk. This was shown in a study by Gill *et al*^[40] of 25468 patients aged ≥ 65 years based on USRDS data who were listed for kidney transplantation, of which 11072 received a kidney transplant either from a LD, standard criteria deceased donor (SCD), or expanded criteria deceased donor (ECD). All patients were categorized based on cardiovascular (CV) risk as either being high, intermediate, or low CV risk. Among patients transplanted and across all CV risk categories, the death rate was lowest for patients who received a LD transplant and highest for recipients of an ECD kidney. Compared to patients who remained on the waiting list, a survival advantage was obtained, but importantly, times to equal risk and equal survival differed depending on the type of kidney transplanted and a patient's risk category. For patients who received a LD transplant, those who were low or intermediate CV risk had an immediately lower risk and higher survival post-transplant, and those who were high CV risk had a time to equal risk of only 43 d compared to similar patients who received an SCD (110 d) or ECD (180 d).

Despite the known advantage that living donor transplantation confers, older patients may have more limited living donor options as they may be hesitant to accept kidneys from younger donors such as their children or grandchildren. An alternative would be to pursue living donor transplantation from older donors such as their spouses or peers. Several studies have shown that recipients of kidneys from older living donors have reasonable outcomes^[41-43]. Englum *et al*^[41] studied 250827 patients based on UNOS data who received a kidney transplant, of which 92646 were LD kidneys and 4186 from donors aged ≥ 60 years. Not surprisingly, graft and patient survivals of patients who received a kidney from an older LD were worse compared to those who received a kidney from a younger LD. However, patients who received a kidney from an older LD aged 60-64 years and 65-69 years had similar graft survivals to patients who received a SCD kidney, superior graft survivals to ECD recipients and superior patient survivals to both SCD and ECD recipients. Patients who received a kidney from a LD aged ≥ 70 years had graft survivals similar to ECD recipients but significantly better patient survival. Given the organ shortage and current waiting times for a deceased donor kidney, it would make sense for an older patient who has an available older LD to pursue transplantation from an older LD rather than wait for an SCD or ECD kidney.

For those without living donor options, patients are faced with an increasing waiting time on the deceased donor list. The median number of years to deceased donor transplant was 5.5 years in 2003 and 7.6 years in 2007^[39]. Waiting time could be shorter or longer depending on where a patient is listed and his or her sensitization status and blood type. As older patients' time on the waiting list increases, the less likely they are to be transplanted as their health deteriorates

and they are either removed from the waiting list or they die^[44]. Compared to younger patients, the risk of death while waiting for a transplant is higher for older patients^[39]. It is therefore of paramount importance for older patients to get transplanted sooner rather than later. Kidneys that are thought to be of lesser quality should be considered for older candidates as waiting times for these kidneys are usually shorter. Rao *et al*^[30] and Merion *et al*^[45] demonstrated that recipients of ECD kidneys had superior survival compared to similar patients who remained on the waiting list or those who received standard therapy (waiting list and non-ECD transplantation). Massie *et al*^[46] examined the outcomes of patients who received high kidney donor profile index (KDPI) kidneys and compared these to outcomes of patients who remained on the waiting list until receipt of a KDPI $< 70\%$ kidney. The times to equal risk and equal survival post-transplant with the comparison group were 6 and 18 mo, respectively for the KDPI 81%-90% group and 7.2 and 19.8 mo, respectively for the KDPI 91%-100% group. At 4 years post-transplant, the KDPI 81%-90% group and 91%-100% group had a 17% and 10% lower mortality, respectively, than the comparison group. However, after 4 years the mortality rate was not statistically significantly different. The study found that the benefit of the high KDPI kidneys was greatest in patients ≥ 50 years who were listed at centers with a median wait time of ≥ 33 mo. In another study, Rose *et al*^[47] found that among 5257 patients that received a kidney from a deceased donor aged ≥ 65 years (defined in this study as an ECD kidney) in the United States, 10-year mean death-censored graft survival exceeded patient survival in patients aged ≥ 60 years. Among those aged ≥ 70 years, the difference was over 20 mo. Of note, there was a 7-8 mo difference in the 10-year mean patient survival between those who received an ECD kidney and similar patients who received a kidney from a deceased donor aged < 65 with a KDPI of 60%-69%. The authors concluded that for patients aged ≥ 60 years, kidneys from older donors can provide a lifetime of allograft function and that ECD transplantation should be encouraged in this age group. In a study from Spain, Pérez-Sáez *et al*^[48] looked at outcomes of 2040 patients waitlisted for transplant, of whom 389 (mean age 68.9 ± 5.8 years) received a kidney from a deceased donor aged ≥ 75 years. They found that there was a 56% lower risk of death in patients who received a transplant compared to those who remained on the waiting list. However, patients ≥ 70 years, diabetics and those with chronic obstructive pulmonary disease did not derive any statistically significant benefit.

HOW DOES THE NEW KIDNEY ALLOCATION SYSTEM (KAS) AFFECT OLDER PATIENTS?

In an attempt to balance equity with utility, kidney allocation in the United States was changed in December

2014^[49]. One of the goals of the new KAS is to increase unrealized graft years by matching high quality kidneys with recipients who have longer life expectancy^[50,51]. As a result, transplant rates among older candidates are expected to decrease^[51]. In an analysis of the early impact of the new KAS a year after its implementation, Stewart *et al*^[52] noted a significant reduction in transplants where donor and recipient age differed by more than 30 years (21.1% pre-KAS vs 16.3% post-KAS). Among recipients aged 65 years or older, transplant rates significantly decreased from 22.9% of all kidney transplants pre-KAS to 18.1% post-KAS across all donor KDPI's, with the most prominent reduction in transplants from donor kidneys with a KDPI of 0-20%. This occurred despite an increase in the number of waitlisted patients aged \geq 65 years (21.3% pre-KAS to 24.9% pre-KAS).

Another important feature of the new KAS is that kidneys from donors with a KDPI > 85% are now being allocated nationally. Whether this would lead to increased utilization of these organs and subsequent shorter waiting times remains to be seen. Broader sharing of these kidneys may lead to increased cold ischemic times and increased discard rates of marginal kidneys. In early analysis^[52], there was a significant reduction in transplant rates of kidneys from donors aged \geq 65 years (3.1% pre-KAS vs 2.5% post-KAS, $P = 0.0085$) and a non-significant reduction in transplanted kidneys with a KDPI of 86%-100% (8.6 pre-KAS vs 7.9% post-KAS, $P = 0.0645$). The kidney discard rate 1-year post KAS was slightly higher (19.4% post-KAS vs 18.5% pre-KAS, $P = 0.05$).

With these changes in the new KAS, we believe that older recipients should be motivated further to look for living donors including older living donors. If no living donor is available, then listing for kidneys with a KDPI > 85% should be highly considered. Consenting for KDPI > 85% kidneys should include a discussion regarding expected outcomes and rationale for accepting these kidneys.

CONCLUSION

Determining who among older kidney transplant candidates is appropriate for transplantation can be challenging and complex. A thorough medical evaluation with particular focus on cardiovascular health must be employed. Additional tools such as measures of comorbidity, functional status, physical performance, and frailty may be helpful. Those older patients who ultimately undergo transplantation have decreased patient and graft survival compared to younger counterparts, but have superior patient survival compared to those who remain on the deceased donor waiting list. Living donor transplantation confers the best outcomes for older recipients with reasonable outcomes from older living donors. If no living donor is available, most older patients will likely benefit from accepting lesser quality kidneys such as those that have a KDPI > 85%. In the era of the new KAS where transplant rates among older patients are expected to decrease, appropriate counseling of older recipients regarding their options is of paramount

importance.

Abstract

Non-melanoma cutaneous carcinomas, or skin cancers, predominantly squamous cell carcinomas (SCCs), are the most common malignancies occurring in kidney transplant recipients (KTRs). Squamous cell carcinoma risk is dramatically elevated in KTRs, occurring at rates of up 45-250 times those reported in general populations. New non-melanoma skin cancers in KTRs with a prior non-melanoma skin cancer also develop at 3-times the rate reported in non-KTRs with the same clinical history. The unique aggressiveness of SCCs in KTRs increases patient morbidity, due to the high rate of new lesions requiring treatment, frequently surgical excision. Oral nicotinamide shows promise in the chemoprevention of the especially aggressive non-melanoma skin cancers which occur in KTRs. This benefit might be conferred *via* its inhibition of sirtuin enzymatic pathways. Nicotinamide's concurrent hypophosphatemic effect may also partially ameliorate the disturbed calcium-phosphorus homeostasis in these patients—a putative risk factor for mortality, and graft failure. Conceivably, a phase 3 trial of nicotinamide for the prevention of non-melanoma skin cancers in KTRs, lasting at least 12-mo, could also incorporate imaging and laboratory measures which assess nicotinamide's impact on subclinical cardiovascular and chronic kidney disease risk, and progression.

Key words: Kidney transplantation; Skin neoplasms; Nicotinamide; Phosphorus

Core tip: Our unique review describes promising evidence

that oral nicotinamide may have dual therapeutic clinical applications in chronic kidney transplant recipients (KTRs). First, nicotinamide, *via* its inhibition of sirtuin-mediated enzymatic pathways, may reduce the rate of KTR non-melanoma skin cancers. Second, nicotinamide's hypophosphatemic effect could lower the rate of cardio-renal outcomes in KTRs. These hypothesized benefits warrant further study in randomized, placebo-controlled trials of nicotinamide treatment with both intermediate, and eventually, hard clinical outcomes.

Bostom AG, Merhi B, Walker J, Robinson-Bostom L. More than skin deep? Potential nicotinamide treatment applications in chronic kidney transplant recipients. *World J Transplant* 2016; 6(4): 658-664 Available from: URL: <http://www.wjnet.com/2220-3230/full/v6/i4/658.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.658>

NON-MELANOMA SKIN CANCER IN GENERAL AND KIDNEY TRANSPLANT RECIPIENT POPULATIONS

Updated United States incidence estimates for non-melanoma cutaneous carcinoma, or skin cancer (NMSC) in the Medicare fee-for-service population indicate a pronounced rise of 100% for the entire two decade period from 1992 to 2012, and a sustained 6-year 2006 to 2012 elevation in NMSC rates of 35%^[1]. Data recorded from kidney transplant recipient (KTR) populations spanning over four decades now, consistently yield 45- to 250-fold general population standardized incident rates for squamous cell carcinomas (SCCs), accompanied by 10-fold greater rates for basal cell carcinomas (BCCs)^[2,3]. Analyzing data from 24088 United States KTRs who underwent an initial kidney transplant between 1995 and 2001, Kasiske *et al.*^[3] reported 3-year age-adjusted NMSC rate ratios of 90.0 for male KTRs, and 92.3 for female KTRs, relative to general population controls. Comparison of KTR and non-solid organ transplant recipient (SOTR) populations with a prior history of NMSC, undergoing surveillance for new NMSCs, also demonstrates a persistently greater risk for additional skin cancers in KTRs. While non-KTRs experience a 3-year cumulative 18% risk of a subsequent SCC after a first SCC^[4], 3-year rates of 52%, and 59%, for a (at least one) new SCC in KTRs after an initial SCC, have been reported^[5].

Pre-cancerous actinic keratoses (AKs), Bowen's disease (SCC *in situ*), and keratoacanthomas are commonly associated with SCCs in KTRs^[2]. Most SCCs among KTRs, as in non-SOTRs, develop, typically, on sun-exposed areas^[2]. However, KTR SCCs have an increased tendency to be multiple, and aggressive, compared to SCCs which develop in non-SOTRs not exposed to chronic immunosuppression^[2] (Figure 1). The characteristic aggressiveness of KTR SCCs exacerbates patient

Figure 1 The unique aggressiveness of squamous cell carcinoma in kidney transplant recipients. Deeply invasive, recurrent, poorly differentiated and ulcerated squamous cell carcinoma in a 73-year-old female kidney transplant recipient with background alopecia from prior radiation therapy for this squamous cell carcinoma.

morbidity, because of the disproportionate rate of new lesions requiring, cryotherapy, electro-dessication and curettage, or surgical excision^[2]. This increased morbidity, although non-fatal, also results in significant medical costs, reflecting the national United States economic burden of NMSC and AK care, tabulated, as of 2007-2011, at \$4.8 billion, annually^[6]. KTR SCCs, additionally, have a greater potential for metastasis, and death^[2,5].

Successful interventions to reduce the incidence and complications associated with all NMSCs, SCCs, in particular, as well as AKs, would represent a significant advance in the management of KTRs. Despite heroic "conversion" protocols from calcineurin inhibitor-based to mechanistic/mammalian target of rapamycin (mTOR) inhibitor-based (primarily, sirolimus) immunosuppressive regimens, KTRs with a predilection for NMSCs, especially SCCs, continue to develop new malignant skin lesions at grossly elevated rates^[7,8]. The sirolimus converted group reported by Euvrard *et al.*^[7], for example, still experienced a 2-year incidence of 22% for SCC, and 47.6% for total NMSCs (71 new lesions in 20 patients). NMSC-prone KTRs converted to sirolimus also appear to increase their relative risk for death after mTOR conversion. A recent meta-analysis of such "conversion trials" underscored the lingering therapeutic dilemma: While sirolimus use significantly lowered SCC risk, it conferred an overall mortality penalty—a 1.59-fold excess risk of death^[8].

Ultraviolet (UV) radiation, immunosuppressive therapy, and human papillomaviruses (the latter with an ostensible link to SCC, specifically), are all believed to contribute to the development of NMSC among KTRs, while their precise etiologic pathomechanisms, alone, or in concert, require elucidation^[2]. Although topical sunscreens are an effective prophylactic against sunburn, their use may not afford protection from UV radiation-induced immunosuppression of the skin^[9], and the incidence of skin carcinomas, especially SCCs, continues to climb, steeply^[1]. The ideal chemopreventive treatment, as an adjunct to barrier sun protection, would

be an oral agent that is safe, well-tolerated, inexpensive, and readily available. A potential candidate emerging to fill that therapeutic niche is oral nicotinamide (NAM).

Nicotinamide as a potential non-melanoma skin cancer chemopreventive agent

Overt, pellagrous nicotinic acid (NA; niacin) deficiency has long been recognized as a cause of severe sunlight sensitivity in exposed skin^[10]. Recent clinical trial reports from an Australian investigative group suggest that oral NAM can reduce the occurrence of both AKs and NMSCs in non-SOTRs who have a history of AKs, and/or NMSCs^[11,12]. The initial 4-mo, placebo-controlled phase 2 studies ($n = 35$, and $n = 41$ participants, respectively) reported that oral NAM lowered the rate of appearance of new AKs (*i.e.*, total AK counts) by 29% to 35%^[11]. In a subsequent 12-mo phase 3, placebo-controlled trial of 386 patients with prior NMSCs, NAM treatment ($n = 193$ active; $n = 193$ placebo) reduced the average unadjusted new NMSC rate (total lesions per patient) by 27%. NAM treatment resulted in comparable rate reductions for SCCs (-30%), and BCCs (-20%), as separate outcomes^[12]. Chen *et al.*^[13], from the same Australian investigative group which conducted these non-SOTR NAM chemoprevention studies^[11,12], recently reported consistent results, in terms of effect sizes, from a phase 2 study of 22 KTRs. Patients at least 12 mo post-transplant, with stable renal function, and a history of ≥ 2 histologically-confirmed NMSCs in the previous 12 mo, were randomized 1:1 ($n = 11$ per group) to receive NAM 500 mg, or placebo, twice daily, for 6 mo. Skin exams and AK counts were performed at 2-mo intervals. The 6-mo NMSC rate (mean lesions per patient) was non-significantly lower for the NAM group (mean = 2.7; 95%CI: 1.4 to 5.3; total = 30 cancers), compared to placebo (mean = 4.2; 95%CI: 2.2 to 7.8; total = 45 cancers), although the numeric trend was dominated by one patient in the placebo group with 20 NMSCs (8 BCC and 12 SCC). The estimated relative rate difference was 0.35 (95%CI: -0.62 to 0.74, $P = 0.36$). Baseline AK counts (reported as means of 61.6 in the placebo, and 60.1 in the NAM groups, respectively), were also non-significantly lower in KTRs receiving NAM compared to placebo by 16% at 6 mo (95%CI: 7% to 34%; $P = 0.15$)^[13]. Also of importance, there were no between groups differences for adverse clinical events, or changes in complete blood counts, liver function studies, eGFR, or urinary microalbumin/creatinine ratios^[13]. Additional, if limited, independent confirmatory data have been provided in a research letter published by Drago *et al.*^[14], in *The New England Journal of Medicine*. These Genoa, Italy investigators studied NAM given at a dose of 250 mg thrice daily, relative to matched placebo, in 24 KTRs ($n = 12$ per group), also followed for 6-mo. The following is a verbatim description of their findings^[14].

At baseline, no significant differences were observed between the sizes of light-damaged areas in patients (identified visually, by touch, and by means of polarized

light dermoscopy), in the two groups. At 6 mo, 88% of the patients who received nicotinamide had partial regression of some or all actinic keratoses and surrounding light-damaged areas; in 44% of the patients who received nicotinamide, there was complete resolution in some of these areas (no lesions were detected on biopsy). In 91% of the patients who received placebo, the size of light-damaged areas increased, new light damaged areas developed, or both.

Two plausible anti-cancer biological effects of nicotinamide have been described by the Australian investigators which provide some independent validation of their clinical trial observations: Nicotinamide has been shown to promote DNA repair after UV exposure, and lessen local UV immunosuppression, in the skin^[15]. NAM's reported effects on sirtuin enzymes and mediated pathways might also confer anti-cancer properties. Briefly, sirtuin (Sir2) enzymes, are an ancient class of nicotinamide adenine dinucleotide (NAD⁺)-dependent deacetylases which have been conserved from bacteria to humans (for example, SIRT1, *etc.*). They perform a myriad of biological functions, including transcriptional silencing, DNA recombination and repair, apoptosis, axonal protection, fat mobilization, and lifespan regulation^[16-18]. Sirtuins deacetylate various proteins, notably p53, as well as histones, acetyl-coA synthetase, alpha-tubulin, Foxo3, Ku70, and NF kappa-beta. Lysine residues are the specific targets of sirtuin deacetylation reactions, allowing for tight cellular regulation. Sirtuin-catalyzed deacetylation is linked to the cleavage of NAD⁺, producing NAM, and O-acetyl ADP-ribose (OAADPr), in conjunction with deacetylated ribose. NAM produced from this reaction is a non-competitive inhibitor of sirtuins, which provides a mechanism for modulation of these enzymes by cellular nicotinamide concentrations^[16-18]. Importantly, the inhibitory activity of NAM on sirtuin-mediated deacetylation is not conferred by nicotinic acid (NA)^[18] (Figure 2). *SIRT1* overexpression has been observed in human prostate cancer, adult T-cell leukemia, primary colon cancer, and, significantly, in skin tissue biopsies from patients with AK, Bowen's disease, SCC, or BCC^[16,17]. One mechanism by which elevated *SIRT1* concentrations are believed to enhance malignant cell growth is *via* deacetylation of "tumor suppressor" p53 protein, inhibiting p53's apoptotic activity^[16,17]. *SIRT1* interacts directly with p53 and deacetylates the protein's C-terminal (Lysine)382 residue, which prevents p53 from trans-activating apoptotic genes, and promoting apoptosis^[17]. NAM may also affect another of *SIRT1*'s downstream target proteins, the retinoblastoma tumor suppressor protein (Rb), reducing Rb phosphorylation (or "hyper"-phosphorylation)^[19]. This has already been demonstrated, for example, in a mouse model of polycystic kidney disease, where NAM treatment reduced sirtuin-enhanced cyst formation^[19]. Anti-cancer chemopreventive agents such as curcumin (a natural phenol responsible for the yellow color of turmeric), which suppresses Rb phosphorylation in prostate cancer cells, are under investigation^[20].

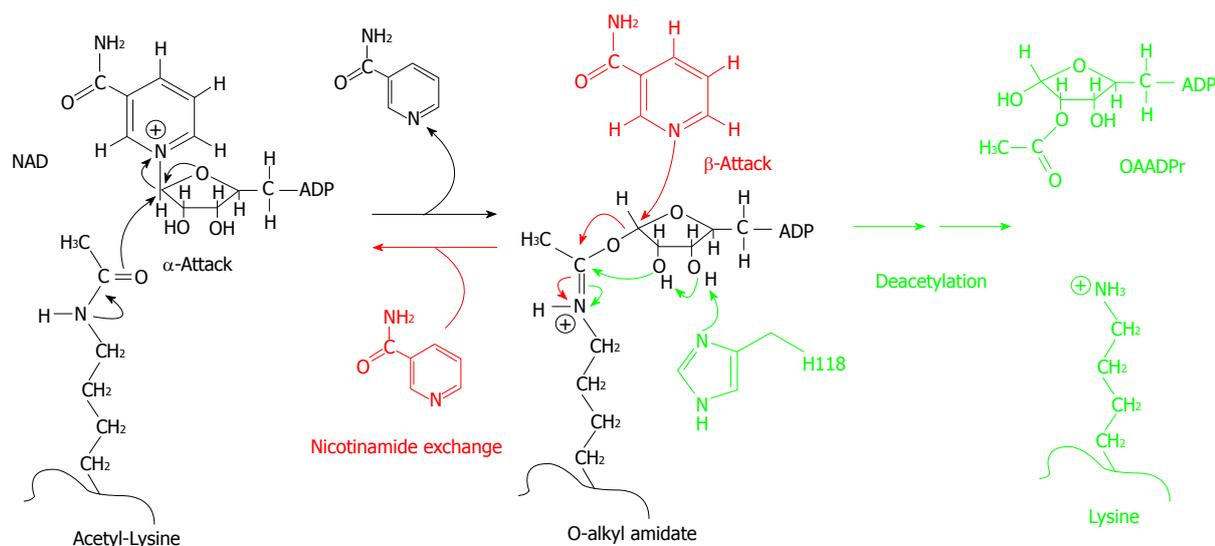

Figure 2 Nicotinamide-SIRT binding. At high concentrations, NAM can bind to SIRT when it contains the O-alkyl-amidate intermediate, resulting in “NAM exchange”, reforming NAD⁺ and acetyl-lysine, and decreasing deacetylation activity - a process unique to NAM, not NA. Reproduced from^[18]. NA: Nicotinic acid; NAM: Nicotinamide.

Comparable NAM-induced p53 and Rb alterations could mediate the potential benefits of NAM treatment for the chemoprevention of AKs and NMSCs, in general, and KTR patient populations^[11-14]. NAM's putative *in vivo* role as an inhibitor of sirtuins, and sirtuin-catalyzed “pro-oncogenic” de-acetylation, and hyper-phosphorylation reactions^[16-19] warrants investigation, as another pathophysiological correlate, in NAM-treated patients.

NICOTINAMIDE AND HYPOPHOSPHATEMIA: FROM TOXICITY MONITORING TO THERAPEUTIC INTERVENTION

Extensive analyses by others^[21], and our group^[22-26] (Figure 3), demonstrate that both NAM and NA lower serum phosphorus in chronic kidney disease (CKD) patients, and indeed across the entire spectrum of renal function. Mediated *via* an elegant mechanism, *i.e.*, direct inhibition of sodium-dependent transport of phosphorus in the small intestine^[21], this consistent phosphorus-lowering effect mandates surveillance of serum phosphorus levels in patients on chronic oral NAM/NA to avoid the theoretical development of clinical hypophosphatemia^[21]. But such potential toxicity might be counterbalanced by a distinctly positive clinical phenomenon: Since baseline serum phosphorus concentrations appear to predict total and/or cardiovascular disease (CVD) mortality in CKD and KTR populations^[27-31], as well as native kidney, or kidney graft failure^[27,30-32], conceivably, NAM-induced phosphorus-lowering could reduce such hard outcomes in these patients. Moreover, as NAM does not induce prostaglandin-mediated flushing, cause hyperuricemia, or adversely affect glucose tolerance, we believe it will have a better tolerability and safety profile relative to NA, confirming

a substantive, decades old body of clinical evidence^[33,34] from non-SOTR patient populations-now updated to include those studied on oral NAM therapy in the recent phase 2 and 3 Australian AK/NMSC prevention trials^[11-13]. The sporadic occurrence of mild thrombocytopenia in end-stage renal disease (ESRD; stage 5 CKD) patients treated with NAM^[35], has not been confirmed from either the recent placebo-controlled studies conducted among patients with normal renal function^[11,12], or KTRs^[13], for NMSC or AK prevention, nor was it reported in the large multicenter ENDIT trial^[34], or a 30-year toxicity review of NAM trials which preceded ENDIT^[33]. COMBINE, an ongoing, randomized, placebo-controlled trial (NCT02258074) in patients with an estimated glomerular filtration rate (eGFR) of 20-45 mL/min per 1.73 m², which includes a NAM treatment arm (1.5 g/d, given as 0.75 g twice daily), will provide more definitive data on the incidence of this toxicity in stage 3b-4 CKD^[35,36].

OVERVIEW OF DYSREGULATED CALCIUM-PHOSPHORUS HOMEOSTASIS AND ITS CLINICO-PATHOLOGIC IMPLICATIONS IN CKD AND KIDNEY TRANSPLANTATION

Deranged calcium-phosphorus metabolism often complicates CKD^[36], worsens with the progressive development of ESRD^[21,36], and is not fully reversed after kidney transplantation^[28-30,37,38]. Moreover, notwithstanding abnormalities, particularly hyperparathyroidism (with resultant increased fractional excretion of urinary phosphorus/decreased tubular reabsorption of phosphorus)^[37], which may persist long term despite successful transplantation, and excellent kidney graft function, chronic

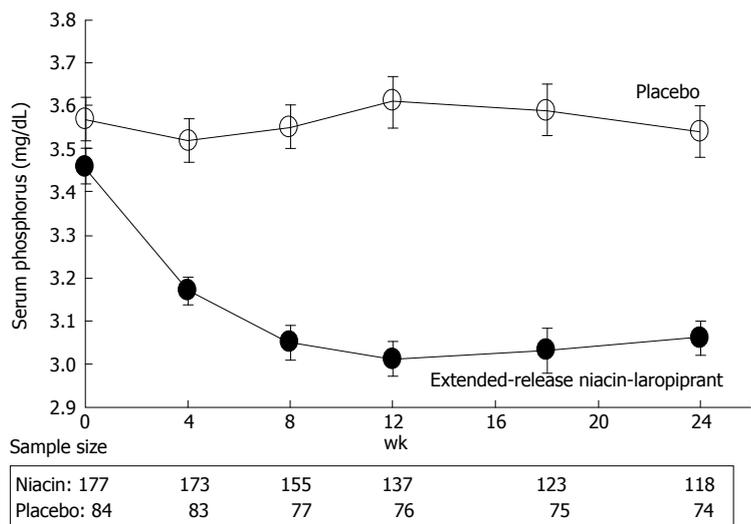

Figure 3 Phosphorus-lowering effect of nicotinic acid in chronic kidney disease. Mean serum phosphorus concentrations in dyslipidemic patients with stage 3 chronic kidney disease receiving extended release niacin-laropiprant, or placebo. Error bars are standard errors. Reproduced from Ref. [24].

KTRs whose GFR subsequently declines to stage 4 (15-29 mL/min per 1.73 m²) to 5 (< 15 mL/min per 1.73 m²), or even 3b (30-44 mL/min per 1.73 m²) CKD, are prone to the hyperphosphatemia, inadequate vitamin D status (*i.e.*, deficiencies of 25-hydroxy vitamin D3, and/or 1,25-dihydroxy vitamin D3), elevated concentrations of parathyroid hormone (PTH), and increased levels of the phosphatonin fibroblast growth factor 23 (FGF23), characteristic of stage 3b to 5 CKD in the native kidneys of non-KTRs^[28-31,37,38].

Chronic upregulation of the hormonal mechanisms evolved to maintain calcium-phosphorus homeostasis, including normal serum phosphorus concentrations, may have adverse clinical sequelae. For example, higher serum concentrations of phosphorus (*via* increased dietary intake, and/or a reduced GFR) apparently stimulate production of the bone-derived hormone FGF23, which induces compensatory renal phosphorus excretion^[30,36]. Elevated FGF23, in turn, may directly induce cardiac myocyte hypertrophy, clinically manifest as left ventricular hypertrophy (LVH)^[36], and lower endogenous production of calcitriol (1,25-OH vitamin D3), from 25-OH vitamin D3^[36]. Significant associations have been reported between FGF23 elevations LVH, CVD events, mortality, and progression to ESRD in patients with CKD stage 3-4^[36]. Accordingly, sustained elevations in FGF23 concentrations, despite being a homeostatic adaptation to maintain normal serum phosphorus, may enhance the risk for developing LVH, CVD, and ESRD^[36]. Higher phosphorus concentrations also stimulate chronic excess PTH secretion, eventually leading to clinical hyperparathyroidism^[36,39]. Inexorable CKD progression, accompanied by further nephron loss, ultimately overwhelms these compensatory hormonal mechanisms, causing a preponderance of advanced CKD patients to manifest concurrent hyperphosphatemia, increased FGF23 and PTH levels, and suppressed 1,25-OH vitamin D3 concentrations^[36,39].

The precise *in vivo* molecular mechanisms through which extracellular phosphate exerts its cytotoxic effects are not fully elucidated. However, investigations have demonstrated that extracellular phosphorus can form insoluble nanoparticles with calcium and fetuin-A,

commonly dubbed calciprotein particles (CPPs)^[39,40]. Highly bioactive ligands, CPPs can have cytotoxic effects such as causing cell death, or inducing osteogenic transformation of vascular endothelium, and renal tubular epithelium. CPPs, furthermore, are detectable in the circulation of both animal models, and humans, notably in patients with CKD, implicating their potential role in tissue injuries mediated by phosphatemia^[39,40]. Recently, a novel assay of serum calcification propensity, the transformation time ("T50") from primary calciprotein particles to secondary calciprotein particles, has been validated, and appears to reflect the pathophysiological milieu engendered by derangement of calcium-phosphorus metabolism which may predispose to ectopic, including vascular, calcification^[29,30]. These interrelated perturbations-hyperphosphatemia, inadequate status of vitamin D, elevations in PTH and FGF23, and more recently, greater calcification propensity (reduced T50)-are of epidemiological, and potentially, clinical relevance, because they have been associated, with fatal CVD^[26,35], graft failure^[30-32,40] or rapid decline in eGFR^[38], and total mortality^[28-31,40], among KTRs.

Even after possible "over-adjustment" for these co-variable measures of disturbed calcium-phosphorus homeostasis-which may be in the causal pathway between "phosphorus toxicity"^[39], and its clinical sequelae-the relationship between serum phosphorus concentrations, and outcomes, can persist in sizable observational KTR cohort studies. Pihlström *et al.*^[31], for example, investigated the association between baseline phosphorus concentrations and major CVD events, kidney graft loss, and all-cause mortality by proportional hazard survival analyses in 1840 stable KTRs derived from the Assessment of LEscol in Renal Transplantation (ALERT) trial, a multicenter randomized, double-blind, placebo-controlled study examining the effect of fluvastatin (40-80 mg daily) on CVD (primarily coronary heart disease, CHD), and renal outcomes in 2102 KTRs. Patients were recruited a mean of 5.1 years after transplantation, and followed for 6 to 7 years. During a mean follow-up of 6.7 years, death censored graft loss was recorded in 333 patients,

277 patients experiencing a major CVD event (defined as time to cardiac death, nonfatal myocardial infarction, or undergoing a coronary revascularization procedure), and 342 died, 168 from CVD, including cerebrovascular, or other major (*e.g.*, thoraco-abdominal aortic) vascular disease. Serum phosphorus (per 1 mg/dL increase) was associated with death from all causes, hazards ratio (HR) 1.23 (CI: 1.07-1.43, $P = 0.005$), and graft loss, HR 2.61 (CI: 2.25-3.04, $P < 0.001$), in unadjusted models. The relationship between serum phosphorus and mortality lost significance, HR 1.07 (CI: 0.89-1.28, $P = 0.488$), upon multivariable modeling (with PTH > 65 pg/mL), but persisted for graft loss, HR 1.52 (CI: 1.27-1.82, $P < 0.001$)^[31]. Similarly, Wolf *et al.*^[30] studied a single center cohort of 984 chronic, stable Hungarian KTRs (median transplant vintage, 72 mo, interquartile range 40-114 mo; mean eGFR 51, SD = 21; 57% men). After a median follow-up of 37 mo (interquartile range, 35-39 mo), 87 patients died and 101 patients suffered kidney graft loss. Outcome data were analyzed in full models that adjusted for eGFR, age, gender, systolic blood pressure, body mass index, albumin, calcium, the modified Charlson Comorbidity index, and graft vintage, as well as serum phosphorus, PTH, and FGF23. These investigators reported that a 0.9 mg/dL (*i.e.*, a 1 SD) increase in phosphorus predicted the composite endpoint of death or graft failure when analyzed as a continuous variable per SD increase (0.9 mg/dL), HR 1.23 (CI: 1.08-1.40, $P = 0.002$), in the fully adjusted modeling, which included FGF23^[30].

CONCLUSION

NAM shows promise^[11-14] as an agent for the chemoprevention of the especially aggressive^[2-5,7] NMSCs which occur in KTRs. This beneficial phenomenon may be mediated *via* its inhibition of sirtuin enzymatic pathways^[16-19]. Phase 3 trials to test this specific hypothesis merit serious consideration. NAM treatment also confers a consistent reduction in serum phosphorus concentrations^[21,35,36], with the accompanying potential to correct disturbed calcium-phosphorus homeostasis—for example, lower FGF23 concentrations, as with NA^[26], and possibly improve calcification propensity^[40]. These combined ameliorative effects of NAM treatment afford unique trial design opportunities. Conceivably, a phase 3 trial of NAM for NMSC prevention in KTRs, lasting at least 12-mo^[12], could also incorporate imaging and laboratory measures which assess NAM's impact on subclinical CVD and CKD risk, and progression, a strategy being employed by the 12-mo COMBINE trial^[36] in stage 3b-4 CKD patients.

ACKNOWLEDGMENTS

Abstract

Allogeneic hematopoietic stem cell transplant (HSCT) remains the only potentially curative option for variety of hematologic disorders. Lack of a suitable fully HLA-matched donor limits this option for many patients. Without a suitable related or unrelated HLA-matched donor,

umbilical cord blood and haploidentical family members provide a potential source of stem cells. Timely donor availability makes haploidentical donors an attractive alternative donor source. Initial attempts at haploidentical HSCT was associated with significantly increased mortality owing to high rates of graft rejection and severe graft-versus-host disease caused by major donor-recipient HLA-disparity. However, over the past decade, outcomes of haploidentical HSCT have improved significantly. Here, we review the advantages and challenges of haploidentical transplantation. We also discuss new developments to attempt to overcome the challenges to a successful haploidentical transplantation.

Key words: Haploidentical donor; Hematopoietic stem cell transplantation; Hematological malignancies; Transplant related mortality

Core tip: Over the past decade, haploidentical donors have emerged as a viable alternate graft source for patients without a HLA-matched donor. Several strategies including graft manipulation, conditioning regimen optimization and better graft-versus-host disease control have significantly improved the outcomes of haploidentical hematopoietic stem cell transplant (HSCT). Here, we summarize some of the recent advances in the field of haploidentical HSCT in adults.

INTRODUCTION

Hematopoietic stem-cell transplantation (HSCT) is

considered to be the only potentially curative therapy for several hematologic diseases. Most institutions currently consider a HLA-matched sibling as a preferred donor source, typically followed by either HLA-matched unrelated or an alternative graft source depending on the clinical scenario. The likelihood of having an HLA-matched sibling donor is approximately thirty percent after consideration of factors such as donor consent and health status. The probability of finding a suitable matched unrelated donor is strongly influenced by patient's ethnicity and can range from more than 75% for Caucasians to less than 20% for certain ethnic groups such as African Americans^[1]. In absence of related or unrelated HLA-matched donor, umbilical cord blood and haploidentical family members provide a potential source of graft. The use of haploidentical hematopoietic stem cell transplantation as an alternative graft source has been substantially increasing.

Utility of haploidentical related donors has a number of advantages including immediate donor availability for many patients facilitating a shorter interval to transplant. In addition, having a related donor makes post-transplant donor-derived cellular therapy more easily accessible. Challenges include major donor-recipient HLA-disparity which can cause delayed immune reconstitution, graft failure and severe graft vs host disease (GVHD) due to T-cell alloreactivity^[2,3]. This review highlights the major advances over the past decade to overcome the obstacles to successful haploidentical transplantation.

DONOR SELECTION

In contrast to unrelated donor transplant HSCT where finding the best HLA matched donor is the most important factor in determining transplant outcome, increasing HLA disparity in haploidentical matching does not have the same detrimental impact with dedicated techniques such as modification of post-transplant T cell reconstitution with cyclophosphamide. In 2010, Kasamon *et al*^[4] evaluated the impact of donor and recipient HLA in 185 patients who underwent un-manipulated bone marrow haploidentical transplant. Post-transplant cyclophosphamide was used as GVHD prophylaxis. In this study, the number of HLA-mismatches did not influence the rate of acute GVHD or disease free survival.

Donor characteristics that influence the outcome of haploidentical transplant were also investigated in a large study by Wang *et al*^[5] involving 1210 patients with hematologic diseases. Grafts consisted of G-CSF mobilized T-cell replete bone marrow and peripheral stem cells. Similar to the prior studies, the degree of HLA disparity did not influence the incidence of acute GVHD and treatment related mortality (TRM). Younger donor age (< 30 years) was associated with a lower incidence of acute GVHD compared to older donor age (> 30 years). Younger donor age and male gender were also associated with less TRM and better overall survival (OS). The benefit of male recipient gender was lost when maternal donors were excluded. There was a higher risk of grade II-IV acute

GVHD with maternal donors compared to paternal donors. In a male recipient, a maternal donor also correlated with a higher TRM rate and decreased OS. The impact of non-inherited maternal antigen (NIMA) disparities was evaluated in 264 patients. NIMA mismatched donors conferred a lower incidence of acute GVHD compared to non-inherited paternal antigen (NIPA) mismatched donors. Based on these results, authors concluded younger, male, NIMA-mismatched donor is a preferred donor in setting of T-cell replete haploidentical transplant. This study did not evaluate the influence of natural killer (NK) cell alloreactivity and donor CMV status. In contrast to Wang *et al*^[5], several trials demonstrated decreased risk of relapse and survival advantage with using maternal donors^[6]. A more potent anti-leukemic effect of maternal donor grafts has been attributed to the maternal immune system exposure to fetal antigens during pregnancy^[7].

Another factor influencing haploidentical transplant outcome is donor vs recipient NK cell alloreactivity. Tumor cells are able to escape T-cell adoptive immune response by down regulating cell surface MHC class I. NK cells are an important component of innate immunity and have MHC-unrestricted ability to target malignant cells. Cytotoxic activity of NK cells are mainly under the negative feedback control from inhibitory killer immunoglobulin-like receptors (KIRs) through binding to self HLA class I antigen. This phenomenon is known as "missing self"^[8-10]. KIR-KIR ligand mismatched in the donor-recipient direction lead to loss of the inhibitory feedback and activation of donor NK cells targeting recipient hematopoietic cells and leukemic cells. In contrast to allo-reactive T-lymphocytes, NK cells are thought to be capable of inducing graft vs leukemia (GVL) effect without promoting GVHD. In 2002, a study by the Perugia group demonstrated therapeutic efficacy of allo-reactive NK cells in 57 patients with acute myeloid leukemia (AML) following haploidentical transplant^[11]. Twenty out of 57 patients had KIR-ligand incompatibility in the graft vs host direction. The probability of OS at 5 years was markedly improved in patients with AML who had NK allo-reactive donors (60% vs 5%, $P = 0.0005$). Similar results were observed in the updated analysis of 112 patients with high risk AML who received T-cell depleted haploidentical transplants^[12]. Fifty one of 112 patients had NK cell allo-reactive donors. The conditioning regimen included TBI (8 Gy), fludarabine (40 mg/m² per day for 4 d), thiotepa (5 mg/kg per day for 2 d) and rabbit ATG. A significantly lower relapse rate (3% vs 47%, $P < 0.003$) and better EFS (67% vs 18%, $P = 0.02$) was observed in patients transplanted in any CR with NK allo-reactive donors compared to recipients of non-allo-reactive grafts. Although transplantation from NK allo-reactive donors improved survival in the entire cohort, subset analysis suggested that transplantation from NK allo-reactive donors did not decrease the incidence of relapse in patients transplanted at chemo-resistant relapse. There was no significant difference in incidence of acute GVHD between the two cohorts (10% vs 11%). These findings reinforced the theory that GVL activity by allo-reactive NK cells translated into prolonged OS. Subsequently, several

studies revealed a favorable impact of allo-reactive NK cells on transplant outcome in patients undergoing HLA-haploidentical transplant^[11,13-15]. An important role of donor-recipient KIR mismatch was also demonstrated after non-myeloablative T cell-replete haploidentical transplantation using post-transplant cyclophosphamide in a retrospective study involving 86 patients with high risk hematologic malignancies^[16]. On the contrary, a deleterious effect of KIR mismatches was seen in the earlier studies^[17,18]. Due to ongoing controversy, currently the KIR testing is not considered mandatory for donor selection in haploidentical transplant setting.

HAPLOIDENTICAL STEM CELL TRANSPLANT STRATEGIES

T-cell depletion

The first successful haploidentical transplants were done in the 1980s in children with severe combined immunodeficiency syndrome (SCIDS) using T-cell depleted bone marrow grafts. T-lymphocyte depletion in this setting mitigated GVHD associated with crossing a major HLA-barrier without compromising engraftment^[19]. Subsequently, this approach was implemented successfully in several studies of patients with SCIDS. In contrast to SCIDS, haploidentical transplantation was less successful in the setting of acute leukemia owing to a high rate of graft failure. Increased risk of graft failure was attributed to host derived T-lymphocytes that survived the conditioning regimen^[20-22]. A decade later, it was shown in preclinical studies (murine models) that infusion of a large number of donor hematopoietic stem cells can overcome the MHC barrier and promote engraftment^[23]. In 1993, cell dose escalation approach was tested in 36 patients with acute leukemia following myeloablative total body irradiation (TBI) based preparative regimen. Mega doses of stem cells (on average $> 10 \times 10^6$ CD34⁺ cells/kg body weight) were obtained by supplementing T cell-depleted bone marrow transplants with granulocyte colony-stimulating factor (G-CSF) mobilized peripheral blood stem cells. Using this approach, nearly 80% of patients achieved primary engraftment. The sole GVHD prophylaxis consisted of T-cell depletion of the graft. Only 18% of the patients developed grade II-IV acute GVHD^[24,25]. Subsequently, several modifications were introduced to optimize the T-cell depletion of the graft including positive immunoselection of the CD34⁺ cells using the Ceparate system in 1995 and Clinimacs device in 1999^[13,26]. In addition, to reduce the toxicity associated with the myeloablative TBI based conditioning regimen, fludarabine was substituted for cyclophosphamide in 1995^[27]. After optimizing the conditioning regimen and graft processing, Aversa *et al.*^[28] investigated haploidentical transplantation in 284 patients with acute leukemia. Ninety five percent of the patients achieved engraftment with minimal GVHD. The relapse rate was 17% in acute myeloid leukemia (AML) and 27% in acute lymphoblastic leukemia (ALL) patients transplanted in any CR. Incidence of TRM was 40% mainly

due to opportunistic infections. Seventeen year DFS was 30% in ALL and 43% in AML patients transplanted in any CR. Among the long term survivors, chronic GVHD was not observed in any patients^[28].

The major disadvantages of using T-cell depleted grafts are the high rate of relapse and life-threatening infections post-transplant^[29]. Due to poor thymic function in adults, post- allogeneic transplant T-cell immune recovery depends on peripheral expansion of donor T-lymphocytes. In a T-cell depleted graft, passive transfer of T-lymphocytes is minimal leading to profound delay in immune recovery. To overcome these obstacles several strategies have evolved over the past decade including selective T-cell depletion, adoptive transfer of donor T-cells post-transplant, and T-regulatory cell (T-reg) add backs.

Selective T cell depletion

The principle behind adoptive T-cell therapy is to eliminate donor allo-reactive T cells responsible for GVHD while sparing other immune cells, which facilitate immune reconstitution. To selectively deplete allo-reactive donor T-cells, *ex vivo* T-cells are activated against host antigen presenting cells. Activated T-cells are removed using several methods including immunotoxin, immune-magnetic selection and photodynamic purging^[30-32].

Another innovative approach is to selectively remove T-cells responsible for GVHD (TCR alpha-beta) while sparing gamma-delta T-cells ($\gamma\delta$ T-cells). Gamma-delta T-cells account for 1% to 10% of peripheral T-cells. Based on *in-vitro* studies, human T lymphocytes which express $\gamma\delta$ T-cells receptor have MHC-unrestricted innate cytotoxic activity against tumor cells^[33,34]. In a recent study, Lang *et al.*^[35] retrospectively evaluated the immune recovery after TCR $\alpha\beta$ /CD19-depleted haploidentical HSCT in 41 pediatric patients with acute leukemia, myelodysplasia and nonmalignant disease. Primary engraftment was seen in 88% of the patients. The incidence of grade II and grade III-IV acute GVHD was 10% and 15% respectively. At one year follow up, the event free survival (EFS) of patients with acute leukemia or myelodysplasia transplanted in CR1-CR3 was 100%. One year EFS of patients with subsequent HSCT (CR2-CR6) or with active disease was 29% and 11%, respectively. The use of TCR $\alpha\beta$ /CD19-depleted stem cells substantially accelerated immune recovery. In comparison to CD34⁺ selected grafts (historic control), patients achieved a higher CD3⁺ at days +30 and +90, CD34⁺ at day +30 and CD56⁺ at day +14. The Italian group also reported similar results in 16 adults with high risk acute leukemia after TCR $\alpha\beta$ /CD19-depleted haploidentical HSCT.

A more recent strategy to separate GVHD and the GVL effect involves selectively depleting naïve T cells identified by CD45RA⁺ expression^[36,37]. Naïve T-cells are shown to be the most allo-reactive amongst the T-cell subsets. *Ex vivo* depletion of CD45RA⁺ T-cells and adoptive transfer of CD45RA-memory T cells hasten the immune reconstitution post-transplant, enhances the GVL effect while abrogating GVHD. This strategy was recently evaluated in a study of

17 adults with high risk hematologic malignancies (16 AML and 1 myelodysplasia) with KIR receptor-ligand mismatched haploidentical donor^[38]. The conditioning regimen included total lymphoid irradiation (8 Gy), fludarabine (150 mg/m²), cyclophosphamide (60 mg/kg), thiotepa (10 mg/kg) and melphalan (140 mg/m²). Patients received a CD34⁺ selected stem cell graft on day 0 followed by an infusion of CD45RA-depleted stem cells on day +1. NK cell infusion was given on day +6. Post-transplant GVHD prophylaxis included sirolimus and mycophenolate mofetil (MMF). All patients achieved primary engraftment. Neutrophil and platelet engraftment was rapidly achieved at median day +11 and +17 respectively. Acute GVHD was not seen in any of the patients. There was no infection related mortality. A phase II study of selective depletion of CD45RA⁺ T Cells from allogeneic peripheral blood stem cell grafts from HLA-matched related and unrelated donors for prevention of GVHD is currently under investigation^[39].

SELECTIVE T-CELL ADD BACK

Con-infusion of donor-derived regulatory T-cells (Tregs) with conventional T-cells (Tcons) is another method to manipulate the T-cell depleted graft to improve haploidentical transplant outcome. In pre-clinical studies of bone marrow transplantation, infusion of donor-type CD4⁺CD25⁺Tregs abrogated GVHD without compromising the cytotoxic ability of T-cons against tumor cells^[40,41]. A first in human study by Di Ianni *et al.*^[42] investigated infusion of Tregs, followed by Tcons in 28 patients with high risk hematologic malignancies who underwent haploidentical transplantation. After TBI containing conditioning regimens, patients received infusion of donor derived Tregs (2 × 10⁶ Tregs) on day-4. CD34⁺ stem cells were infused on day 0 followed by Tcons. Two out of five patients who received 2 × 10⁶ Tcons/kg developed acute GVHD which led to decreasing the cell dose of Tcons to 1 × 10⁶ cells/kg. Chronic GVHD was not observed in any patients. All patients achieved primary engraftment. Compared to conventional mismatched HSCT, pathogen specific CD4⁺ and CD8⁺ were detected earlier in the study cohort (as early as 2 mo vs 9-12 mo). CMV-related death, a major cause of mortality in original T-cell depleted HSCT, was not observed. At median 1 year follow up, 46% of the patients were disease free. Subsequently, Martelli *et al.*^[43] evaluated the impact of Tregs - Tcons infusion in reducing post-transplant relapse risk in 43 adults with acute leukemia. This method significantly reduced the risk of relapse and ameliorated GVHD. Grade 2 or more acute GVHD was seen in 15% of patients. At median follow up of 46 mo, only two patients relapsed resulting in an incidence of relapse that was significantly lower than historical controls. Despite promising results of T-cell depleted haploidentical transplant, this approach is costly, technically demanding and labor intensive which limits its application to highly experienced centers.

T CELL REPLETE GRAFT

Earlier attempts at using un-manipulated haploidentical

transplant were associated with an unacceptably high rate of GVHD related mortality due to donor T-cell alloreactivity. To overcome this obstacle, several strategies have evolved over the past decade including G-CSF primed graft^[44,45] and more recently post-transplant high dose cyclophosphamide.

HIGH-DOSE POST-TRANSPLANT CYCLOPHOSPHAMIDE

Cyclophosphamide is an alkylating chemotherapeutic agent which has been used for many years as a component of conditioning regimens. Preclinical trials in the early 1970s revealed short course of cyclophosphamide after bone marrow transplantation can target allo-reactive T-cells and reduce the risk of GVHD^[46-48]. In contrast to calcineurin inhibitors, cyclophosphamide is capable of inducing T-lymphocyte apoptosis^[49]. Hematopoietic stem cells are resistant to high dose cyclophosphamide due to expression of high levels of aldehyde dehydrogenase^[50]. Original clinical trials exploring cyclophosphamide efficacy as the post-transplant GVHD prophylactic agent were performed in the haploidentical transplant setting. In 2002, O'Donnell *et al.*^[51] evaluated the transplant outcome of 13 patients with high risk hematologic malignancies who received T-cell replete haploidentical transplant after a non-myeloablative conditioning regimen with TBI and fludarabine. GVHD prophylaxis included post-transplant cyclophosphamide 50 mg/kg on day +3 in combination with MMF and tacrolimus. Due to high rate of graft failure (2 out of 3 patients) the protocol was amended to add cyclophosphamide 14.5 mg/kg to the conditioning regimen. Subsequently, 8 of 10 patients obtained primary donor cell engraftment. After 99 d follow up, 6 patients (46%) developed acute GVHD. Six months incidence of DFS was 50%. This study demonstrated the feasibility and possibility of rapid engraftment in a non-myeloablative haploidentical transplant setting using post-transplant cyclophosphamide.

Subsequently, Luznik *et al.*^[52] compared safety and efficacy of administration of cyclophosphamide on day +3 and +4 rather than only on day +3 among 68 patients with hematologic malignancies after non-myeloablative haploidentical bone marrow transplant. Primary engraftment was achieved in 87% of the patients. Notably, a very low incidence of grade III acute GVHD (6%) with no grade IV acute GVHD was observed at one year follow up. The only difference between the two cohorts was a trend toward a lower incidence of chronic GVHD after two doses of post-transplant cyclophosphamide (5% vs 25%, *P* = 0.05). The 2-year OS and EFS rates were 36% and 26%, respectively. A major contributor to the low OS rate was a high incidence of relapse (58% at 2 years).

A similar outcome was observed in a large phase II study of high dose post-transplantation cyclophosphamide as GVHD prophylaxis after non-myeloablative HLA-haploidentical bone marrow transplantation in 210 patients with hematologic malignancies^[53]. Sustained donor cell

engraftment was obtained in 87% of the patients. The cumulative incidences of grades II-IV acute GVHD was 27%. At 5 year follow up, OS and EFS were 35% and 27%, respectively. As seen in the prior studies, relapse was a major cause of mortality. Five year cumulative incidence of relapse was 55%.

In parallel multicenter phase 2 trials, BMT CTN 0603 and BMT CTN 0604, patients with acute leukemia or lymphoma underwent reduced intensity bone marrow haploidentical transplantation (0603) or double cord blood transplant (0604)^[54]. The conditioning regimens contained 200 Gy TBI in addition to fludarabine and cyclophosphamide. In CTN 0603, the GVHD prophylaxis consisted of post-haploidentical transplant cyclophosphamide 50 mg/kg on day +3 and +4 followed by tacrolimus and MMF. In CTN 0604, GVHD prophylaxis included MMF and cyclosporine after double umbilical cord transplant. Among haploidentical transplant recipients, 100-d incidence of grade II-IV acute GVHD and 1-year incidence of chronic GVHD were 32% and 13%, respectively. After double cord transplant 100-d incidence of grade II-IV acute GVHD and 1-year incidence of chronic GVHD were 40% and 24%, respectively. One year cumulative incidence of relapse after haploidentical and double umbilical cord transplant were 45% and 31%, respectively. The OS and EFS rates were 62% and 48% respectively after the haploidentical transplants. Similar OS (54%) and EFS (46%) were seen after double cord transplant. The authors concluded that both RIC haploidentical and double umbilical cord HSCT are valid options in patients with hematologic malignancy. Currently a multicenter randomized phase III trial (BMT CTN 1101) is investigating the effectiveness of haploidentical and double umbilical transplant in patients with leukemia or lymphoma^[55].

Despite relatively low rates of GVHD with non-myeloablative haploidentical transplant, a high incidence of relapse has remained the main challenge in high risk hematologic malignancies. To address this obstacle, use of more intense (myeloablative) preparative regimens and peripheral blood stem cell graft was explored. In a prospective study by Solomon *et al.*^[56], 20 adults with high risk (relapsed/refractory) hematologic malignancies were treated with myeloablative conditioning followed by peripheral blood derived haploidentical transplant. The conditioning regimen consisted of fludarabine 30 mg/m² for 4 d, intravenous busulfan 130 mg/m² per day for 4 d, and Cy 14.5 mg/kg per day for 2 d. GVHD prophylaxis included high dose cyclophosphamide on day +3 and +4 followed by tacrolimus and MMF. All patients achieved primary engraftment. One year cumulative incidence of grade II-IV acute GVHD and chronic GVHD were 10% and 5%, respectively. At median follow up of 20 mo, DFS and OS were 69% and 50%, respectively. The cumulative incidence of relapse was approximately 40%. The major drawback of this trial was high incidence of hemorrhagic cystitis due to BK virus infection. This adverse event was observed in two third of the patients. This was attributed to the combination of high dose busulfan and cyclophosphamide. Association

of BK induced hemorrhagic cystitis and high dose busulfan in setting of mismatched HSCT was reported previously in several studies^[57]. To alleviate this problem, the conditioning regimen was changed to TBI-based myeloablative regimen in the subsequent study^[58]. In this phase II prospective trial, 30 patients underwent peripheral stem cell haploidentical transplant using fludarabine 25 mg/m² per day for three days and 1200 cGy TBI as the preparative regimen. All patients achieved primary engraftment. Median time to neutrophil and platelet engraftment was 16 d and 25 d, respectively. Incidence of grade II-IV acute GVHD was 23%, whereas moderate to severe chronic GVHD occurred in 22% of patients. In the entire cohort, 2-year NRM and OS were 3% and 78%, respectively. Among patients with low or intermediate risk disease NRM and OS were 0% and 100%, respectively. Relapse rate was significantly reduced in comparison to patients treated at the same center with matched related transplant. Incidence of post-transplant BK virus associated hemorrhagic cystitis was significantly reduced after TBI-based regimen compared to the busulfan-based conditioning regimen (30% vs 75%, $P = 0.005$).

Similar results were observed in several other trials of myeloablative haploidentical transplant^[59,60]. Raiola *et al.*^[59] confirmed the low rate of GVHD and encouraging rate of DFS and OS in 50 patients with high risk hematologic disease (23 patients in CR and 27 patients with active disease) after un-manipulated myeloablative haploidentical transplant^[59]. GVHD prophylaxis contained post-transplant cyclophosphamide on day +3 and +5 followed by cyclosporine and MMF. In the entire cohort, 12% of the patients developed grade II-III acute GVHD. Moderate chronic GVHD was seen in 10% of patients. The actuarial 22-mo DFS for patients transplanted in CR and patients with active disease was 68% and 37%, respectively^[61]. The overall risk of relapse after myeloablative haploidentical HSCT was approximately 40% which compares favorably with that reported for non-myeloablative haploidentical HSCT. Therefore, despite the lack of randomized trials, myeloablative haploidentical transplant may be a reasonable option in younger patients with high risk hematologic malignancy in absence of timely access to a conventional donor.

Haploidentical related donor vs matched related sibling or matched unrelated donor (Table 1)

Encouraging results of haploidentical transplant compared to matched related or matched unrelated transplant has been suggested by several non-randomized studies. In 2015, a large retrospective study compared the transplant outcome of 868 patients with acute leukemia after haploidentical transplant and 9815 patients with HLA-matched sibling donor (MRD)^[62]. However, leukemia free survival was significantly longer after matched sibling donor transplant compared to haploidentical transplant (T-cell depleted or T-cell replete grafts). Haploidentical transplant was associated with higher TRM. The probability of relapse was not significantly different between the two

Table 1 Unmanipulated haploidentical hematopoietic stem cell transplant vs matched related and matched unrelated hematopoietic stem cell transplant

AML: Acute myeloid leukemia; ATG: Anti-thymocyte globulin; CR: Complete remission; CNI: Calcineurin inhibitor; DFS: Disease free survival; GVHD: Graft vs host disease; Haplo: Haploidentical; MMF: Mycophenolate mofetil; MTX: Methotrexate; RIC: Reduced intensity conditioning; MA: Myeloablative; MDS: Myelodysplasia; MUD: Matched unrelated donor; MRD: Matched related donor; NE: Neutrophil; NR: Not reported; NS: Not significant; OS: Overall survival.

cohorts. Therefore, the authors concluded haploidentical GVL effect is similar to MRD.

Ciurea *et al*^[63] also retrospectively compared the transplant outcome of patients with AML after haploidentical transplant (n = 192) using post-transplant cyclophosphamide and MUD (n = 1982). In the haploidentical cohort, 104 patients received MA and 88 had reduced intensity conditioning. In MUD cohort, 1245 patients (63%) received MA and 737 (37%) received RIC regimens. Compared to MUD, thirty day neutrophil engraftment was lower after haploidentical transplant in

MA setting (97% vs 90%, P = 0.02). In RIC setting, day 30 neutrophil engraftment rate was similar between the two cohorts (96% and 93%, P = 0.25). Acute and chronic GVHD was notably lower after haploidentical transplant. In the MA setting, three month incidence of acute GVHD (16% vs 33%, P < 0.0001) and 3-year incidence of chronic GVHD (30% vs 53%, P < 0.0001) were significantly lower with haploidentical in comparison to MUD transplant. Similar results were obtained in RIC setting. A lower rate of GVHD with haploidentical transplant was attributed to the use of bone marrow as a graft source and the use

of post-transplant cyclophosphamide. Among patients receiving myeloablative and RIC regimens, three-year DFS and OS were comparable in haploidentical and MUD transplant.

Transplant results of matched sibling donor (MSD) transplant and T-cell replete haploidentical transplant was also evaluated by Wang *et al*^[64]. In this prospective, multicenter, nonrandomized trial, 450 patients with acute leukemia in CR1 underwent MSD ($n = 219$) or haploidentical ($n = 231$) transplant. Cyclosporine, MMF, and low dose methotrexate was used as GVHD prophylaxis regimen in both groups. All individuals in both cohorts achieved donor-cell engraftment. The median time to achieve neutrophil engraftment was 2 d longer after MSD transplant. The 100-d cumulative incidence of grade II-IV acute GVHD after haploidentical and MSD transplant was 36% and 13% ($P = 0.001$), respectively. The incidence of chronic GVHD was significantly higher after haploidentical transplant compared to MSD (42% vs 15%, $P < 0.001$). However, the rate of GVHD related death was similar in both groups. Among haploidentical and MSD recipients, the 3 year probability of DFS (74% vs 78%, $P = 0.34$) and OS (79% vs 82%, $P = 0.36$) were comparable. There was no difference in 3-year cumulative incidence of relapse between the two cohorts (15% vs 15%, $P = 0.98$). Lower incidence of GVHD after MSD was attributed to combination of cyclosporine, methotrexate and MMF for GVHD prophylaxis. Prior studies also reported significantly lower rate of GVHD using this combination in recipients of MSD transplant^[65,66].

More recently Ghosh *et al*^[67] performed a registry analysis comparing outcomes of 987 patients with lymphoma following reduced intensity haploidentical HSCT ($n = 180$) with MSD HSCT ($n = 807$). GVHD prophylaxis for the haploidentical group consisted of post-transplant cyclophosphamide with or without calcineurin inhibitor and MMF. GVHD prophylaxis for the MSD group contained calcineurin inhibitor based approaches. The cumulative incidence of grade II-IV acute GVHD was similar between the two cohorts (27% in haploidentical cohort vs 25% in MSD cohort, $P = 0.84$). Cumulative incidence of chronic GVHD was significantly lower with haploidentical HSCT (12% vs 45%, $P < 0.001$). Chronic GVHD was the main cause of death in 5 patients in MSD cohort. There was no significant difference in the three-year cumulative incidence of relapse (37% in haploidentical vs 40% in MSD, $P = 0.51$), DFS (48% vs 48%, $P = 0.96$) and OS (61% vs 62%, $P = 0.82$). Therefore, based on this retrospective registry study in patients with lymphoma, RIC haploidentical HSCT using post-transplant cyclophosphamide provides comparable survival outcome to MSD HSCT with significantly lower risk of chronic GVHD.

CONCLUSION

HSCT is the only curative option for a large number of hematologic diseases. A minority of patients (30%) have a suitable HLA-identical sibling donor. For patients who lack MSD, MUD HSCT is frequently the preferred graft source.

However, the presence of a suitably matched unrelated donor depends on factors such as the ethnicity of the patient, with a likelihood of finding an acceptably matched unrelated donor less than 20% in certain minorities compared to approximately 80% in Caucasians. A major disadvantage of MUD transplant is the prolonged time from patient referral to donor identification and collection of stem cells. Delay in the process of unrelated donor search due to logistical issues may increase the risk of disease progression or relapse^[68]. Immediate availability of a haploidentical donor makes this approach an attractive treatment option for patients who lack an HLA-identical MSD or those for whom a MUD cannot be found in a timely manner. The field of haploidentical HSCT has matured significantly over the past two decades. In earlier studies of haploidentical HSCT, HLA-incompatibility barrier resulted in unacceptably high rate of GVHD and graft rejection leading to inferior OS. While effective T-cell depletion followed by infusion of mega doses of highly purified stem cells permitted high engraftment rates and reduced incidence of GVHD, higher risk of relapse and delay in immune reconstitution remained a significant obstacle. Newer methods of graft manipulation including adoptive T-cell immunotherapy and selective T-cell depletion have been shown to hasten immune recovery and reduce the risk of relapse. Despite the promising results, these approaches are costly and labor intensive, hence may not be globally available. In recent years, use of post-transplantation cyclophosphamide for GVHD prophylaxis after T-cell replete haploidentical HSCT has yielded encouraging results in adults. In several non-randomized studies, survival outcomes following haploidentical HSCT with post-transplant cyclophosphamide have been comparable to MSD or MUD transplant. Ultimately, a prospective randomized controlled trial such as BMT CTN 1101 is needed to determine the optimal approach to haploidentical transplant.

Abstract

Solid tumors in adults constitute a heterogeneous group of malignancy originating from various organ systems. Solid tumors are not completely curable by chemotherapy, even though some subgroups are very chemo-sensitive. Recently, oncologists have focused on the use of allogeneic hematopoietic stem cell transplantation (allo-HSCT) with reduced intensity conditioning (RIC) for the treatment of some refractory solid tumors. After the demonstration of allogeneic graft-versus-leukemia effect in patients with hematological malignancies who received allo-HSCT, investigators evaluated this effect in patients with refractory metastatic solid tumors. According to data from experimental animal models and preliminary clinical trials, a graft-versus-tumor (GvT) effect may also be observed in the treatment of some solid tumors (*e.g.*, renal cell cancer, colorectal cancer, *etc.*) after allo-HSCT with RIC. The use of RIC regimens offers an opportunity of achieving full-donor engraftment with GvT effect, as well as, a reduced transplant-related mortality. Current literature suggests that allo-HSCT with RIC might become a choice for elderly and medically fragile patients with refractory metastatic solid tumors.

Key words: Renal cell carcinoma; Allogeneic hematopoietic stem cell transplantation; Colorectal cancer; Ovarian cancer; Sarcoma

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Some refractory metastatic solid tumors including renal, ovarian and even colon cancers may respond well to allogeneic hematopoietic stem cell transplantation (allo-HSCT) with reduced intensity

conditioning (RIC). Their lower toxicity profiles and lower non-relapse mortality rates constitute the advantages of RIC. The use of allo-HSCT with RIC or non-myeloablative regimens can be a feasible option among fragile patients, such as geriatric patients and patients with comorbidities. Future studies are needed for a clear-cut understanding of the mechanisms of graft-versus-leukemia and graft-versus-tumor effects of donor T-cells and their subsets in order to optimize the efficacy of such treatment modalities in patients with refractory solid tumors.

Review of allogeneic hematopoietic stem cell transplantation with reduced intensity conditioning in solid tumors excluding breast cancer. *World J Transplant* 2016; 6(4): 675-681 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/675.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.675>

INTRODUCTION

Allogeneic hematopoietic stem cell transplantation (allo-HSCT) is primarily used in patients with relapsed or high-risk hematologic malignancies and the efficacy of this treatment has been substantially demonstrated. The first allo-HSCT in the literature in a patient with a solid tumor was published in late 90s^[1]. The principles of allo-HSCT consist of maximal tumor cytoreduction with high-dose chemoradiotherapy and adequate immunosuppression in order to provide engraftment of donor stem cells, as well as graft-versus-tumor (GvT) effect^[2]. Studies investigating high dose chemotherapy with autologous stem cell rescue in patients with solid tumors yielded controversial and disappointing results^[3-7]. This has led to the development of novel approaches, including allo-HSCT with reduced intensity conditioning (RIC) regimens, which aim to create and take advantage of a GvT effect in order to induce more durable responses^[1,2,8-10]. Today, types of conditioning regimens that are used prior to allo-HSCT include myeloablative (MA), RIC and non-myeloablative (NMA) regimens. MA regimens lead to irreversible cytopenia and therefore, stem cell support is needed. In contrast, NMA regimens cause minimal cytopenia and can be given without stem cell support. RIC regimens do not completely fit in the criteria for MA and NMA regimens. The marrow aplasia is reversible; however, stem cell support is mandatory.

NMA/RIC regimens for allo-HSCT have introduced a new era for treating elderly and those with comorbidities^[11-13]. The RIC regimens are currently being used for as much as 40% of all allo-HSCTs and becoming increasingly popular. The growing knowledge on the immune system and T-cell biology has made allo-HSCT a promising approach for the treatment of some solid tumors. Several phase I and II studies, which were conducted by the European Society for Blood and Marrow

Transplantation Solid Tumors Working Party (EMBT-STWP) documented the presence of a GvT effect in patients with various solid tumors, such as renal, ovarian and colon cancers and soft tissue sarcomas^[2].

This novel strategy provides a switch from a chemotherapy-based to an immunotherapy-based approach^[14]. Replacing conventional MA regimens with NMA/RIC regimens prior to allo-HSCT has two main goals: (1) to diminish the high transplant-related morbidity and mortality^[15-19]; and (2) to induce allo-reactivity against the metastatic solid tumor *via* a GvT effect^[1,12].

The successful engraftment rates together with a lower transplant related mortality (TRM) and the presence of GvT effect made allo-HSCT with RIC an attractive option for the treatment of several solid tumors within the last decade^[20-24]. The lower toxicity obtained by the reduction of chemoradiotherapy dose also enables allo-HSCT with RIC to become a choice for the elderly and medically fragile patients with metastatic solid tumors^[1,12]. This review briefly describes the background, rationale, and clinical results of allo-HSCT with RIC as an immune-based strategy *via* GvT effect for the treatment of some metastatic solid tumors, including renal cell carcinoma (RCC), metastatic colorectal cancer (mCRC) and ovarian cancer.

CYTOTOXIC ADOPTIVE T-CELL THERAPY

Advances in systemic therapy for metastatic cancer have focused on important cellular pathways with critical roles in cancer development and progression^[25]. Although a dramatic success is obtained in the minority of patients, this approach provides a relatively short-term benefit in the majority and exposes them to chronic toxicities, including cardiac and dermal toxicities and thus, is not cost-effective^[26].

The mechanisms during the evasion of adoptive immune system by tumor cells have been described as growth, angiogenesis and tissue remodeling. During this process, the tumor cells also exploit the innate inflammatory response. Besides these mechanisms, the role of tumor microenvironment is also regarded as a new target for therapy^[27]. Advances in understanding of cancer immunology and especially the role of the adoptive immune system, have identified new targets for the treatment of solid tumors^[27].

The term, adoptive T-cell therapy (ATCT), involves the expansion of cytotoxic immune effector cells. It may be either specific or non-specific^[25]. The GvT effect and tumor response after allo-HSCT with RIC may be regarded as a non-specific ATCT, as it involves leukocyte-activated killer cells (LAKs) and cytokine-induced killer cells (CIKs), which are described and discussed in this paper. ATCT is not yet considered as a standard treatment modality in the medical oncology practice. However, it is considered as the most potent immunotherapeutic approach according to the results of some early phase trials^[27].

GVT EFFECT

The effect of immune system in inducing tumor regression is well-described. Graft-versus-host disease (GvHD) that occurs after allo-HSCT contributes to and maintains an anti-leukemic effect^[28]. Thus, it is referred as graft-versus-leukemia (GvL) effect. This effect was first demonstrated with the eradication of leukemia in mice receiving non-syngeneic allogeneic transplant after irradiation^[29]. Since then, several direct and indirect evidences of GvL effect after allo-HSCT have been reported. The GvL effect is generally associated with GvHD^[30]. A stronger GvL effect is observed in chronic GvHD than in acute GvHD^[31]. The probability of being in remission is also higher in patients with GvHD when compared to patients without GvHD^[32]. Other strong evidences for the presence of an immune-mediated GvL effect are the significantly increased relapse risk in patients receiving T-cell depleted transplants and the lower risk of relapse observed in patients undergoing allo-HSCT rather than autologous HSCT^[2,33-36]. The direct evidence of GvL effect comes from the studies reporting that donor lymphocyte infusions (DLI) given after transplant might augment the GvL effect of allo-HSCT and DLI infusion without cytotoxic therapy might induce and maintain remission in patients who relapse after allo-HSCT^[37-40].

The GvL effect, which eradicates malignant cells *via* fas-dependent killing and perforin degranulation, is mediated by donor T cells (CD4⁺, CD8⁺ and natural killer - NK-cells)^[41,42]. The major cytokines that potentiate the GvL effect include interleukin-2 (IL-2), interferon- γ and tumor necrosis factor- α ^[43]. Post-transplant adoptive therapy with cytotoxic T-lymphocytes (CTLs) against human cancer-associated antigens, minor histocompatibility antigens (e.g., HA-1, HA-3, etc.) or T-cell receptor genes may be used to induce anti-tumor effects^[44]. The development of acute and chronic GvHD has been linked to a better response to therapy in solid tumors^[2]. Identification of antigen targets of GvT and development of targeted therapies may further improve the immune effect of allo-HSCT for solid tumors and reduce the treatment toxicity^[2].

Allo-HSCT is an immuno-modulatory therapy aiming at exploiting a GvT effect. However, it has to be emphasized that a delicate balance between effective immuno-suppression, GvHD and relapse should still be considered.

Allo-HSCT with RIC in renal cell carcinoma

RCC is a common malignancy diagnosed in patients older than 50 years of age and almost one third of cases are metastatic at the time of diagnosis^[45]. Despite various treatment strategies including hormonal therapy, chemotherapy and immunotherapy, the prognosis of metastatic RCC is extremely poor with a median survival of 10 mo and a 5-year survival of less than 5%^[46,47]. RCC is sensitive to immunotherapy. Interferon- α with or without IL-2 (especially at high doses) have been widely used. However, the rates of response (10%-20%) and long-term progression-free survival (4%-15%) are still

unsatisfactory^[48-50]. Allo-HSCT with RIC is considered as a promising option in this setting^[11,13].

A response rate of 53% has been reported in the first series of allo-HSCT with NMA conditioning for cytokine-refractory RCC^[11]. Another trial included 75 metastatic RCC patients and reported a sustained engraftment in 74 out of 75 patients after allo-HSCT with NMA conditioning^[51]. In this study, chronic GvHD was observed in 50% and was associated with a significant tumor response.

The largest series of allo-HSCT with NMA conditioning in RCC patients was published by the EBMT-STWP, in which a fludarabine-based conditioning regimen was administered to all 124 patients prior to peripheral blood allo-HSCT^[52]. Engraftment failure was observed in 2.4%. TRM at the end of first year was 16% and associated mostly with acute GvHD. A response rate of 22.5% was achieved including complete response in 4 patients at a median of 150 (42-600) dpost-transplant.

Nowadays, patient selection for allo-HSCT has become an important issue, since disease progression after transplantation is more frequent among patients with rapidly progressive tumors. In order to determine which patients benefit most from allo-HSCT, 70 patients who underwent allo-HSCT were evaluated according to pre-transplant characteristics, such as performance status, C-reactive protein and lactate dehydrogenase levels in a study conducted by EBMT. This study suggested that these parameters could be used to stratify patients with advanced RCC who are candidates for allo-HSCT and to assist clinicians in decision-making and selection of an appropriate treatment program. As a result the patients with good prognostic criteria had a longer median survival than those with poor prognostic criteria, 23 mo vs 3.5 mo, respectively^[45]. Another study reported a higher response rate in the presence of an early transplantation, HLA-mismatched donors, higher Karnofsky score, lower number of metastatic sites and limited chronic GvHD^[52]. Currently, some other scoring systems are also developed for predicting survival in previously treated RCC patients^[46].

In conclusion, NMA conditioning followed by allo-HSCT in patients with RCC is feasible and it might prolong survival, especially in patients with favorable prognostic characteristics.

Allo-HSCT with RIC in colorectal cancer

Inoperable metastatic colorectal cancer (mCRC) is an incurable disease. Despite advances in therapy, median survival with fluorouracil-leucovorin, irinotecan, and oxaliplatin as first-line therapy is 18 to 22 mo and in case of resistance to these agents, the median survival declines 9 to 12 mo with second-line chemotherapy^[53,54]. Combination of chemotherapy with monoclonal antibodies such as cetuximab or bevacizumab improves remission rates and survival; however, long-lasting remission usually cannot be achieved, especially in the presence of resistant disease^[55,56].

Allo-HSCT following RIC has emerged as a novel

immunotherapy-based therapeutic strategy for the management of mCRC^[15,57,58]. In a study including six advanced mCRC patients, one complete response and one mixed response, including regression of lung and lymph-node metastasis and progression of liver metastasis were obtained^[59]. In a multicenter EBMT trial, among 39 patients with progressive mCRC overall disease control was achieved in 18 (46%) and 1 complete (2%), 7 partial (18%), and 10 stable disease responses (26%) were reported after allo-HSCT^[60]. Allo-HSCT with RIC might be an alternative to conventional strategies, especially in young patients with refractory mCRC.

Allo-HSCT with RIC in ovarian cancer

Ovarian cancer (OC) is the most fatal gynecologic malignancy and the fifth-leading cause of death among women in the developed countries^[61]. Despite extensive surgery and use of new generation drugs such as taxanes (mostly in combination with carboplatin), relapse rates may reach up to 50%. Although sensitive to high-dose chemotherapy (especially based on carboplatin combinations), the median overall survival is about 2 years for relapsing disease^[62,63]. The only benefit of high-dose chemotherapy does appear to be delayed relapse^[64,65].

In a study, including five refractory OC patients who underwent allo-HSCT with RIC, tumor regression were observed in four patients during acute or chronic GvHD and relapse occurred in one patient treated with methylprednisolone for chronic GvHD^[66]. A retrospective study from the EBMT-STWP database included 17 heavily pre-treated OC patients and mortality was reported in 11 patients, 8 of which were due to tumor progression at a median follow-up of 296 d (5-1599)^[67]. Grade 2-4 acute GvHD was reported in eight patients, seven (41%) of which had a partial response. Tumor regression was achieved in one out of three patients who received DLI. This data supports the existence of a graft-versus-ovarian cancer effect in correlation with GvHD. In another retrospective multicenter study with 30 allografted OC patients, objective response was observed in 50% and TRM was 20% at the end of first year^[68]. The median overall survival was 10.4 mo with a median follow-up of 74.5 mo (16-148). Overall survival was significantly higher among patients with chronic GvHD (17.6 mo vs 6.5 mo, $P < 0.05$).

Allo-HSCT with RIC for OC could be a feasible treatment option. However, supporting data are limited.

Allo-HSCT with RIC in soft tissue sarcomas

Soft tissue sarcomas (STS) constitute a rare and heterogeneous group of malignant tumors, which include less than 1 percent of all adult malignancies. Prognosis of STS is poor with a median survival of about 1 year with conventional treatments^[69].

In experimental animal models of allogeneic transplantation, immune-mediated effect against sarcoma has been shown^[70,71]. However, reports on STS treated with allo-HSCT mostly consist of single case reports and small series of patients from HLA-matched sibling donors.

Although some authors have reported the evidence of a graft-vs-sarcoma effect, no evidence of cancer regression following allo-HSCT with RIC regimens were reported among patients with various histologic subtypes^[72-74]. In a retrospective study, 14 adult patients from EBMT database with advanced STS received allo-HSCT with RIC for chemo-refractory disease, excluding rhabdomyosarcoma (most frequently a pediatric disease with an extremely different natural history) and they were assessed regarding whether a GvT effect could be generated in this setting. TRM was reported in two patients and progressive disease was observed in eight patients. Four patients experienced long-lasting disease stabilization following allo-HSCT. Authors concluded that an immune-mediated effect cannot be excluded in some STS^[75].

In conclusion, allo-HSCT with RIC may give rise to some degree of significant responses in some refractory metastatic solid tumors, such as renal, ovarian and even colon cancers. The advantages of RIC regimens are their lower toxicity profiles and lower non-relapse mortality rates. Allo-HSCT with RIC or NMA can be a feasible option for geriatric patients and patients with comorbidities. Future studies are needed for a clear-cut understanding of the mechanisms of GvL and GvT effects of donor T-cells and their subsets in order to optimize the efficacy of such treatment modalities in patients with refractory solid tumors.

Abstract

The risk of contrast-induced nephropathy (CIN) in renal transplant recipients is increased in diabetics, patients with impaired basal kidney function, patients in shock, patients presenting with acute emergency and in old age recipients. Approximately one-third of all hospitalized patients with acute kidney injury is attributed to CIN. In the United States, it is the third leading cause of hospital-acquired renal failure. Therefore, efforts should be directed to minimize CIN-related morbidity and mortality as well as to shorten hospital stay. While the role of peri-procedural prophylactic hydration with saline is unequivocal; the use of acetyl cysteine is not based on robust evidence. The utility of theophylline, aminophylline, calcium channel blockers, natriuretic peptide, and diuretics does not have proven role in attenuating CIN incidence. We aim to analyze the evidence for using various protocols in published literature to limit CIN-associated morbidity and mortality, particularly during surveillance of the renal allograft survival.

Core tip: The renal transplant is usually a solitary kidney with diverse hemodynamic changes and exposed to the immunosuppressive agents for a long period. Any superadded stress such as contrast-induced nephropathy (CIN), will definitely affect allograft function. We provide in this article a comprehensive review of the current evidence on the true incidence, the mechanism of damage induced by CIN and available preventive measures to counteract the possible effect induced by CIN.

INTRODUCTION

Perioperative transplant complications are reported to involve about 15%-20% of the kidney transplant recipients. Diagnostic ultrasound (US) is the most common and first line imaging modality^[1], since it is safe, noninvasive, gives a rapid diagnosis and also a portable tool for many surgical emergencies requiring bedside imaging^[2-5]. The utility of ultrasonography in management of hydronephrosis, renal masses, renal artery stenosis (RAS) and pyelonephritis in renal allograft is well documented^[1].

Computed tomography (CT) scanning and CT-guided interventions play a vital role in investigating post-operative complications. Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) can be used safely where there is renal dysfunction, since the "Gadolinium-based" contrast media can be safely used with minimal nephrotoxic effects. Post-transplant complications such as vessel thrombosis can also be assessed using these modalities. Allograft "morphology and function" can be effectively assessed by using intravenous Gadopentetate Dimeglumine (DTPA) to the MRA technique^[6].

However, the patients with pacemakers, aneurysmal clips, or evident claustrophobia cannot be safely exposed to MRI studies. Gadolinium-based media have been linked to the development of nephrogenic systemic fibrosis (NSF). Another drawback of MRI, is the "layering" of the excreted gadolinium in the urinary bladder causing multiple image artifacts. Alternatively, CT is better for the evaluation of the kidney and urinary bladder for renal stones and ureter and bladder abnormalities. To summarize, MRI is usually dedicated to the evaluation of transplant recipient, whereas CT and CT angiogram are reserved for potential donors^[6].

MECHANISM OF CONTRAST-INDUCED NEPHROPATHY

Vasoconstriction induced by the contrast media (CM) can be explained by the direct action of contrast media on vascular smooth muscle and from metabolites such as adenosine and endothelin. Moreover, the osmotic criteria of contrast media, especially in the tubular lumen, affects water reabsorption, leading to a magnifying interstitial pressure. This will be augmented by the increased salt and water load to the distal tubules, will decrease GFR and lead to local compression of the vasa recta. All these factors will aggravate medullary hypoxemia and renal vasoconstriction in an already volume depleted patient.

Finally, contrast media could increase resistance to blood flow by increasing its viscosity and by deranging red blood cells (RBCs) deformability. These manifest as local ischemia leading to activation of reactive oxygen species that result in damage to renal tubules^[7].

Up till now, we are sure why renal failure patients are sensitive to contrast utilization. Whether their primary disease is a contributing factor or not, this has to be elucidated by additional future research.

CONTRAST NEPHROPATHY IN RENAL TRANSPLANTATION

Intravenous contrast (Table 1)

Only a relatively handful of studies have looked into the contrast-induced nephropathy (CIN) in the renal transplant recipients. Light *et al*^[8], 1975 studied thirty-four renal transplant recipients received drip infusion urograms post-transplantation. Twenty-two patients exhibited a change in renal function within 1-4 d of the urogram that was indistinguishable from allograft rejection that is a tender swollen kidney, a rise in serum creatinine, oliguria, diminished urinary sodium, weight gain and hypertension. Two patients developed acute tubular necrosis (ATN) and required hemodialysis, but renal function in the remaining 20 patients improved after therapy for "graft rejection" with intravenous methylprednisolone sodium succinate. Kidneys from older-age donors that were functioning sub-optimally at transplant and kidneys, which exhibited subsequent clinical allograft rejection, were more at risk for CIN. These suggested occult vascular lesions might have been present in the allograft, which was exacerbated when exposed to the irritant vascular effects of contrast media, producing a mild, reversible toxic nephritis. However, several renal grafts with normal function and also those, which never exhibited rejection activity, were also adversely affected by exposure to contrast media. Therefore these agents should be used cautiously, if at all, in the early post-transplant period^[8]. CIN was more common and more severe in those with impaired kidney function. This study also found that kidneys from older donors were at higher risk for CIN. In this study, contrast was used before stable creatinine was achieved, these kidney transplant recipients were not on a CNI, and there is no mention of use of any prophylaxis to prevent CIN. More than half of these patients were thought to have acute rejection and were treated as such without consistent biopsy documentation^[8].

The incidence of acute kidney injury (AKI) induced by CIN resulting from direct exposure to contrast media in kidney transplants recipients still controversial. The main insult is the ensuing vasoconstriction of the afferent glomerular arterioles and reduction in renal blood flow and glomerular filtration rate. Renal vasoconstriction, as well as direct tubular epithelial toxicity, is the two major mechanisms by which contrast causes AKI as explained by Haider *et al*^[9] in 2015. Immediately after contrast

Table 1 Trials concerned with contrast nephropathy

No.	Trial	Year	No. of KTRs	Need for HDX	CIN	Comments
1	Light <i>et al</i> ^[8]	1975	34	Two	22	20 patients improved after therapy for "graft rejection"
2	Moreau <i>et al</i> ^[12]	1975	231	None	Nil	No increase in risk of CIN in KTRs if contrast studies were performed with normal renal function
3	Peters <i>et al</i> ^[11]	1983	93	None	Very high (84.3%)	No increased risk was found > 120 d post-transplant
4	Ahuja <i>et al</i> ^[10]	2000	35	None	> 21%	Patients received high osmolality contrast, and 94% were on CyA therapy
5	Charnow <i>et al</i> ^[16]	2015	76	None	> 13.2%	CIN did not affect allograft function and survival, according to the researchers
6	Haider <i>et al</i> ^[9]	2015	124	None	5.60%	The largest retrospective study evaluating incidence of CIN in KTRs. CNIs were being used in 95% patients at the time of contrast administration
7	Bostock <i>et al</i> ^[15]	2016	40	One	12.50%	Renal dysfunction is 3 times more frequent in KTR treated with EVAR, though overall survival did not differ between groups. Decreased pre-operative eGFR and higher iodine/eGFR ratio are associated with post-operative renal dysfunction
8	Fananapazir <i>et al</i> ^[14]	2016	104	None	7% and 3%	Incidence of CNI = 7% (7/104) based on a rise of ≥ 0.3 mg/dL and 3% (3/104) based on a rise of ≥ 0.5 mg/dL. With a strict definition (≥ 0.5 mg/dL) had a pre-CT eGFR < 60 mL/min per 1.73 m ² . No patients required DX or had allograft loss 30 d after contrast use

CIN: Contrast-induced nephropathy; HDX: Hemodialysis; KTRs: Kidney transplant recipients; CNIs: Calcineurin inhibitors; EVAR: Endovascular aortic aneurysm repair; eGFR: Estimated glomerular filtration rate.

use, there is a transient increase in renal blood flow followed by a prolonged reduction in flow resulting in renal ischemia. So, there is "clustering" of two risk factors here, as both calcineurin inhibitors and IV contrast cause renal ischemia by the dual mechanism: (1) by increasing the release of the vasoconstrictors such as endothelin; and (2) by blocking the release of vasodilators including prostaglandins and nitric oxide^[10].

Ahuja *et al*^[10] (2000) also studied 35 kidney transplantation recipients (KTRs) as regard the effect of "volume expansion" as well as the effect of cyclosporine therapy; which documented the presence of CIN in a percentage exceeding 21%, with incidence of CIN was about 15% in patients received volume expansion and exceeds 42% in those who did not. None of these patients had AKI requiring dialysis. In this study, two main insults were reported, first: They received "high osmolality" contrast, and second: 94% were on cyclosporine therapy. The baseline serum creatinine in patients with and without CIN was 1.54 ± 0.17 mg/dL and 1.97 ± 0.20 mg/dL, respectively, $P = 0.15$, but the volume of contrast was not reported here. Another study- demonstrated by Peters *et al*^[11] in 1983-reported a very high incidence of CIN (84.3%) in the early post-transplant period, but no increased risk was found > 120 d post-transplant.

Moreau *et al*^[12] (1975) demonstrated clear evidence that there was no increase in the risk of CIN in kidney transplant recipients if contrast studies were performed against a background of normal renal function. Data observed from these studies showed that older donor kidney, early post-transplant period, impaired baseline kidney function, and lack of prophylactic volume expansion, appear to be important risk factors for increasing the incidence of CIN in kidney transplant recipients (Figure 1). In fact, a direct comparison between these studies regarding the incidence

of CIN among is challenging, as the definition of AKI used was not uniform. There were differences in baseline serum creatinine; use of hyper-, hypo-, or iso-osmolar contrast; volume of contrast given; and the proportion of patients with known risk factors for CIN, including: Diabetes Mellitus, congestive heart failure, and concomitant use of CNI, in these studies which make it difficult to conclude the actual incidence of CIN in kidney transplant recipients.

To date, Haider *et al*^[9] (2015) study is considered the largest retrospective study evaluating the incidence of CIN in kidney transplantation. The incidence of CIN in this study was low (5.6%), much lower than reported by Ahuja *et al*^[10] (2000). Two fundamental factors were implicated in this low incidence of CIN in this landmark study first: the relatively elevated baseline eGFR (> 70 mL/min per 1.73 m²) and second: The use of "hypo-osmolar" contrast applied in this procedure^[9].

Another possible explanation for the low incidence of CIN in this study is that Diabetes Mellitus and hypertension in these patients may not have damaged the renal allograft to the extent to potentiate CIN. Another important factor is the age of the kidney rather than the age of recipient may affect the susceptibility for CIN. Furthermore, among all procedures utilizing iodine-based contrast, coronary angiography with the percutaneous intervention was responsible for 49% of cases of CIN^[13]. However in Haider *et al*^[9] (2015) work, only 4.8% of patients have had cardiac catheterization (none of them had CIN), and this might also have leading to low incidence of CIN-AKI in this group of patients. Their inability to identify association with known risk factors for CIN may be explained by the very small number of patients complicated by CIN events.

On the other hand, Fananapazir *et al*^[14], 2016, declared in the most recent trial that CIN incidence was very low,

Incidence of CIN after kidney transplant

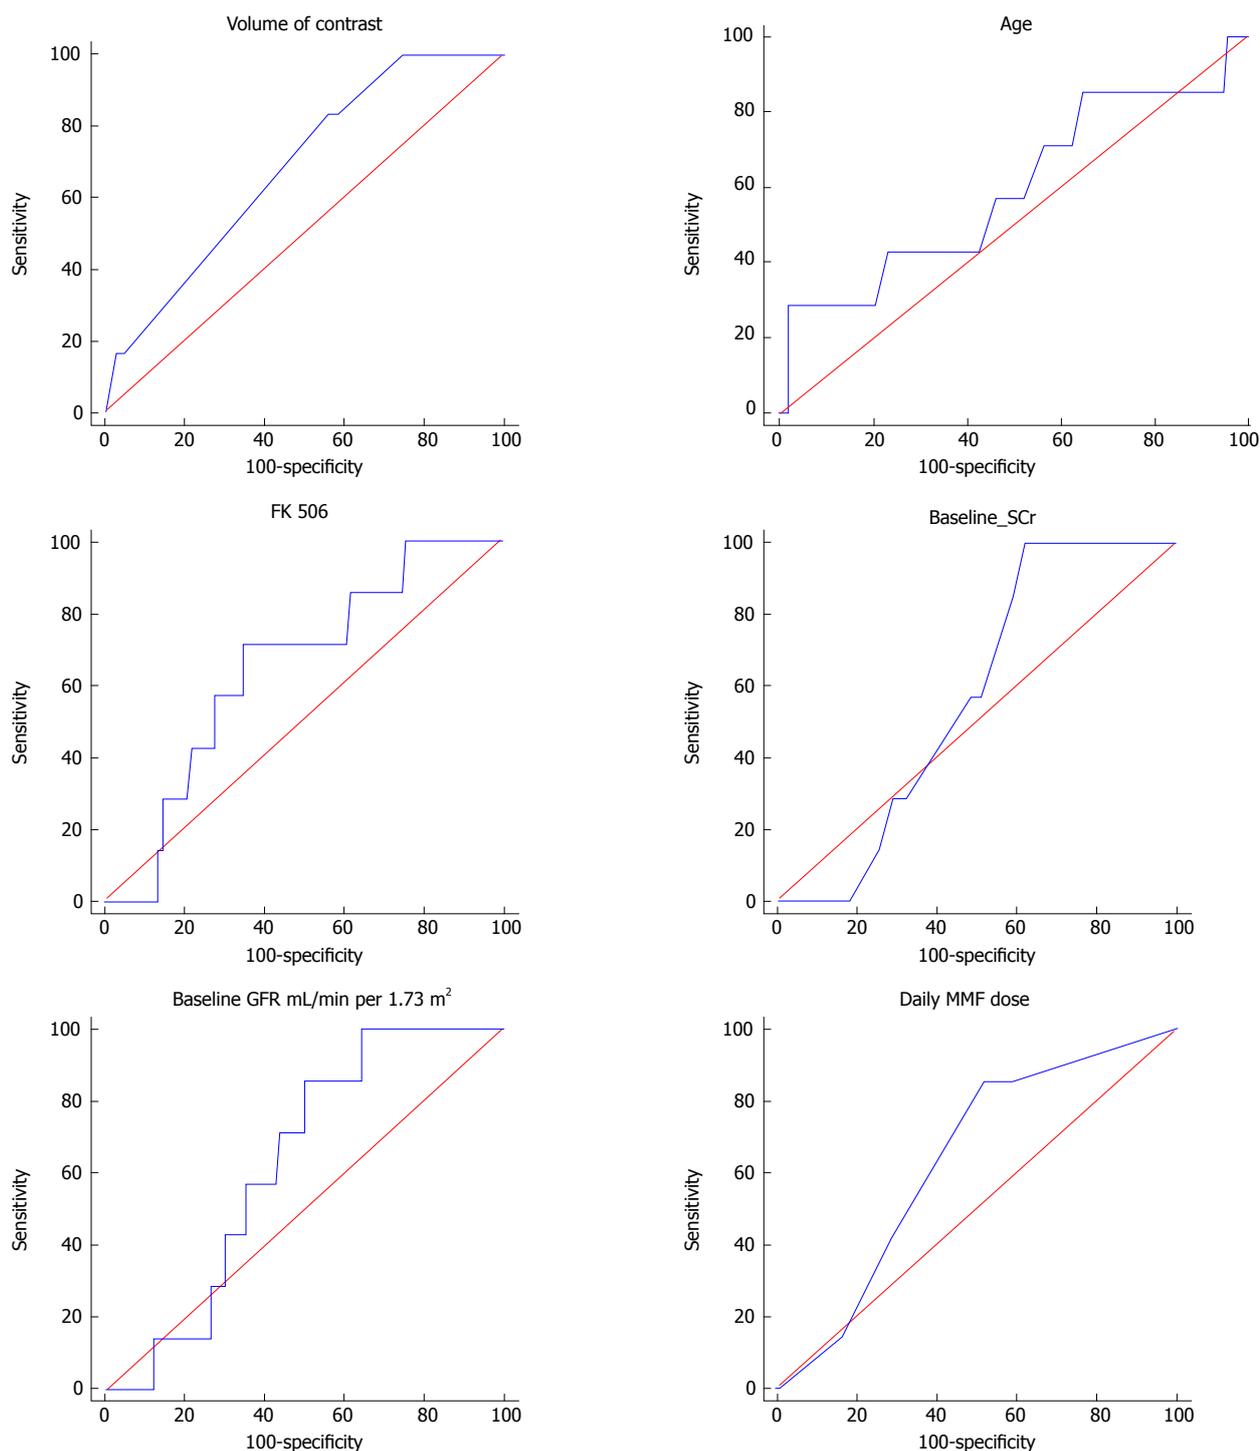

Figure 1 Receiver operating characteristics curves for age, FK506 levels, daily Cellcept dose, baseline Cr., eGFR, and volume of IV contrast. Area under the curve (AUC) for age, FK506 levels, daily Cellcept dose, baseline creatinine, eGFR, and volume of IV contrast were 0.60, 0.64, 0.63, 0.57, 0.63, and 0.68, respectively^[9]. Adapted from Haider *et al*^[9], Incidence of Contrast-induced Nephropathy in Kidney Transplant Recipients. *Transplantation Proceedings* 2015; **47**: 2379-2383 (with permission). GFR: Glomerular filtration rate.

i.e., 7% and 3% according to an elevation of SCr of > 0.3 and 0.5 respectively, after a low osmolality contrast administration. There was with no need for emergent dialysis or an allograft loss 30 d post-operative^[14].

Moreover, Bostock *et al*^[15] in 2016, also demonstrated that CIN following endovascular aortic aneurysm repair

(EVAR) in kidney transplant recipients could have de-raging sequelae. The Vascular Quality Initiative (VQI) database was interrogated to select all kidney transplant recipients who underwent EVAR between 01/2003 and 12/2014. Their primary outcome was renal dysfunction, defined as AKI (rise in serum creatinine concentration

> 0.5 mg/dL above the baseline or new post-operative hemodialysis requirement). Within the EVAR VQI dataset, 40 subjects were kidney transplant recipients (40/17, 213, 0.2%). Renal dysfunction occurred in 5/40 patients in the kidney transplant recipients group in comparison to 779/17173 patients in the non-transplanted group (12.5% vs 4.5%, $P < 0.01$). Emergency EVAR was indicated in 2 (5%) patients who required hemodialysis after surgery and died later. One-year survival after EVAR was similar in both groups (92.9% vs 93.1%, $P = 0.73$). Kidney transplant recipients who developed renal dysfunction had significantly lower pre-operative eGFR's (29.5 vs 54.7, $P = 0.007$) and a significantly higher iodine/eGFR ratio (0.78 vs 0.39, $P = 0.02$) despite receiving a similar volume of contrast (70.0 vs 68.8, $P = 0.97$). Renal impairment was three times more frequent in kidney transplant recipients treated with EVAR, despite the overall survival did not differ between groups. Diminished pre-operative eGFR and a higher iodine/eGFR ratio were associated with post-operative renal dysfunction^[15]. Charnow *et al*^[16] 2015, showed an incidence about 13% of CIN in allograft recipients undergoing CT or cardiac catheterization with contrast media. CIN was relatively common in kidney transplant recipients undergoing (CT) or cardiac catheterization with contrast media. Charnow *et al*^[16] (2015) at the University of Cincinnati in Ohio studied 76 contrast exposures (45 CT scans and 31 catheterizations) in 50 kidney transplant recipients (50% male) with a mean age of 53.3 years and means. Cr level of 1.46 mg/dL. The investigators reported CIN - defined as a rise in s. Cr by > 0.3 mg/dL or 25% from baseline within 4 d. after the procedure - in 10 of 76 procedures (13.2%). Results demonstrated: 6 (13.3%) of the 45 CT scans and 4 (12.9%) of the 31 catheterizations resulted in CIN^[16].

Abu Jawdeh's group (2015)^[16] also examined the risk factors for CIN. In a multivariate model, exposure to N-acetylcysteine (NAC) and a lower hemoglobin level was significantly associated with an increased risk of CIN, but not with CNI use. They assumed that NAC might have been used in high-risk subjects for CIN, a bias that could explain the increased risk of CIN associated with NAC use. At the last follow-up, CIN did not affect allograft function and survival, according to the investigator^[16].

CIN is accompanied by a significant rise in mortality and morbidity; Abu Jawdeh suggested that extrapolation of knowledge about CIN affecting the native kidneys and applying this to allografts might not necessarily reflect the best practice. Allografts are solitary kidneys that exposed to significant hemodynamic alterations and also under the effect of lifelong immuno-suppressive agents. Both these factors might affect susceptibility to contrast-induced renal injury. They also suggested that CIN is potentially modifiable if risk factors are well identified and the proper preventive precautions are performed. The 13.3% incidence of CIN identified in this study is consistent with previous studies looking at native kidneys^[16]. Due to the retrospective nature of

this study and the small sample size, this study should be interpreted with caution.

Finally, it appears that the strict "definition of CIN" in various studies was not universal. While Charnow *et al*^[16] defined CIN as a rise in s. Cr by > 0.3 mg/dL or 25% rise from baseline within four days of contrast exposure, Bostock *et al*^[15] defined CIN as an AKI with elevation of SCr > 0.5 mg/dL from baseline, or new post-operative hemodialysis (HD) requirement%. Haider *et al*^[9] (2015) defined CIN as either an absolute rise in serum creatinine of ≥ 0.5 mg/dL or a $\geq 25\%$ drop in estimated glomerular filtration rate (eGFR) after contrast administration. On the other hand Fananapazir *et al*^[14] (2016) applied two definitions for CIN in the most recent study, they found CIN in 7% based on a rise of ≥ 0.3 mg/dL and 3% based on a rise of ≥ 0.5 mg/dL. Patients with the more strict definition (≥ 0.5 mg/dL) had a pre-contrast eGFR < 60 mL/min per 1.73 m².

"Ultrasound with contrast": Contrast enhanced ultrasound (CEUS) is a promising radiological technique with increased popularity. It has a superiority over the color Doppler ultrasound in evaluation of kidney microvasculature studies. A wide variety of diagnoses can be applied including differentiation of cystic from solid lesion, solid mass assessment, pseudotumor and RAS. Moreover, CEUS can help in elucidating the hemodynamic changes associated with chronic allograft nephropathy (CAN)^[17].

US contrasts are gas microbubbles of nearly the same size of RBCs, which enclosed in a protein, lipid or polymer shell^[18]. They last intravascular only for few minutes (time of CEUS examination), after that, the gas exhaled through the lungs and the shell metabolized by the liver^[19], so renal excretion is not a possibility. As these contrast agents is not excreted through the kidney, allograft integrity cannot be deranged. So, their use in KTRs with impaired renal function is completely safe. Furthermore, CEUS is the sole available technique for dynamic evaluation of kidney perfusion, particularly so, when the use of contrast media is mandatory in CT and MR studies in patients with renal dysfunction. CEUS has a wide safety margin in comparison with other radiological modalities^[20,21].

Prevention of CIN-induced AKI in the renal transplant recipient: There are no specific measures dedicated to prevent CIN-induced AKI in the renal allograft, but rather universal recommendations. The optimal recommendations for CIN prevention are still uncertain.

The following precautions are suggested with increased risk of CIN (S. creatinine ≥ 1.5 mg/dL (132 micromols/L) or an eGFR < 60 mL/1.73 m²), especially in diabetics: (1) Avoid volume depletion and NSAID^[22,23]; (2) Avoid use of high osmolar agents (1400-1800 mosmol/kg)^[24,25]; (3) Try to use US and MRI without gadolinium contrast, or CT scanning without contrast media when possible; (4) Choose iodixanol or nonionic low-osmolar

agents, *e.g.*, iopamidol or ioversol rather than iohexol^[25]; (5) Apply lower doses of contrast and avoid repetitive, closely spaced studies (< 48 h apart)^[12,13,15,16,25]; (6) In an absence of contraindications to volume expansion, start isotonic intravenous fluids before and continued several hours after contrast use. Optimal type and timing are not well documented. "Isotonic bicarbonate" is preferred to isotonic saline as a "volume expander"^[23,26-29]. "Isotonic bicarbonate" regimen: A bolus of 3 mL/kg for one hour prior to the procedure, and continued at a rate of 1 mL/kg per hour for "6" h after the procedure^[23,26-29]. Suggested regimen for isotonic saline: Isotonic saline (1 mL/kg per hour), starting at least 2-6 h before, and continued for 6-12 h after the procedure. Duration of intravenous fluid should be directly proportional to the degree of renal dysfunction (*i.e.*, longer duration for severe renal impairment); (7) Based upon potential benefit, low toxicity, and cost, Acetylcysteine (AC) can be given: 1200 mg orally twice/day, the day before and the day of the procedure. Intravenous AC is NOT recommended due to lack of evidence of benefit and potential risk of anaphylactoid reactions^[30,31]; and (8) Prophylactic use of "mannitol" or other diuretics is NOT recommended^[32,33]. Prophylactic HF/HDX after contrast exposure is NOT advised on stage 3 and 4 CKD^[34].

Oral contrasts

Two documented contrast media are already in use for oral imaging procedures: First: Barium sulphate, a commonly used oral contrast agent (for GI studies); Second: Gastrografin, which is a substitute agent for the barium in special situations. Generally, barium, as well as gastrografin, is safe, passing through the gastrointestinal tract easily like food and drink^[35].

Barium sulphate is by far the most common contrast material used orally. It can also be utilized rectally. Multiple forms are available, including powder, liquid, paste and tablets. They are generally safe. Only mild unpleasant taste can be observed. If given by enema, abdominal fullness, change in bowel habits and whitish discoloration may be observed for only a few days^[36].

Nephrostogram

A nephrostogram is a radiological tool performed to check the nephrostomy catheter and to rule out any abnormalities in the kidney and ureters, for example, obstructive uropathy. It is performed by disconnecting the catheter from its drainage bag and injecting the iodinated contrast through its lumen, monitored with fluoroscopy and static X-ray imaging. Nephrostogram is a very safe technique with few documented complications. Only mild pain with the possibility of the introduction of infection can occur. Unfortunately, this procedure has no known alternative technique^[37].

significant especially in diabetics, old age and in volume depleted subjects. This risk can be greatly mitigated through optimizing the hydration status in peri-procedure period, by avoiding nephrotoxic medications, by careful use of safe and widely spaced contrast media with the possible minimal amount of contrast media and possibly by prophylactic peri-procedural administration of isotonic bicarbonate. Some of the questions remain unanswered that require randomized controlled trials involving larger number of renal transplant recipients in order to maximize safety of the renal allograft.

Abstract

AIM

To analyze the clinical impact of preformed antiHLA-Cw vs antiHLA-A and/or -B donor-specific antibodies (DSA) in kidney transplantation.

METHODS

Retrospective study, comparing 12 patients transplanted with DSA exclusively antiHLA-Cw with 23 patients with preformed DSA antiHLA-A and/or B.

RESULTS

One year after transplantation there were no differences

in terms of acute rejection between the two groups (3 and 6 cases, respectively in the DSA-Cw and the DSA-A-B groups; $P = 1$). At one year, eGFR was not significantly different between groups (median 59 mL/min in DSA-Cw group, compared to median 51 mL/min in DSA-A-B group, $P = 0.192$). Moreover, kidney graft survival was similar between groups at 5-years (100% in DSA-Cw group vs 91% in DSA-A-B group, $P = 0.528$). The sole independent predictor of antibody mediated rejection (AMR) incidence was DSA strength (HR = 1.07 per 1000 increase in MFI, $P = 0.034$). AMR was associated with shortened graft survival at 5-years, with 75% and 100% grafts surviving in patients with or without AMR, respectively (Log-rank $P = 0.005$).

CONCLUSION

Our data indicate that DSA-Cw are associated with an identical risk of AMR and impact on graft function in comparison with "classical" class I DSA.

Key words: Donor-specific antibodies; Antibody-mediated rejection; Anti human leukocyte antigen class I ; AntiHLA-Cw antibodies; Graft survival; Solid-phase immunoassays

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The clinical importance of preformed antiHLA-Cw donor-specific antibodies (DSA) in kidney transplant patients remains controversial, so we performed a retrospective study comparing 12 patients with DSA exclusively antiHLA-Cw with 23 patients with preformed DSA antiHLA-A and/or B. Antibody-mediated rejection occurrence and graft survival frequency, respectively, at one and at five years of follow-up, were comparable between groups. Our data support a similar deleterious impact considering DSA-Cw or DSA-A/-B in terms of risk of AMR and impact on graft function.

INTRODUCTION

In kidney transplantation the presence of preexisting anti human leukocyte antigen (HLA) donor-specific antibodies (DSA) has impact on graft outcomes. Their presence is associated with an augmented risk of antibody-mediated rejection (AMR)^[1] and worst graft survival^[2].

Classically, antibodies against major HLA Class I (A and B) and Class II (DR and DQ) antigens are considered to be responsible for most cases of AMR. AntiHLA-Cw are considered less immunogenic when are paralleled

to other class I antiHLA antibodies, mainly due to minor HLA-Cw antigen expression on cell surface^[3]. Indeed, some studies found that the incidence of antiHLA-Cw antibodies in sensitized patients was lesser than that for HLA-A or HLA-B antibodies^[4-6].

However, the progress of additional sensitive assays that identify HLA antibodies, namely solid-phase immunoassays, demonstrated that HLA-C locus may induce an antibody reaction comparable to the other usually tested loci^[4,5,7,8]. In 2012, Ling *et al*^[5] showed that kidney transplantation in patients with isolated antiHLA-Cw antibodies was effective (no rejections occurred) when using induction treatment with anti-thymocyte globulin (ATG) and IVIG. Another study evaluated 22 patients with pretransplant DSA antiHLA-Cw in comparison with 88 patients allosensitized but with no detectable preformed DSA and concluded that they seem to be at superior risk for AMR occurrence^[9]. Recently, Bachelet *et al*^[10] in their retrospective and multicenter study showed that antiHLA-Cw DSA have the same effect on graft outcome as DSA against "classical" HLA loci (A, B, DR, DQ), suggesting that antiHLA-Cw should also be considered in transplant allocation procedures and in immunologic risk stratification of patients.

As this subject remains controversial, we decided to conduct a retrospective study in kidney transplant patients to investigate the clinical impact of preformed antiHLA-Cw DSA comparing them to DSA against the other HLA class I loci, namely antiHLA-A and/or B.

MATERIALS AND METHODS

Patients

From the database of our Histocompatibility Center 35 adults who received a kidney transplant since 2007 were identified as having pretransplant donor specific antibodies (DSA) exclusively antiHLA-A and/or -B or exclusively antiHLA-Cw. Twenty-three patients had DSA antiHLA-A and/or antiHLA-B: 6 with DSA antiHLA-A only; 11 with DSA antiHLA-B only and 6 with DSA antiHLA-A and -B. This group was designated DSA-A-B. Twelve patients had DSA exclusively antiHLA-Cw, and this group was designated DSA-Cw. The patients were all transplanted with a negative T- and B-cell cytotoxic crossmatch (standard NIH technique). The Institutional Review Board at Hospital Santo António, CHP approved this study.

AntiHLA antibody testing

Patients in the waiting list were examined for antiHLA IgG by multiplex microsphere based on Luminex X-map® Technology (LABScreen® Mixed kit, OneLambda, Canoga Park, CA, United States). The cut-off for positive samples was the Normalized Background (NBG) ratio advocated by the manufacturer and executed by the HLA fusion® software (One Lambda Inc.). To determinate the specificity of the HLA antibodies, single-antigen bead (SAB) assays (LabScreen Single Antigen Beads®, OneLambda, Canoga Park, CA) were executed in patients with a positive

screening, using the same pretransplant sera. The mean fluorescence intensity (MFI) was measured using LABScan™ 100 flow analyzer (Luminex®, Austin, TX, United States). The analysis was performed using HLA fusion® software (One Lambda Inc.) and a cut-off for a positive reaction were set in MFI value of ≥ 1000 .

Donor typing and crossmatch

Samples of all deceased donors were routinely typed before recipient selection in loci HLA-A*, B*, Cw* and DRB1* using polymerase chain reaction (PCR) amplification with specific sequence primers (SSP; Olerup SSP® low resolution HLA typing kits, Stockholm, Sweden). After donor HLA typing, using that information, a virtual crossmatch (virtual XM) was executed. The strength of each single DSA was based on the MFI of one SAB. In the case of several DSA against different HLA-antigens, we considered the cumulative strength of all DSA by adding the individual MFI values.

Immunosuppression

Thirty-three of the total of 35 patients (94.3%) received induction therapy: Ten patients with a monoclonal antibody anti-IL-2 receptor (Basiliximab Novartis®, 20 mg twice at day 0 and 4), and 23 patients with polyclonal ATG Fresenius® (3 mg/kg for 5-7 d). All patients had an equivalent maintenance immunosuppression using three oral drugs: A calcineurin inhibitor [tacrolimus (FK-506) in the majority of patients (32/35 patients) or cyclosporine (CsA) in 3 patients], mycophenolate mofetil (MMF) and a corticosteroid. FK-506 was started at a dose of 0.1-0.15 mg/kg per day, and was adjusted to maintain levels between 8 and 12 ng/mL during the first month post-transplant, between 7 and 10 ng/mL the next 2-3 mo and between 5 and 8 ng/mL thereafter. MMF was started at a dose of 2000 mg/d, and decreased based on white blood cells count. Methylprednisolone was administered intravenously at doses of 500, 250 and 125 mg/d on the day of transplantation, days 1-2 and days 3-4 after the operation, respectively. Oral prednisolone was started on day 5 after the operation at the dose of 20 mg, being then tapered to 5-10 mg/d within 2-3 mo after transplant. Living donor recipients ($n = 3$) were prescribed FK-506 and MMF 7 d before transplant.

Eight patients underwent a desensitization protocol. Five patients received intravenous immunoglobulin (IvIg) 2 g/kg at transplant (0.5 g/kg immediately before transplant, and at day 1, 2 and 3) and 1-mo after transplant (1 g/kg in 2 consecutive days). One patient received a similar dose of IvIg and underwent plasmapheresis every other day (first session immediately before transplant, for a total of 6-9 sessions) and two other patients received additionally a dose of Rituximab (375 mg/m²) on day 3 post-transplant.

Patients' data and outcomes

The data concerning patients' characteristics and transplantation variables was collected retrospectively. Estimated glomerular filtration rate (eGFR) was assessed using the 2006 Modification of Diet in Renal

Disease (MDRD) equation and dialysis requirement in the first week post-transplant was defined as delayed graft function. Patients were followed until graft failure, death or end of follow-up (five years after transplant or December 31, 2015, which came first). Graft survival was evaluated considering graft failure censored for death with a functioning graft.

Follow-up

Graft biopsies were performed "for cause" only. Allograft rejection was classified according Banff classification (updated in 2013) and defined by biopsy where specimens were evaluated by light microscopy and immunofluorescence (with C4d staining). Mild acute cellular rejection (ACR Banff grade I) was treated with 500 mg methylprednisolone for 3 d and increased maintenance immunosuppression. All other ACR were treated with ATG. AMR patients were treated with plasmapheresis every other day (the number of plasmapheresis sessions was 4 per protocol) and IvIg 100 mg/kg after each session. After the last plasmapheresis session, they received a high-dose IvIg (2 g/kg) divided in four daily doses and the same dose was repeated 1 mo later. If not used at transplant, patients received, additionally, one dose of rituximab (375 mg/m²).

Statistical analysis

Categorical data were expressed as numbers (frequencies) and continuous data were described using median (interquartile range). Categorical data (demographic and medical characteristics) were compared using Pearson χ^2 test or Fisher's exact test, as appropriate. Continuous variables were compared with Mann-Whitney *U* test. Predictors of AMR were explored by univariate and multivariable (using a backward elimination method, with a *P*-value < 0.05 necessary for retention in the model) Cox regression. For graft survival curves was used the Kaplan-Meier method, and the comparison between groups was done by log-rank test.

RESULTS

Baseline characteristics

Baseline characteristics of DSA-Cw and DSA-A-B groups are given in Table 1. DSA-Cw patients tended to be younger compared to patients in DSA-A-B group (respectively, 39 years vs 48 years), (*P* = 0.061). There was no significant difference between groups concerning gender, history of previous transplant or previous pregnancies. However DSA-Cw patients had significantly higher prevalence of previous blood transfusions (75% vs 39%, *P* = 0.044).

Concerning donor characteristics and pretransplant immunological data, namely donor age, donor gender, type of donor transplant (living vs deceased), peak PRA, and DSA number, none of these characteristics significantly differed between groups. Although DSA strength median was higher in DSA-A-B (MFI 7583) in comparison with DSA-Cw group (MFI 2939), this difference was not

significant (*P* = 0.110).

Flow cytometry crossmatch (FCXM) was performed for 29 of 35 patients. Positive T- and/or B- cell FCXM was similarly uncommon between groups. Three (27%) patients had a positive T-cell FCXM in the DSA-Cw group and only one (6%) in the DSA-A-B group (*P* = 0.139). Only two patients had a positive B-cell FCXM and both belonged to the DSA-A-B group.

Immunosuppression and induction treatment were similar between groups. ATG induction was used in 14 (61%) and 9 (75%) patients from the DSA-A-B and DSA-Cw groups, respectively (*P* = 0.476). Additionally, 5 patients in the DSA-A-B group were desensitized: 2 of them using only IVIG, 1 with IVIG and plasmapheresis and another 2 combining IVIG, plasmapheresis and rituximab. In DSA-Cw group 3 patients were treated with IVIG.

Clinical outcomes

Transplant outcomes are detailed in Table 2. There was no difference in terms of acute rejection at one year between the two groups (6 and 3 cases, respectively in the DSA-A-B and the DSA-Cw groups; *P* = 1). All cases of acute

rejection were diagnosed as AMR in the DSA-A-B group, while in the DSA-Cw group there were 2 cases of AMR and 1 of ACR. Figure 1 shows the incidence of AMR at one-year post-transplant, between DSA-A-B and DSA-Cw patients groups, (respectively, 26% and 17%, Log-rank *P* = 0.531) with no significant difference being detected. At one year, eGFR tended to be higher in DSA-Cw group (median 59 mL/min) compared to DSA-A-B group (median 51 mL/min), (*P* = 0.192) (Figure 2). Importantly, follow-up was significantly longer for the DSA-A-B group (median 60 mo) than in the DSA-Cw group (median 18 mo) (*P* < 0.001). Kidney graft survival at 5-years was also similar between groups (Figure 3, 91% for the DSA-A-B group vs 100% for the DSA-Cw group, *P* = 0.528).

Antibody-mediated rejection: Incidence, predictors and clinical impact

AMR occurred in 8 patients (23%) of the overall cohort. Possible associations between clinical and immunological data and AMR incidence through a Cox regression analysis is shown in Table 3. The sole independent predictor of AMR incidence was the DSA strength, both in uni- and multi-

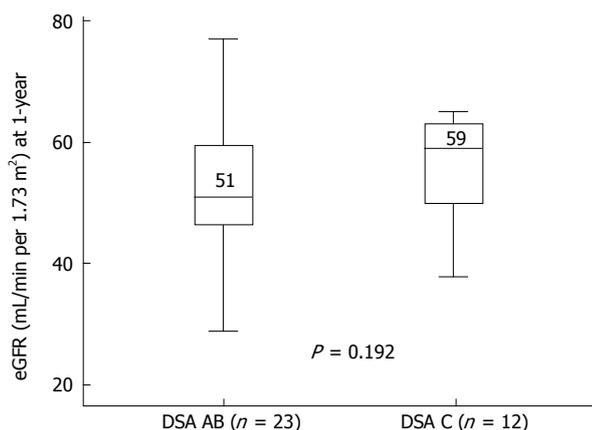

Figure 2 Graft function (estimated glomerular filtration rate at 1-year) post-transplantation according to donor-specific antibodies human leukocyte antigen loci. Boxes show the interquartile range of the values (median and percentile 25-75); whiskers show the lowest and the highest value within 1.5 times below or above the interquartile range, respectively. DSA: Donor-specific antibodies; eGFR: Estimated glomerular filtration rate.

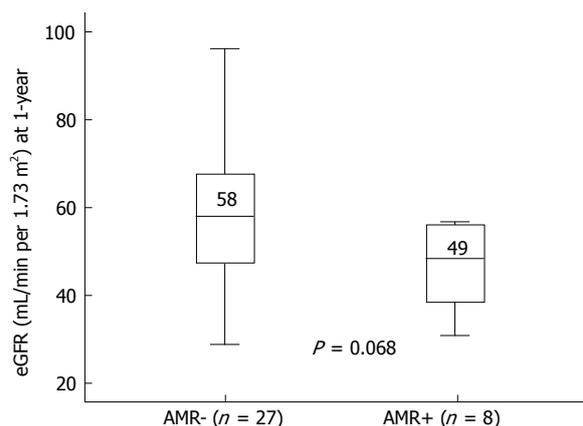

Figure 4 Graft function (estimated glomerular filtration rate at 1-year) post-transplantation according to antibody-mediated rejection occurrence. Boxes show the interquartile range of the values (median and percentile 25-75); whiskers show the lowest and the highest value within 1.5 times below or above the interquartile range, respectively. AMR: Antibody-mediated rejection; eGFR: Estimated glomerular filtration rate.

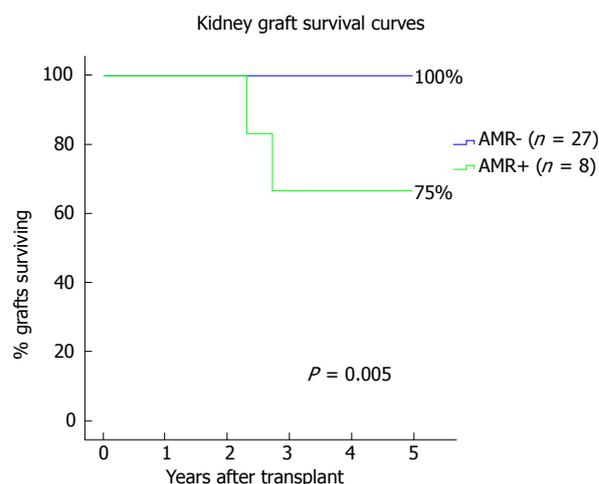

Figure 5 Kidney graft survival curves according with antibody-mediated rejection occurrence. AMR: Antibody-mediated rejection.

variable analysis (HR = 1.07 per 1000 increase in MFI, $P = 0.034$). At 1-year, eGFR was lower in AMR⁺ (median 49 mL/min) in comparison with AMR⁻ patients (median 58 mL/min) ($P = 0.068$), as shown in Figure 4. At the end of follow-up, kidney graft survival (Figure 5) was 75% in patients that experienced AMR and 100% in those who did not (Log-rank $P = 0.005$).

DISCUSSION

This retrospective study demonstrates that patients with preformed DSA solely antiHLA-Cw had a similar impact on post-transplant outcomes comparing to those patients with preformed antiHLA-A/-B DSA. Both groups had a relative high incidence of AMR at one year, 26% in the DSA-A-B group and 25% in DSA-Cw group. Also, the impact on graft outcomes measured by eGFR at one-year and graft survival at the end of follow-up was comparable

between groups.

HLA-Cw molecules are scantily expressed at the cell surface compared with HLA-A and HLA-B locus products, but intracellular HLA-A, HLA-B and HLA-Cw alleles are expressed in similar quantities^[3,11]. One reason pointed for this low amount at the cell surface is the fact that HLA-Cw alleles interact in a very stable way with the transporter associated with antigen processing (TAP) and they are kept in the endoplasmic reticulum, where they are degraded^[11]. Another justification for finding low HLA-Cw at cell proposed by McCutcheon *et al*^[3] is that HLA-Cw heavy chain mRNA is unstable and rapidly degraded, resulting in a lower rate of protein. This fact, associated with the modest sensitivity of the lymphocytotoxicity-based assays used in the past for identification of HLA-Cw antigens, probably explains why for many years they were considered less immunogenic and neglected in the matching systems of most kidney allocation procedures.

Table 3 Analysis of possible predictors of acute antibody-mediated rejection occurrence by univariable Cox regression

	HR for AMR	95%CI	P
Recipient			
Age (yr), per year	0.96	0.89-1.03	0.269
Female (<i>vs</i> male) gender	0.26	0.05-1.26	0.094

Recent studies confirm their lower frequency. Bryan *et al*^[6] in 2010 described in their sensitized transplant patients a 42% positivity to HLA-Cw, which was significantly lesser than sensitization to HLA-A (80%) and HLA-B (83%). In 2012, Ling *et al*^[5], obtained similar results and showed that the frequency of antiHLA-Cw antibodies in sensitized patients was about 56%, lower than HLA-A (79%) and B (86%) antibodies. Our group evaluated 453 sensitized kidney transplantation candidates to determine the presence of antiHLA class I and class II antibodies, comparing how different sensitization events, such as pregnancy, transfusion or previous organ transplantation, affected the degree of HLA alloimmunization^[12]. For antiHLA antibodies against class I, if the sensitization event was previous transplant only, the antiHLA antibodies prevalence was 21.2% for -A, 28.8% for -B and 21.1% for -Cw; if the single sensitization event was previous transfusion, the antiHLA antibodies prevalence was 3.9% for -A, 5.5% for -B and 1.6% for -Cw. At last, if the sensitization event was pregnancy only, the antiHLA antibodies prevalence was 13.6% for -A, 11.1% for -B and 6.2% for -Cw.

In spite of their lower frequency, some reports have been published concerning their association with AMR and impact on graft function and survival^[8,13,14]. Besides, the recent development of the solid-phase immunoassays, in particular the single-antigen flow bead (SAFB) assays, allowed us to detect and properly identify anti-HLA-Cw antibodies. Tambur *et al*^[15] compared virtual flow-cytometry cross-match to actual cross-match and described that 40% of the cases with a positive actual flow-cytometry cross-match and negative virtual cross-

match were explained by the presence of antiHLA-Cw antibodies. Gilbert *et al*^[7] compared two groups of sensitized recipients, one group with only classical HLA-A, -B, -DR, -DQ antibodies (*n* = 176) and the other group with classical plus HLA-C and/or -DP antibodies (*n* = 27). They concluded that there was a significant increase in the number of AMR among the group with pre-transplant anti-Cw and -DP antibodies. However, they did not distinguish between pre-transplant anti-DP or anti-Cw antibodies, and they speculated that anti-DP antibodies seemed to be involved more often in poorer graft outcomes. Ling *et al*^[5] investigated the clinical outcomes in kidney transplant patients with isolated Cw-DSA. They identified eight patients with pre-transplant DSA antiHLA-Cw, exclusively. During a median 6 mo of follow-up (range 3-24 mo), patient and graft survival was 100% without any acute rejection occurring. In this group, all the patients had induction therapy with thymoglobulin or basiliximab and additionally all patients received intravenous immunoglobulin, similar to patients with positive FCXM and/or cPRA > 50%. Even so, the median time of follow up was relatively short and may have underestimated the incidence of rejection. Aubert *et al*^[9] evaluated retrospectively 22 renal transplant recipients with isolated antiHLA-Cw DSA at day 0 of renal transplant, comparing them with 88 allosensitized patients with no preformed DSA (control group), and followed for a period of 1 year. Acute AMR was diagnosed in six patients (27.3%) in patients with DSA-Cw vs 9% in those without DSA. In this study, the patients with DSA antiHLA-Cw received less-intensive immunosuppression than the control group of sensitized patients, including ATG induction (only 59.1%), and this may probably be a plausible explanation for this high rate of AMR. However they alert for the necessity of screening pre-transplant DSA HLA-Cw and subsequent modulation of immunosuppression in cases of positivity. More recently, Bachelet *et al*^[10] investigated the clinical effect of DSA antiHLA-Cw and/or -DP, comparing 48 patients transplanted with isolated preformed DSA antiHLA-Cw and/or -DP with a group of HLA-sensitized recipients with no DSA (104 patients) and 47 kidney transplant recipients with preformed DSA antiHLA-A, -B, -DR, and/or -DQ. Two years after transplantation, the groups with DSA (both -Cw/-DP or -A/-B/-DR/-DQ) had similar incidence of AMR and graft survival (and worse than the group with no DSA), showing that preformed DSA anti-HLA-Cw and/or -DP were as deleterious as DSA anti-HLA -A/-B/-DR/-DQ.

Our data reached similar results of these previous studies, confirming that DSA-Cw is associated with a similar incidence of AMR and impact on graft survival in comparison with "classical" DSA against class I^[9,10].

We have also shown that patients that experienced AMR had a significant lower kidney graft survival in comparison to patients who did not (respectively, 75% vs 100%, Log-rank *P* = 0.005), with the sole independent predictor of AMR incidence being DSA strength. The negative impact of DSA for AMR occurrence and adverse results on kidney graft

survival has been previously established^[2]. Lefaucheur *et al.*^[16] stated that it is the occurrence of AMR associated with DSA that has impact on graft survival, since graft survival of DSA-positive patients, in the absence of AMR, is the same as DSA-negative patients. Furthermore, DSA characteristics as number, class or strength may have a negative impact on graft outcomes^[1,17-19]. Malheiro *et al.*^[20] showed that DSA strength (MFI) had a reasonable ability to predict AMR occurrence, with no cases of AMR occurring below a MFI < 3000. However when the MFI values increased from this value, also did the risk of AMR. Again, Aubert *et al.*^[9] in their retrospective study with 22 renal transplant recipients with preformed isolated antiHLA-Cw DSA, showed that the level of DSA at day 0 was predictive for AMR: Measurement of MFI was 4966 (978-17941) in the AMR group and 981 (530-8012) in the group of patients without AMR ($P = 0.017$).

This study has limitations. First, the small number of patients in the cohort limits our ability to generalize the results. Second, follow-up time difference may have limited the comparative analysis of graft survival according with DSA HLA loci. Contrarily, AMR incidence was not influenced by it, since it was analyzed at 1-year post-transplant. Third, there was no protocol biopsies performed in our patients and it is an important tool for HLA incompatible kidney transplantation^[21,22]. Lastly, the limitations of SAB assay are well established and their reported MFI values should be considered for analyzing our results^[23].

In summary, our data show that preformed DSA antiHLA-Cw exerts a deleterious effect in presensitized kidney transplant recipients that is similar when compared to antiHLA antibodies against other class I locus (antiHLA-A or -B). Also, the association between AMR occurrence and reduced graft survival is clear, with DSA strength being predictive of rejection. Therefore, HLA-C typing and respective antibody identification will benefit sensitized patients during organ allocation.

COMMENTS

Background

Classically, antibodies to major human leukocyte antigen (HLA) Class I (A and B) and Class II (DR and DQ) antigens are considered to be responsible for most cases of AMR. Compared to other class I antiHLA antibodies, antiHLA-Cw are considered less immunogenic.

Research frontiers

Preformed antiHLA-Cw donor-specific antibodies (DSA) seem to have the same impact on graft outcome as DSA against "classical" HLA loci (-A, -B, -DR and -DQ), suggesting that it should also be considered in transplant allocation systems and in immunologic risk stratification algorithms.

Innovations and breakthroughs

The clinical relevance of preformed antiHLA-Cw DSA in kidney transplant patients remains controversial, so the authors performed a retrospective study comparing 12 patients with DSA exclusively antiHLA-Cw with 23 patients with preformed DSA antiHLA-A and/or B. Antibody-mediated rejection occurrence and graft survival rates, respectively, at 1 and at 5-years of follow-up, were comparable between groups.

Applications

The data show that preformed DSA antiHLA-Cw exerts a deleterious effect in presensitized kidney transplant recipients that is similar when compared to antiHLA antibodies against other class I locus (antiHLA-A or -B). Also, the association between AMR occurrence and reduced graft survival is clear, with DSA strength being predictive of rejection.

Terminology

HLA: Human leukocyte antigen; DSA: Donor-specific antibodies; AMR: Antibody-mediated rejection.

Peer-review

The topic is very interesting. The authors investigated the possible role of preformed donor-specific antibodies against HLA antigens, specially anti-Cw antibodies compared to standard anti A/B antibodies. The importance of Cw antibodies is still under investigation and this study is valuable about this topic. This article is worthwhile for publication.

Abstract

AIM

To compare the impact of tacrolimus (FK) and cyclosporine (CYA) on acute rejection and graft survival and to assess the predominant causes of graft loss between patients receiving these two calcineurin inhibitors (CNIs).

METHODS

Retrospective review of 1835 patients who received a kidney transplant (KTX) between 1999-2012. Patients were grouped based on initial CNI utilized: 1195 in FK group, 640 in CYA group. Data on baseline characteristics, clinical outcomes, and causes of graft loss in both groups were analyzed.

RESULTS

Cumulative acute rejection rates were 14% in the FK vs 24% in the CYA group. Despite more marginal donor characteristics in the FK group, these patients had better graft survival rates compared to the CYA group. Three and five year graft survival rates were 88% and 84% respectively in the FK group compared to 79% and 70% respectively in the CYA group ($P < 0.001$). After multivariate analysis, which controlled for confounders, FK use was a strong predictor for lower acute rejection

rates [odds ratio (OR) 0.60, 95%CI: 0.45-0.79] and better renal allograft survival (OR 0.740, 95%CI: 0.58-0.94). Death with a functioning graft was the most common cause of graft loss in both groups. Common causes of death included cardiovascular disease, infections, and malignancies. Chronic allograft nephropathy was also found to be an important cause of graft loss, being more prevalent in the CYA group.

CONCLUSION

The use of FK-based maintenance immunosuppression therapy is associated with a significantly lower rate of acute rejection and better graft survival compared to CYA-based regimen. Individualizing immunosuppression through risk-stratified CNI choice may lead to improved outcomes across all spectra of KTX patients.

Key words: Tacrolimus; Cyclosporine; Renal allograft survival

Core tip: Tacrolimus (FK) has surpassed cyclosporine (CYA) as the calcineurin inhibitor (CNI) of choice for the vast majority of kidney transplant (KTX) programs. Yet, CYA continues to be an important alternative for patients intolerant to FK. FK is associated with significantly lower rate of acute rejection and better graft survival compared to CYA. Individualizing immunosuppression through risk-stratified CNI choice may lead to improved outcomes across all spectra of KTX patients.

Tacrolimus confers lower acute rejection rates and better renal allograft survival compared to cyclosporine. *World J Transplant* 2016; 6(4): 697-702 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/697.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.697>

INTRODUCTION

Calcineurin inhibitors (CNIs) are the main immunosuppressive agents utilized in kidney transplantation^[1]. Cyclosporine (CYA) and tacrolimus (FK) are currently the most widely used maintenance immunosuppressants for prevention of acute rejection in kidney transplant recipients. CYA-based regimen was more common in the era of 1990 until 2002, after which FK-based regimen became more commonly used in most transplant programs. In our transplant center, FK became the primary CNI of choice in 2005. FK and CYA show variable side effect profiles. Hypertension, hyperlipidemia, gum hypertrophy, and hirsutism occur more frequently with CYA use. On the other hand, a higher incidence of post-transplant diabetes mellitus is observed with FK therapy. Prolonged use of CNI may result in nephrotoxicity.

FK use is associated with less acute rejection

compared to CYA, as documented in different studies^[2,3]. Mayer *et al*^[2] found that among 448 renal transplant recipients who were on triple therapy (FK or CYA + Azathioprine + Prednisone), patients who were in the FK group had a significant reduction in the frequency of acute rejection at 12 mo (FK 25.9% vs CYA 45.7%; $P < 0.001$). Ekberg *et al*^[3] also found that at 12 mo post-transplant, the use of FK-based regimen is associated with less biopsy-proven acute rejection compared to CYA use (12.3% vs 25.8%, $P < 0.01$).

FK is frequently preferred in patients with high immunologic risk (highly sensitized, ABO-incompatible organ recipients), delayed graft function, and African American race. Data regarding graft survival based on the use of FK vs CYA is controversial with most studies showing similar graft survival rates with the use of either agent^[4]. Vincenti *et al*^[5] showed comparable patient (79.1% vs 81.4%; $P = 0.472$) and graft (64.3% vs 61.6%; $P = 0.558$) survival between treatment arms at 5 years of follow-up among FK and CYA-treated patients. However, after accounting for patients initially on CYA who crossed over to FK, the authors found significantly reduced graft failure in the FK group^[5]. Gonwa *et al*^[6] showed that among 223 kidney transplant recipients who experienced delayed graft function, patients who used FK-based therapy had a better 3-year graft survival compared to CYA use (84.1% vs 49.9%, $P = 0.02$). Given these conflicting findings, this study aims to compare rates of acute rejection and graft loss among patients who receive FK and CYA.

MATERIALS AND METHODS

Patients

This was a retrospective cohort study of 1835 patients who received a KTX between 1999-2012 at a single center. Patients were grouped based on the type of CNI they were prescribed: 1195 patients utilized FK-based immunosuppression whereas 640 patients were on a CYA-based regimen. All patients received an antimetabolite and prednisone in combination with CNI. The initial CYA dose was 4-5 mg/kg PO BID. Target CYA levels were 350-400 ng/mL for weeks 1-4, 250-350 ng/mL for weeks 5-12, 200-300 ng/mL within the first year post-transplant, and 100-200 ng/mL thereafter. Initial FK doses were given at 0.025-0.05 mg/kg PO BID. Target FK levels were kept between 8-12 ng/mL within the first four weeks post-transplant, then 6-10 ng/mL within the first year post-transplant, and 4-6 ng/mL subsequently. Characteristics of recipients (age, race, sex, BMI, etiology of kidney disease, history of heart disease, diabetes, hypertension, years on dialysis, panel reactive antibody, preemptive transplant, living donor transplant), and donors [age, race, kidney donor risk index (KDRI)] were compared between groups. Characteristics of the kidney transplant (cold ischemia time, induction agent) as well as clinical outcomes (cumulative acute rejection rate, delayed graft function, three, and five year graft survival) were also analyzed. The Banff '97 criteria were used to define the

different grades of rejection. Based on center protocol, Banff 1A and 1B rejection episodes were treated with Methylprednisolone IV. Rejection episodes with Banff 2A grade or higher were treated with anti-thymocyte globulin. Subset analysis was conducted on subjects who had graft loss to retrospectively investigate the factors leading to graft loss. For patients who died, causes of death were presented as overall prevalence of infections (encompassing sepsis, bacterial, fungal, CMV, and other viral infections), malignancies (encompassing solid organ tumors, hematologic malignancies, and post-transplant lymphoproliferative disorder), and cardiovascular diseases (encompassing acute myocardial infarction and cerebrovascular accident). Cause of death classified under "other" includes accidents, unknown, or undocumented. Non-adherence was defined as documentation in the medical record by a provider that a patient was not taking their immunosuppressive regimen as prescribed. Under immunosuppression was defined as evidence of kidney transplant injury related to rejection that led or contributed to graft loss.

Statistical analysis

The statistical review was performed by a clinician with advanced biostatistical training and experience.

Two-sided independent student's *t*-test was used to compare continuous data while the χ^2 test was used to compare categorical data. A two-sided *P*-value of less

than 0.05 was considered statistically significant.

Multivariate survival analysis, using both logistic and Cox regression, was used to assess the association between CNI choice and acute rejection (logistic), graft survival (Cox), and patient mortality (Cox), while controlling for additional transplant variables known to influence outcomes or those that differed across CNI choice. In a subset analysis of patients who had graft loss, causes of graft loss, and causes of death were compared between the two groups using standard univariate comparative statistics. All analyses were conducted using SPSS version 21.0 (IBM Corp, Armonk, NY).

RESULTS

Patient characteristics

Table 1 displays demographic characteristics of the two groups. Mean recipient age, race, BMI, etiology of kidney disease, comorbidities, and dialysis vintage, were similar between the two groups. Patients on FK had higher PRA compared to patients on CYA group (17% vs 5%, *P* < 0.01). Rates of living donor transplants were similar between the two groups. Among patients who received a deceased donor transplant, KDRI was higher in those who received FK. More patients in the FK group received induction agent with depleting antibodies (46% vs 11%, *P* < 0.01).

Table 2 Clinical outcomes

Parameter	Tacrolimus <i>n</i> = 1195	Cyclosporine <i>n</i> = 640	<i>P</i> -value

Acute rejection	1.59	1.26-2.01	< 0.001

CNI: Calcineurin inhibitor; DM: Diabetes mellitus; HTN: Hypertension.

Clinical outcomes

Patients in the FK group had better clinical outcomes in terms of delayed graft function (DGF) rate (15% vs 18%, *P* = 0.049), cumulative biopsy proven acute rejection rates for Banff 1A and higher, as well as antibody-mediated rejection (14% vs 24%, *P* < 0.01), three year graft survival (88% vs 79%, *P* < 0.010), and five year graft survival (84% vs 70%, *P* < 0.01) (Table 2). FK was a strong predictor of lower acute rejection rates. After multivariate analysis, which accounted for recipient immunologic risks (age, gender, re-transplant, PRA, HLA mismatches, cold ischemic time, induction), donor characteristics (deceased status, ECD, age, race) and delayed graft function, FK continued to be strongly associated with lower acute rejection rates, as compared to CYA (OR = 0.60, 95%CI: 0.45-0.79; *P* < 0.001) (Table 3). Further analysis showed that even after controlling for all other variables, including delayed graft function and acute rejection, FK remained a strong and statistically significant predictor of graft survival (OR = 0.740, 95%CI: 0.58-0.94; *P* = 0.012) (Table 4) (Figure 1).

Graft loss

During the study period, there were 106 patients in the FK group and 123 in the CYA group who had graft loss. Death with a functioning graft was the cause of graft loss

in the majority of these patients. The leading causes of death among the patients include cardiovascular disease, infections, and malignancies (Table 5). The contribution of non-adherence and underimmunosuppression in patients who had graft loss was not significantly different between the FK and CYA groups.

DISCUSSION

The utilization of potent immunosuppressive medications such as CYA and FK has led to progressive improvement in renal allograft survival. Two large studies on kidney transplant recipients showed that the incidence of acute rejection is much lower with FK-based immunosuppression compared to CYA-based regimen^[2,3]. Our study demonstrated similar findings of lower acute rejection rates in patients using FK compared to those on CYA. Acute rejection rate was significantly lower in the FK group despite the relatively higher degree of sensitization, as evidenced by higher PRA, in this group. Multivariate analysis showed that FK was a strong predictor for lower acute rejection rates while controlling for recipient, donor, and transplant characteristics.

The shortage of deceased donor kidneys and the growing number of patients on the waiting list has driven the increased utilization of organs with relatively marginal donor characteristics. Donor factors affect initial graft function and survival^[7]. Donor factors that may influence graft survival include age, gender, hypertension, and cardiovascular disease^[8]. The KDRI is a comprehensive metric that was recently developed to assess the relative risk of graft failure associated with various combinations of donor characteristics. Kidneys with the highest KDRI quintile are associated with lower graft survival^[9]. Although many trials have shown similar graft survival outcomes with FK when compared with CYA-based regimen^[4], some studies showed better survival and outcomes with FK-based immunosuppression^[6]. Our

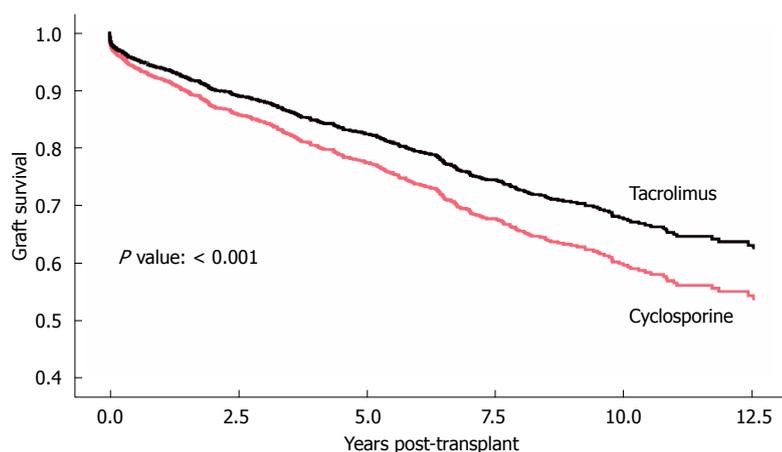

Figure 1 Kaplan Meier curve showing effect of tacrolimus vs cyclosporine on graft survival.

Table 5 Graft loss *n* (%)

Parameter	Tacrolimus <i>n</i> = 106	Cyclosporine <i>n</i> = 123	<i>P</i> -value
Death with functioning graft	61 (58)	66 (54)	0.55

study showed that although patients in the FK group received kidneys from more marginal donors (higher KDRI), the three year and five year graft survival was still more superior in this group compared to the CYA group (Figure 1).

The risk of infections after kidney transplant depends on the net state of immunosuppression. As FK was shown to be associated with less acute rejection compared to CYA^[10], it may concurrently cause more intense immunosuppressive effects compared to CYA. Thus, risk of infections after kidney transplant may be higher with FK compared to CYA. This may be exemplified by the higher incidence of polyomavirus (BK) viremia in patients on FK-based regimen compared to CYA^[11]. Progression of BK viremia may lead to BK nephropathy, which can then eventually cause premature renal allograft failure^[11]. However, in our subjects who had graft loss, we did not observe a significant difference in the prevalence of infections (including BK) in the FK and CYA groups.

The use of maintenance immunosuppressive medications among transplant recipients increases the long-term risk of malignancy, compared with that of the general population. The overall level of immunosuppression appears to be the principal factor that increases the risk of post-transplant malignancy. Both FK and CYA are associated

with an increased risk of malignancy following kidney transplant^[12,13]. No direct comparison between these two agents has been reported regarding the incidence of malignancy following kidney transplant. However, FK was found to have higher incidence of *de novo* malignancy after liver transplant compared to CYA^[14]. In our study, we did not find a significant difference in the prevalence of malignancies between the two groups.

Cardiovascular disease is a leading cause of mortality among kidney transplant recipients. Death from cardiovascular disease is the most common cause of renal allograft loss^[15]. CNIs potentially contribute to increased risk of cardiovascular events indirectly by the development of new-onset diabetes mellitus, hypertension, and hyperlipidemia. Clinical trials have shown a higher incidence of post-transplant diabetes mellitus with FK. However, the risk of hypertension and hyperlipidemia is slightly higher with CYA than FK. No direct comparison has been done between FK and CYA regarding the incidence of cardiovascular disease. In our study, we found that FK was associated with a slightly higher prevalence of cardiovascular disease compared to CYA, although the difference was not statistically significant.

In conclusion, FK is associated with lower prevalence of acute rejection compared to CYA. It confers better three and five year graft survival even with the use of

organs with marginal deceased donor characteristics. An individualized approach to the choice of CNI needs to be employed in order to achieve the best possible outcome while minimizing adverse effects. The use of either FK or CYA should be individualized according to the patient's comorbid conditions and immunological risk.

COMMENTS

Background

Calcineurin inhibitors (CNIs) [cyclosporine (CYA) and tacrolimus (FK)] are currently the most widely used maintenance immunosuppressants for prevention of acute rejection following kidney transplantation. However, data on the impact of these CNIs on acute rejection rate and graft survival have remained equivocal.

Research frontiers

The choice of immunosuppressive regimen that will achieve the best renal allograft outcomes remains an important focus in the care of kidney transplant recipients.

Innovations and breakthroughs

The data showed lower acute rejection rates and better graft survival in patients on FK compared to those on CYA.

Applications

The use of either FK or CYA should be individualized based on patient's comorbidities and immunological risk.

Terminology

FK: Tacrolimus; CYA: Cyclosporine; CNI: Calcineurin inhibitor; DGF: Delayed graft function; DM: Diabetes mellitus; HTN: Hypertension; FSGS: Focal segmental glomerulosclerosis; PRA: Panel reactive antibody; CIT: Cold ischemia time; KDRI: Kidney donor risk index; GFR: Glomerular filtration rate.

Peer-review

The authors are presenting their experience in the use of CNIs in the immunosuppression post renal transplantation.

Abstract

AIM

To evaluate the relationship between the state of transplanted liver graft and the recipient quality of life (QOL) of histologically proven lesions in a 10-year post liver transplantation (LT) cohort of patients.

METHODS

Seventy-two recipients with a functional first graft at 10 years post-LT underwent liver biopsy and completed a QOL questionnaire. Logistic regression analysis was used to explore associations between histological, clinical and

QOL criteria.

RESULTS

Ten years after LT, fibrosis was detected in 53% of patients, and affected the general health perception, while ductopenia, present in 36%, affected the well-being ($P = 0.05$). Hepatic steatosis (HS) was present in 33% of patients and was associated with the worst QOL score on multiple domains. When compared to patients without HS, patients with HS had significantly higher incidence of fibrosis ($P = 0.03$), hepatitis C virus (HCV) infection ($P = 0.007$), and more patients had retired from their job ($P = 0.03$). Recurrent or *de novo* HCV-associated fibrosis and patient retirement as objective variables, and abdominal pain or discomfort and joint aches or pains as subjective variables, emerged as independent determinants of HS.

CONCLUSION

Long-term liver graft lesions, mainly HS presumably as a surrogate marker of HCV infection, may have a substantial impact on QOL 10 years after LT.

Key words: Liver transplantation; Quality of life; Liver biopsy; Hepatic steatosis; Liver fibrosis

Core tip: Objective and subjective parameters are helpful in the accurate assessment of long-term outcome in liver transplantation recipients. The main finding of this study was that histological lesions in the transplanted liver 10 years after liver transplantation can affect the recipient quality of life. Hepatic steatosis had the most significant impact on quality of life and this was independent of alcohol consumption, fibrosis, diabetes and body mass index. The strongest determinants of a worse quality of life in patients with hepatic steatosis were hepatitis C virus infection and retirement from job irrespective of patient-age.

INTRODUCTION

The goal of liver transplantation (LT) is to ameliorate not only survival, but also quality of life (QOL) while minimizing the effects of disease and costs of care. Analysis of data from the European Liver Transplant Registry (ELTR) shows that 38% of the patients transplanted in 1991 were still alive with their first graft at least 10 years post LT^[1]. The increasing proportion of recipients alive at long-term follow up has incited transplant professionals to focus on long

term morbidity-free survival and an acceptable QOL.

The QOL is increasingly recognized as an important measure of outcome after solid organ transplantation^[2-4]. We showed in a previous study that the challenge of maintaining long-term well-being is achieved to a greater extent in liver transplant recipients than in other solid-organ transplant recipients^[4]. However, short term and long term QOL in liver transplant recipients is still inferior to that of the general population^[3,4].

Studies of long-term survivors have been mainly based on clinical data and histological follow up at long term, or with respect to indication for LT, immunosuppressive regimen or recipient and donor criteria^[5-10]. In previous studies, we justified the use of biopsies in the follow-up protocol to adjust treatments, not only in HCV-infected patients (in whom fibrosis progression was rapid and non-linear), but in all recipients^[11,12].

No study has been published assessing the relationship between the state of transplanted liver graft and the recipient QOL of histologically proven lesions in a 10-year post LT cohort of patients.

MATERIALS AND METHODS

Patients

Between September 1989 and December 1992, 485 LT were performed in 432 patients at Paul Brousse Hospital (Villejuif, France). During the 10th year post LT, among the 145 patients who were alive with a first functional graft, 126 accepted to complete the QOL questionnaire, and among these 72 accepted to have a liver biopsy done. For the purpose of this study, only the 72 subjects who underwent both a 10-year post LT liver biopsy and completed the QOL auto-questionnaire were included.

Questionnaire

QOL data was obtained using the NIDDK questionnaire^[2]. The questionnaire includes 21 disease-specific items assessing symptoms related to chronic liver disease. We used a validated French version of the questionnaire developed previously using the back-translation method

Five domains of QOL; physical distress (PHD), psychological distress (PD), personal function (PF), social/role function (SRF), and general health perception (GHP) are well represented in the questionnaire. Each symptom is numerically graded according to severity and then a composite overall score is calculated from all domains^[3,4].

Histological evaluation

Prospectively obtained reperfusion biopsies and ten-year post LT liver biopsies were reviewed by the same experienced pathologist (MS) who was blinded to clinical information.

Portal tracts, hepatic veins and parenchyma were systematically analysed according to a preformed format. Fibrosis was staged on a five-point scale: 0, none; 1, portal fibrosis without septa; 2, few septa; 3, numerous septa without cirrhosis; 4, cirrhosis. Ductopenia evaluated on

liver biopsy was analysed according to the Banff criteria^[13], and ductopenia was considered as significant when the percentage of bile duct lost exceeded 20%. Steatosis was scored according to the percentage of biopsy tissue involved. Patients were considered in Hepatic Steatosis (HS) group when the percentage of steatosis exceeded 10%. Minimal changes were defined as the absence of all the above cited lesions or the existence of only one of the following criteria: steatosis < 10%, sinusoidal fibrosis, or minimal bile duct or lobular inflammation. The final diagnosis was established by joint review of records; biochemical, virological, and immuno-histochemical data.

Statistical analysis

Continuous variables are given as mean \pm SD. Comparisons of continuous variables were performed with the Mann-Whitney test and those of nominal variables with χ^2 contingency test or Fisher's exact test when appropriate. Logistic regression was conducted to examine determinants of HS. We conducted two separate regressions: (1) with the objective (clinical) variables; and (2) with the subjective (QOL) variables. A *P*-value of < 0.05 was considered statistically significant.

RESULTS

Characteristics of patients who were not included in the study

Only 72 patients accepted to complete the QOL questionnaire and undergo liver biopsy amongst the 145 patients who survived for a minimum of 10 years with a first functional graft. Since this could create a selection bias in our study, we compared the selected and unselected patients with respect to characteristics at the time of LT and at 10-years post-transplant. Clinico-demographic characteristics like age at transplantation, sex, donor age, ABO group, CMV and reperfusion biopsy status, indication for LT, liver enzyme tests at the time of 10 year control of included patients were not statistically different from the non-included patients. Moreover, comparison of all domains of QOL has not shown any statistically significant difference between the selected and unselected patients (data not shown).

Patient characteristics at the time of LT

The mean age at time of transplantation was 35 ± 19 years and proportion of female patients was 52%. Mean donor age was 27 ± 11 years. The main indications for LT were PBC (25%), acute liver failure (24%) and viral cirrhosis (20%) [mostly hepatitis C virus (HCV) related (12%)]. The reperfusion biopsies showed steatosis ($\geq 10\%$) in 18% of patients and reperfusion injury related lesions in 86% of reperfusion biopsies. Twenty-six percent of these lesions were classified as mild while 60% were of moderate to severe-degree (Table 1).

Patient status and histological findings 10 years after transplantation

As regards co-morbidities present in the recipients

at follow-up, thirty eight (53%) patients had arterial hypertension and 7 (10%) suffered from diabetes mellitus (mostly type II). According to the body mass index (BMI), 9 (13%) patients were underweight, 50 (69%) patients were within normal limits, 10 (14%) were overweight and 3 (4%) were obese. Fifteen (21%) patients consumed alcohol with 1.1 ± 0.3 drinks/day (one drink = 1 bottle of beer or 1 glass of wine or 1 mixed drink, the equivalent of 1.25 grams of alcohol) and 12 (17%) were tobacco smokers with 1.9 ± 0.8 cigarettes/day (Table 2).

Forty one patients (57%) had HCV infection, amongst them 35 (49%) had *de novo* infection whereas 6 (8%) had recurrent HCV infection. Most patients had been transplanted before the screening of blood and organ of donors for HCV serology began (pre HCV era). The predominant HCV genotype in our study cohort was genotype 1 (60%), mostly 1b subtype (51%). The proportion of other genotypes was; genotype 2 (12%), genotype 3 (9%) and genotype 4 (6%). In 13% of cases HCV-infection was established by RNA revelation. At the time of biopsy and QOL evaluation, none of the patients was being treated with interferon.

The immunosuppression was mainly using Cyclosporine-based (96%) in the study population.

The main histological findings were as follows: (1) fibrosis F1-F4 ($n = 38$, 53%), with F1 ($n = 16$, 22%), F2 ($n = 13$, 18%), F3 ($n = 4$, 6%). Cirrhosis (F4) was found in 7% ($n = 5$) of cases; (2) ductopenia ($n = 26$, 36%) with a mean percentage of bile duct loss of $40\% \pm 20\%$; and (3) steatosis ($n = 24$, 33%) with a mean percentage of $19 \pm 17\%$, which was mostly macrovacuolar ($n = 23$, 32%). Combined fibrosis and steatosis was found in 24% ($n = 17$) of patients. Only 23% ($n = 16$) of biopsies contained minimal-change lesions (as defined above).

Relation between QOL and histological lesions

Overall-QOL was not affected by fibrosis or ductopenia (Figure 1A and B). Nevertheless, GHP score was lower in patients with fibrosis ($P = 0.02$) and well-being score was lower in patients with ductopenia ($P = 0.05$). The overall-QOL score was the lowest in HS patients ($P = 0.007$) (Figure 1C). HS impaired particularly the PHD ($P = 0.002$), PD ($P = 0.01$) and GHP ($P = 0.05$). According to these results, we focused our study on the group of patients with HS.

Profile of patients with hepatic steatosis

As the worst QOL score on multiple domains was associated strikingly with HS we made a detailed analysis to compare the group with steatosis on 10 year liver biopsy, with those without. There were no statistically significant differences between the groups with respect to data at the time of LT except for recipient age (32 ± 21 years vs 42 ± 12 years; $P = 0.04$) (Table 1). At 10 year post LT follow-up, the BMI (22.6 ± 3.4 vs 22.3 ± 3.9), rate of diabetes (13% vs 9%), rate of arterial hypertension (54% vs 54%) and immunosuppressive dosage were not statistically higher in HS group. No difference was found

Continuous data are represented as mean ± SD, and categorical data as percentage. ¹Comparison between HS and No HS; ²Reperfusion biopsy not done in 10 cases (9 in Non HS group and 1 in HS group). HS: Hepatic steatosis; NS: Not significant; HCV: Hepatitis C virus.

in liver function tests (Table 2).

For the 24 patients with HS, three of the studied objective variables were statistically significant when compared to patients without HS at 10 years post LT: Fibrosis (71% vs 44%, $P = 0.03$), HCV infection (79% vs 46%, $P < 0.007$) (Table 2), and patient retirement (50% vs 21%, $P = 0.03$) (Table 3). Fibrosis was present in 17 (71%) patients and was mainly related to HCV infection. The HCV genotype 1 was predominant and represented 63%, mostly 1b subtype (42%). Despite the equally distributed mean age and the percentage of more than 60 years old patients in the two groups (29% vs 27%, $P = ns$), retired recipients were more prevalent in the HS group (46% vs 21%, $P = 0.03$).

Regarding the subjective QOL variables, a detailed analysis showed that the HS has an impact on 17 symptoms belonging to each one of the 5 domains of QOL (Table 4). The most affected physical symptoms were: Abdominal pain or discomfort ($P < 0.0001$), joint aches or pains ($P < 0.001$) and change in facial appearance ($P < 0.001$). Nervousness/anxiety was the most affected psychological symptom followed by a feeling of being depressed, sad or blue ($P < 0.01$). As regards PF, the health of HS patients currently limits their ability to perform vigorous activities such as running, heavy lifting or sport ($P < 0.001$). The SRF was affected by the patients' decreased interest in sex ($P = 0.003$). Finally, bodily pain during the last month represented the worst symptom of GHP ($P < 0.01$).

In multivariate regression analysis, two objective

variables emerged as independent determinants of HS: HCV infection ($P < 0.01$) and patient retirement ($P = 0.04$). So also, two subjective variables were significantly associated with HS: Abdominal pain or discomfort ($P < 0.01$) and joint aches or pains ($P = 0.04$) (Table 5).

DISCUSSION

The developments in surgical techniques, immunosuppressive treatment modalities and better patient care have led to an increasing number of long-term survivors after LT, yet the QOL of transplant recipients does not always return to normal. The constant need for drug ingestion and monitoring the high incidence of recurrent or intervening diseases after LT, all seem to impair QOL^[14,15]. Nevertheless, reported data shows that most of the QOL parameters are better after transplantation than before^[2,3,16]. This study is an attempt to identify those factors which prevent long term liver transplant survivors from returning to a near normal lifestyle, with a specific focus on the relationship of QOL with graft histological status. One can recognize that a key challenge specific to this study could be its face validity, *i.e.*, comparison of histologic changes to QOL, which in the absence of advanced histologic changes is not intuitively related. In order to attenuate the relative fluctuations liver biopsies were reviewed by the same experienced pathologist (MS) who was blinded to clinical information. Moreover, we used the NIDDK questionnaire considered as one of the most appropriate and validated instruments for QOL

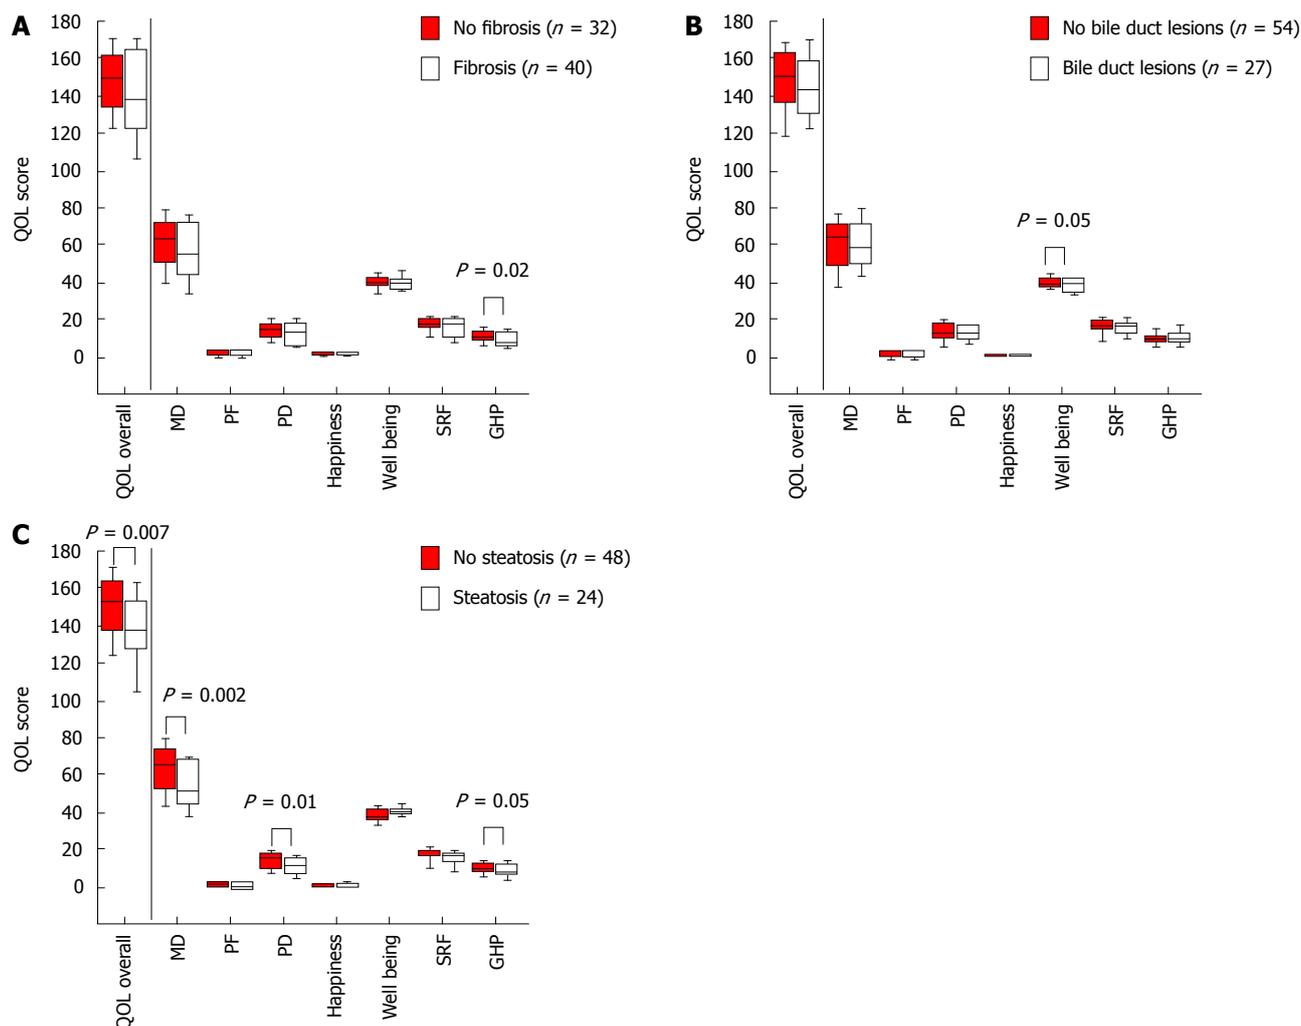

Figure 1 Relationship between quality of life domains and histological findings on 10 year post-liver transplantation liver biopsy. A: Fibrosis; B: Bile duct lesions; C: Steatosis. QOL: Quality of life; PF: Personal function; SRF: Social/role function; GHP: General health perception.

evaluation in transplant recipients^[17].

The main finding of this study was that histological lesions (especially HS) in the transplanted liver 10 years after LT can affect the recipients' QOL. Overall-QOL was not affected by fibrosis or ductopenia, but there was a significant decrease in GHP score in patients with fibrosis and in well-being score in patients with ductopenia. HS had the most significant impact on overall-QOL score and this was independent of alcohol consumption, fibrosis, diabetes and BMI.

Post-LT development of HS in recipients has only been analyzed in few studies so far^[18]. Post-transplant metabolic syndrome and graft NAFLD are being increasingly recognized as long term problems in LT recipients^[19,20]. Patients with post-LT NAFLD develop at the least an increased risk of cardiovascular events, rejection and infection^[21]. Recently, a retrospective study reported that the reasons for long term steatosis in liver allografts may be related to seven factors either present alone or in combination, such as graft steatosis at the time of transplantation, HCV infection, recurrence of NAFLD or alcoholic liver disease, metabolic syndrome, diabetes

mellitus and *de novo* NAFLD^[22]. Most of these factors are known risk factors for NAFLD in the non-transplant setting also.

For the determination of such potential underlying factors, we compared the groups with and without HS in our series. We could not find any significant difference between the groups, neither with respect to known metabolic risk factors not related to LT (such as incidence of diabetes, hypertension or recipient BMI) nor with respect to transplant-related factors (such as donor liver steatosis, reperfusion injury, alcohol abuse and immunosuppressive dosage). Only three of the objective variables were significantly different; HCV infection, fibrosis and patient retirement irrespective of age.

The post-transplant setting is a good background for the development of one or several components of the metabolic syndrome^[18], *de novo* NAFLD seems to be one of the most probable reasons for HS. For instance, high incidence of hypertension and hyperlipidemia in patients on Cyclosporine-based immunosuppressive regimen and diabetes mellitus in patients on Tacrolimus-based

regimen are well-known side effects^[23]. We acknowledge that at the time of this study almost all patients (96%) were on Cyclosporine and our results may not be applicable to patients who are on Tacrolimus.

Interestingly, in our series HS in the 10 year allograft

biopsies were related to HCV infection, rather than NAFLD or other causes. HCV infection is well known to highly influence the rate of not only liver fibrosis but also HS. In the non-transplant setting steatosis is a very common lesion in chronic HCV infection^[24], and

the pathogenesis of steatosis may differ according to the genotype of HCV. Strong clinical and experimental evidence suggests that steatosis in patients infected with genotype 3 is partly related to a direct cytopathic effect, whereas in genotype 1, steatosis is mainly related to an associated metabolic syndrome and insulin resistance^[25]. Because the predominant HCV genotype in our patients with HS was the genotype 1 (63%), mostly 1b subtype, and genotype 3 represented 16% (all in HS group), we can consider that both mechanisms were involved.

HCV seems to dominate other risk factors in our study. One explanation for this findings may be that a type II error occurred because of the relatively small sample size ($n = 72$ and only 24 in HS group). Otherwise, HS is presumably a surrogate for chronic hepatitis C, which is more directly affecting the QOL from chronic viral infection than the presence of histologic steatosis.

Unfortunately, HCV recurs in nearly all liver transplant recipients, and the reduction in long-term survival observed in these patients is the result of progressive fibrosis and evolution into cirrhosis^[26-30]. Among the recipients with HCV infection, those who achieved 10 year post-transplant survival in our series can probably be categorized as "slow fibrosers". Fibrosis was present in 71% of our patients with HS and was mainly related to HCV infection.

Other symptoms like changes in facial appearance, fluid retention or swelling of ankles, and headaches affected the QOL of long term survivors. These symptoms are probably associated to the long term medication that patients require after LT. Moreover, in addition to muscle weakness, these physical affections presumably had a repercussion on PD; predominantly nervousness, anxiety, sadness or depression associated with sleeplessness

Table 5 Multivariate analysis of independent factors of hepatic steatosis at 10-year biopsy

Factors	Multivariate <i>P</i>
Objective factors	
Retirement	0.04
Hepatitis C virus infection (<i>de novo</i> or recurrence)	< 0.01
Subjective factors	
Abdominal pains or discomfort	< 0.01
Joint aches or pains	0.04

or insomnia. As a consequence, PD, SRF, and GHP also worsened in patients with HS.

The impact of HS on QOL has been already reported in non-transplanted patients. Recent studies demonstrated the negative impact of NAFLD on the physical and psychological function^[31-33]. Newton *et al.*^[31] refuted the misconception that symptoms associated with NAFLD are entirely related to excessive weight, a concept that supported by our data. It is well recognized that the major risk factor for HS is excessive consumption of food, alcohol, or both. However, many people who over-consume do not have fatty livers, and steatosis can develop in those who do not engage in these behaviors. Thus, genetic or environmental factors or both could influence one's susceptibility to hepatic triglyceride accumulation^[34-36].

Future perspectives in the transplant setting must inevitably imply the host and the graft. At the present time, the gold standard for diagnosis remains liver biopsy but its costs and risks limit its practice in the non-transplant setting. Some demographic factors, blood tests, and imaging studies can be used to predict a higher risk of steato-hepatitis or advanced fibrosis, but are of limited sensitivity and specificity. More accurate predictors and scoring systems would allow identification of those who would benefit most from liver biopsy and monitor disease progression and response to therapy^[19].

In conclusion, we could demonstrate that in patients with long-term follow-up after LT, HS is the most important histological finding that has an impact on the patients' quality of life. Interventions are needed to restore and optimize QOL in patients with *de novo* or recurrent HS during long-term follow-up. Future research should focus on identifying factors that lead to the development of HS after LT.

COMMENTS

Background

The goal of liver transplantation is to ameliorate not only survival, but also quality of life (QOL) while minimizing the effects of disease and costs of care. The increasing proportion of recipients alive at long-term follow up has incited transplant professionals to focus on long term morbidity-free survival and an acceptable QOL. In this study the authors evaluated the relationship between the state of transplanted liver graft and the recipient QOL of histologically proven lesions in a 10-year post liver transplantation (LT) cohort of patients.

Research frontiers

Studies of long-term survivors have been mainly based on clinical data and follow up at long term with respect to indication of LT, immunosuppressive

regimen or recipient and donor criteria. Few studies assessed the graft histology by long-term graft biopsy protocol and, to our knowledge; no report assessing the relationship between the histological state of long-term transplanted liver graft and the recipient QOL has been published.

Innovations and breakthroughs

The results of this study showed a potential impact of graft's steatosis on the QOL of transplant patients 10 years after surgery.

Applications

These results are encouraging and may represent the beginning of further studies in the area and, consequently the establishment of a specific care of these patients.

Peer-review

An interesting experience on the histological explore the outcome of 10-year liver transplantation. Manuscript is well written.

Abstract

AIM

To evaluate and compare the outcomes of kidney transplant (KT) from deceased donors among standard criteria, acute kidney injury (AKI) and expanded criteria donors (ECDs).

METHODS

This retrospective study included 111 deceased donor kidney transplant recipients (DDKT). Deceased donors were classified as standard criteria donor (SCD), AKI donor and ECD. AKI was diagnosed and classified based on change of serum Cr by acute kidney injury network (AKIN) criteria. Primary outcome was one-year estimated glomerular filtration rate (eGFR) calculated from Cr by CKD-EPI. Multivariate regression analysis was done by adjusting factors such as type of DDKT, %Panel-reactive antibodies, cold ischemic time, the presence of delayed graft function and the use of induction therapy. Significant

factors that can affect the primary outcomes were then identified.

RESULTS

ECD group had a significantly lower eGFR at one year (33.9 ± 17.3 mL/min) when compared with AKI group (56.6 ± 23.9) and SCD group (63.6 ± 19.9) ($P < 0.001$). For AKI group, one-year eGFR was also indifferent among AKIN stage 1, 2 or 3. Patients with AKIN stage 3 had progressive increase of eGFR from 49.6 ± 27.2 at discharge to 61.9 ± 29.0 mL/min at one year. From Kaplan-Meier analysis, AKI donor showed better two-year graft survival than ECD (100% vs 88.5%, $P = 0.006$). Interestingly, AKI group had a stable eGFR at one and two year. The two-year eGFR of AKI group was not significantly different from SCD group (56.6 ± 24.5 mL/min vs 58.6 ± 23.2 mL/min, $P = 0.65$).

CONCLUSION

Kidney transplantations from deceased donors with variable stage of acute kidney injuries were associated with favorable two-year allograft function. The outcomes were comparable with KT from SCD. This information supports the option that deceased donors with AKI are an important source of organ for kidney transplantation even in the presence of stage 3 AKI.

Key words: Acute kidney injury donor; Rising of terminal serum creatinine; Acute kidney injury network stage; Deceased donor; Estimated glomerular filtration rate stabilization; Stabilize allograft function

Core tip: Many concerns about problems from using kidneys donated from donors who had acute kidney injury (AKI) before organ procurement lead to underutilization of such kidneys. Several kidneys have unnecessary been discarded in recent year. Here, we describe the comparable allograft and patient outcomes between using kidney from standard criteria donor and donor with AKI. Kidney transplantations from deceased donors with variable stages of acute kidney injuries were associated with favorable allograft function. This information supports the option that deceased donors with AKI are an important source of organ for kidney transplantation and can remedy the problem of organ shortage.

Stabilization of estimated glomerular filtration rate in kidney transplantation from deceased donors with acute kidney injuries. *World J Transplant* 2016; 6(4): 712-718 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/712.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.712>

INTRODUCTION

An increasing tendency to perform kidney transplant

(KT) from deceased donors other than standard criteria donor (SCD) is the result of disparity between the number of patient being in the waiting list for transplantation and utilized donor pool^[1]. Types of non-ideal deceased donor include donors with acute kidney injury (AKI) and expanded criteria donor (ECD) are being used for expanding donor pool^[2]. However, there are concerns about worse allograft outcomes when using kidneys from AKI donors. Therefore, a significant number of kidneys from AKI donors with high terminal serum creatinine level have been discarded. Hence, the plan to solve problem of organ shortage cannot be accomplished.

Increased incidence of delayed graft function (DGF)^[3,4] is a significant disadvantage of using kidneys from AKI donors. This can lead to increased hospital stay and cost of treatment or even worse allograft function^[5] when compare with KT from SCD. In addition, it is uncertain whether KT from AKI donor is associated with increased risk of acute rejection or allograft loss when compare with KT from using kidney from standard deceased donor^[3,4]. Since AKI can occur from different causes and have different severities, the outcomes of KT from donors with AKI may be varied. Theoretically, KT from donors with mild degree of AKI may have favorable outcomes than KT from severe AKI. However, it is not universally agreed to use kidneys from donors with AKI. There are studies reporting association of discarding kidney in the presence of AKI of deceased donor^[6]. We conducted a study aimed to determine outcomes of kidney transplantation from deceased donors with variable degrees of acute kidney injuries.

MATERIALS AND METHODS

Patients

A retrospective cohort of 243 KT recipients from our single center hospital during 1st January 2012 to 31st December 2013 was reviewed. Inclusion criteria were (1) deceased donor kidney transplant (DDKT) recipient; (2) Age ≥ 15 years old; (3) Negative lymphocytotoxic cross match result at the time of transplantation; and (4) Panel-reactive antibodies (PRA) luminex $< 20\%$. Exclusion criteria were: (1) recipients who had combined solid organ transplantation; and (2) donor whose terminal serum creatinine increased ≥ 0.3 mg/dL but not ≥ 1.5 -fold from baseline. From these inclusion and exclusion criteria (excluded 115 cases due to living related kidney transplantation, 8 cases due to age < 15 years, 1 case due to combined solid organ transplant and 8 cases due to terminal serum creatinine increased ≥ 0.3 mg/dL but not ≥ 1.5 -fold from baseline), total 111 KT recipients who received DDKT were enrolled in the study. This study was approved by the study center Institutional Review Board/Ethics Committee.

Study procedure

Baseline transplantation data and the clinical outcomes at two-year were collected from all patients then compared

outcomes by statistical analysis. Study populations were stratified into 3 groups according to the donor status: (1) Standard criteria deceased donor (SCD); (2) Deceased donor with AKI donor; and (3) Expanded criteria deceased donor (ECD). AKI donor was recognized by a rising of serum creatinine more than 0.3 mg/dL and defined by AKI Network criteria (AKIN criteria^[7]) based on baseline to terminal serum creatinine (Cr) as follows: Stage 1, increase in Cr ≥ 1.5 to < 2 -fold increase; stage 2, 2 to < 3 fold increase and stage 3, ≥ 3 -fold increase. However, we did not included AKI donors who have terminal serum creatinine less than 1.5 fold from baseline to ensure that degree of AKI was significant enough to have impacts on transplantation outcomes. ECD was defined by any donor over the age of 60, or a donor over the age of 50 with two of the following: A history of high blood pressure, a creatinine greater than or equal to 1.5 mg/dL, or death resulting from a stroke. All other donors were classified as SCD.

Outcomes

Primary outcome was estimated glomerular filtration rate (eGFR) at one year as calculated from Cr by CKD-EPI equation. Secondary outcomes were eGFR at discharge and two year, rate of DGF (defined as requirement of dialysis within 7 d after transplantation), two-year allograft and patient survival.

Statistical analysis

Continuous variables were described as mean values (SD) and median values (range) for data with normal distribution and non-normal distribution respectively. Categorical variables were described as frequency and percentage. Student *t* test (or Mann-Whitney *U* test) was used to compare the difference between groups for continuous data. A χ^2 test (or Fisher's exact test) was used to compare the difference between groups for categorical data. Multivariate regression analysis was used to determine independently significant factors (type of DDKT, %PRA, cold ischemic time, the presence of DGF and the use of induction therapy) that may affect one-year eGFR. Allograft survival and patient survival were presented by Kaplan Meier analysis. All analyses were performed using Stata statistical software, version 13.0 (Stata Corp., Collage Station, TX). $P < 0.5$ was considered significant. The statistical review of the study was performed by a biomedical statistician.

RESULTS

A total of 119 DDKT recipients were enrolled. Eight recipients receiving kidney from AKI donors whose terminal serum creatinine increased ≥ 0.3 mg/dL but not ≥ 1.5 -fold from baseline and were excluded. One hundred and eleven patients were included in the analysis. There were 32 recipients in SCD group, 51 in AKI group and 28 in ECD group. Recipient and donor characteristics are shown in Table 1. All recipient baseline characteristics

were similar among 3 groups. Donor age was older in ECD group than the other groups. Most donors were male and the proportion was highest in AKI group. Basiliximab (Simulect[®]) was commonly used for induction in both SCD (34.4%) and AKI group (47.1%). Antithymocyte globulin (ATG) was frequently used in ECD group (39.9%). However, the different in prescribing induction therapy was not statistically significant ($P = 0.19$). Maintenance immunosuppressive regimens were shown in Table 1. The combination of cyclosporine and everolimus was more commonly used in AKI and ECD donor when compared with standard criteria deceased donor ($P = 0.05$).

eGFR at discharge was 64.1 ± 22.1 , 52.5 ± 22.9 and 35.5 ± 17.9 mL/min for SCD, AKI and ECD group. eGFR at one year was 63.6 ± 19.9 , 56.6 ± 23.9 and 33.9 ± 17.3 mL/min for SCD, AKI and ECD group. eGFR at two year was 58.6 ± 23.2 , 56.6 ± 24.5 and 29.9 ± 19.2 mL/min in SCD, AKI and ECD group respectively (Table 2). Two-year eGFR was significant lower in ECD group ($P < 0.001$) when compared with the other groups but was not different between SCD group and AKI group ($P = 0.65$). For AKI group, two-year eGFR was also indifferent among degree of AKI as classified by AKIN stage 1, 2 or 3 (Table 3). Two-year eGFR for AKI group with AKIN stage 1, 2 and 3 was 53.4 ± 24.3 , 54.0 ± 21.4 and 64.0 ± 29.4 mL/min ($P = 0.79$). While two-year eGFR in both SCD and ECD groups decreased over time after transplantation, two-year eGFR in AKI group had tendency to improve over time after transplantation especially in AKIN stage 3 (Table 3). In AKIN stage 3 group, two-year eGFR progressively improved from 49.6 ± 27.2 mL/min after transplant to 64.0 ± 29.4 mL/min. However, this change was not statistically different ($P = 0.12$). Univariate regression analysis showed that the use of ECD and presence of DGF were significantly associated with decreased of eGFR at one year by univariate model. However, multivariate regression analysis showed that use of ECD is the only factor that was associated with declining one-year eGFR (Table 4).

Rate of DGF was lowest in SCD group and highest in ECD group. DGF occurred 31.2%, 56.9% and 77.8% for each group ($P = 0.001$). Rate of acute rejection was not differed among the three groups (Table 2). Two-year allograft survival was 100%, 100% and 88.5% for each group (Figure 1, $P = 0.01$). Two-year patient survival rate was similar among three groups (Figure 2). Cardiovascular death was responsible for cause of death in 1, 3 and 1 recipient in SCD, AKI and ECD group respectively. Infection related death was responsible for cause of death in 1 recipient both from SCD and ECD group. Rate of CMV and BK virus infection were not difference among 3 groups (Table 2).

DISCUSSION

Our findings suggest that transplantation from deceased donors with AKI have comparable outcome when compared with SCD. The outcomes include both eGFR and

two year patient survival. In addition, eGFR of AKI group did not decline after two year follow up. In contrast, eGFR in ECD group significantly declined after two year. This finding supports the view that kidneys with AKI may have recovery after a period of time.

In native kidney, after injury subsides, kidney can repair itself and restore normal or sub-normal function over time depends on severity and duration of injury^[8]. Our finding suggests that these processes also occur in transplanted kidney. As shown in AKI group, one-year eGFR had progressive increase from baseline and stable at two-year follow up in all three groups. However, there are difficulties to predict the ability of each kidney allograft regarding the ability to recovery from acute kidney injuries. A calculation of "Kidney Donor Profile Index"^(9,10) has been proposed to predict the risk of graft loss after deceased donor kidney transplantation. The involved donors' parameters include age, height, weight, ethnicity, history of hypertension, history of

diabetes, causes of death, serum creatinine, HCV status and donation after circulatory death status. However, the calculations of KDPI use a single value of serum creatinine and may or may not be indicative the presence of AKI in the donors. Evidences from some studies showed worse allograft function from AKI donor. These suggested that not all kidneys from AKI donor were suitable for transplantation. Researches providing such information are necessary and useful for making decision on which kidney should be used or discarded.

In the recent years, kidneys from AKI donor were underutilization. As shown in some studies that there are high discard rate of deceased donor with high serum creatinine. About 20%-30% of kidneys from AKI donors were discarded and sometime more than 40 percent were discarded when terminal serum creatinine > 2.0 mg/dL^[3,6,11]. In contrast, our study has shown that KT from deceased donors with AKI is associated with comparable clinical outcomes with standard criteria deceased donors.

The B-coefficient values were calculated from univariate and multivariate regression analysis. SCD: Standard criteria donor; AKI: Acute kidney injury; ECD: Expanded criteria donor; PRA: Panel reactive antibody; DGF: Delayed graft function; HLA: Human leukocyte antigen.

Thus, our results show that kidneys from AKI donor are important source for organ transplantation and should not be discarded.

The limitation of our study is that there may be selection bias regarding the quality of kidneys when compare with other studies^[3,6]. Pre-implantation biopsy and organ perfusion machine are not routinely used in this study for the organ procurement process. These can

lead to more kidneys being used when organ retrieval process was satisfied as judged by the clinician.

In summary, kidney transplantations from deceased donors with variable stages of acute kidney injuries were associated with favorable two-year allograft function and survival. The outcomes were comparable with KT from those of standard criteria deceased donors. This information supports the option that deceased donors

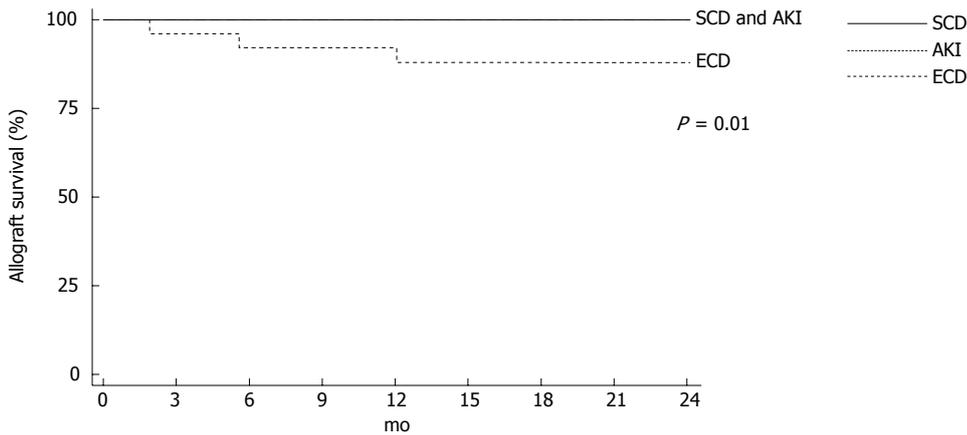

Figure 1 Comparison of two year actuarial allograft survival of standard criteria deceased donor, acute kidney injury donors and expanded criteria donors. SCD: Standard criteria donor; AKI: Acute kidney injury; ECD: Expanded criteria donor.

with AKI are an important source of organ for kidney transplantation even in the presence of stage 3 AKI. However, not all kidneys from AKI donor may be used for transplantation. Further studies are required to determine and clarify the optimal use of kidneys with AKI and the precise parameters that can identify suitable kidneys from AKI donor suitable for proceeding to transplantation.

plantation from AKI donor. These suggest that not all kidneys from AKI donor were suitable for transplantation. Researches providing such information are necessary and useful for decision whether which kidney should be used or discarded.

COMMENTS

Background

Organ shortage is a common problem worldwide. Kidney transplantations from non-ideal deceased donors are a potential option to minimize this problem. Acute kidney injury (AKI) donor and expanded criteria donor (ECD) are important sources of deceased donors. However, there are several challenging issues about the outcomes of using kidney from AKI donors or ECD. This can lead to the discard of using deceased donors with high terminal serum creatinine (Cr). The “old to old” concept has been proposed to be the model of allocating kidneys from ECD. However, there is no consensus guideline regarding the use of kidneys from AKI donors. The authors therefore evaluate the outcomes of kidney transplant from deceased donors with several stages of AKI and compare with that of standard criteria donors (SCDs) and ECDs.

Innovations and breakthroughs

Many kidneys from AKI donors were discarded because of concerning about poor allograft outcomes. This study showed that kidney transplantation from deceased donors with variable stage of acute kidney injuries was associated with equivalent allograft function and survival when compare with SCD.

Applications

Kidneys from AKI donors are important sources of organ for transplantation that can mitigate the problem of organ shortage.

Abstract

AIM

To investigate the incidence, risk factors and clinical outcomes of acute antibody-mediated rejection (ABMR) after intestinal transplantation (ITx).

METHODS

A retrospective single-center analysis was performed to identify cases of acute ABMR after ITx, based on the presence of donor-specific antibody (DSA), acute tissue damage, C4d deposition, and allograft dysfunction.

RESULTS

Acute ABMR was identified in 18 (10.3%) out of 175 intestinal allografts with an average occurrence of 10 d (range, 4-162) after ITx. All acute ABMR cases were presensitized to donor human leukocyte antigens class I and/or II antigens with a detectable DSA. A positive cross-match was seen in 14 (77.8%) cases and twelve of 18 patients (66.7%) produced newly-formed DSA following ITx. Histological characteristics of acute ABMR include endothelial C4d deposits, interstitial hemorrhage, and severe congestion with focal fibrin thrombin in the lamina propria capillaries. Multivariate analysis identified a liver-free graft and high level of panel reactive antibody

as a significant independent risk factor. Despite initial improvement after therapy, eleven recipients (61.1%) lost transplant secondary to rejection. Of those, 9 (50%) underwent graft removal and 4 (22.2%) received second transplantation following acute ABMR. At an average follow-up of 32.3 mo (range, 13.3-76.4), 8 (44.4%) recipients died.

CONCLUSION

Our results indicate that acute ABMR is an important cause of intestine graft dysfunction, particularly in a liver-exclusive graft and survivors are at an increased risk of developing refractory acute rejection and chronic rejection. More effective strategies to prevent and manage acute ABMR are needed to improve outcomes.

Core tip: Antibody-mediated rejection (ABMR) has appeared to be an important cause of allograft failure after intestinal transplantation (ITx). This study aimed to evaluate the incidence, risk factors and clinical outcomes of acute ABMR after ITx. The incidence of acute ABMR after ITx was as high as 10.3% in our series, which was closely associated with poor graft and patient survival. Our results indicate that acute ABMR is an important cause of intestinal graft failure, especially in a liver-free allograft and survivors are at an increased risk of developing chronic rejection. Effective strategies to prevent and treat acute ABMR are needed to improve outcomes.

INTRODUCTION

Intestinal transplantation (ITx) has increasingly become a viable option for most patients with irreversible intestinal failure. Short-term patient and graft survival have improved to a great extent due to advances in surgical technology and immunosuppressive management^[1,2]. However, long-term outcomes after ITx have been inferior to other solid-organ transplants, especially with less intestinal allograft survival more than 10 years^[3,4]. Allograft failure secondary to acute and chronic rejection remain a significant impediment to the success of ITx^[5].

Traditionally, intestine transplant rejection has been considered as a T-cell-mediated course that can be effectively controlled with T-cell targeted immunosuppressive agents. Harmful effects of antibodies to human leukocyte antigens (HLA) in intestinal allograft rejection have not been studied thoroughly although

these HLA antibodies were often detectable after ITx^[6-8]. To date, HLA antibodies are believed to be a major risk factor for hyperacute rejection, acute antibody-mediated rejection (ABMR) and chronic ABMR after kidney or heart transplantation^[9]. Several case reports imply that HLA antibodies are also associated with lung, liver, or pancreas allograft dysfunction^[10-12]. Increasing data suggest that an early diagnosis and prompt management of acute ABMR are essential for improving patient and graft outcomes^[13,14].

The impact of HLA antibodies has got less attention in the assessment of acute intestinal allograft rejection. Similar to other solid-organ transplantation, many patients who require ITx become sensitized and form alloantibodies that originate either from previous exposure to blood products, pregnancies, transplants, and/or infections or *de novo* formation of donor-specific antibody (DSA) following transplantation^[15,16]. In recent years, we and others have shown that the presence of DSA was closely associated with the incidence and severity of intestinal allograft rejection and decreased the overall graft and patient survival^[17,18]. Although hyperacute rejection, caused by preformed DSA, rarely occurs in highly sensitized recipients after ITx^[19], clinicopathological findings consistent with acute ABMR have increasingly been recognized as an important form of rejection^[20,21]. Currently diagnostic standards for acute ABMR after ITx have not been set up yet and its incidence and clinical significance have remained unknown.

The diagnostic standards for acute ABMR in a kidney or heart transplant have been well-established. According to the guidelines, acute ABMR is defined by circulating DSA, C4d deposition, tissue pathology and clinical allograft dysfunction. In this series, we reviewed our institutional experience to identify recipients with acute ABMR that fulfill the criteria for kidney transplantation, and to evaluate the rate, risk factors and consequences after acute ABMR.

MATERIALS AND METHODS

Patient selection

Since August 2003, patients who received small bowel transplants at the University of Pittsburgh Medical Center have started to have a routine serum DSA specificities determinations, by either the purified HLA antigen-based ELISA or the Luminex single-antigen bead analysis. We performed a retrospective electronic medical records review of patients who underwent a small bowel transplant between August 2003 and May 2010. The clinical charts were reviewed as needed for additional data and the Institutional Review Board approved this study.

Donor and recipient demographics are summarized in Table 1. The transplant type consisted of a liver-exclusive transplant (isolated intestine graft and modified multivisceral graft without liver) and a liver-inclusive full multivisceral transplant. T cell complement-dependent lymphocytotoxic cross-match (CDC-XM) was performed by anti-human globulin (AHG)-enhanced method and

CMV: Cytomegalovirus; PRA: Panel reactive antibody; HLA: Human leukocyte antigens; DSA: Donor-specific antibody.

B cell CDC-XM was performed by extended-incubation/modified Amos technique. In our practice, a positive CDC-XM was not considered as a contraindication to ITx. HLA panel reactive antibody (PRA) was determined by LAT ELISA assay. The HLA antibodies were checked by the purified HLA antigen-based ELISA prior to April 2007 and have since then been replaced by the Luminex single-antigen bead assay. A value of the mean fluorescence intensity (MFI) ≥ 1000 was considered positive. We did not routinely follow up DSA levels post-transplant and indications for DSA monitoring were usually higher PRA levels, refractory rejection, or suspicious of acute ABMR.

The majority of patients underwent induction therapy with alemtuzumab (Campath-1H; Genzyme, Cambridge, MA) (*n* = 124), administered at day 0 (30 mg each dose) and some patients received antithymocyte globulin (ATG; Genzyme, Cambridge, MA) (*n* = 7), the IL-2 receptor antagonist basiliximab (Simulect; Novartis, East Hanover, NJ) (*n* = 3) or no induction therapy (*n* = 41) during the early period of this study. The basic immunosuppressive regimen was tacrolimus (Prograf; Astellas, Deerfield, IL) and steroids. The 12-h trough levels of tacrolimus during the initial six months were targeted at 10-15 ng/mL with Campath-1H or ATG induction therapy, and 15-25 ng/mL with Simulect induction or without any treatment. Maintenance immunosuppression was similar between a

positive and negative CDC-XM. All patients with a positive preformed DSA were given a single-dose of intravenous immunoglobulin (IVIG) at 2 g/kg body weight on day of transplantation. A 5-d steroid tapering was also given followed by a 10-20 mg daily dose for at least 6 mo. Recipients with acute ABMR underwent steroid boluses and/or OKT3. No patients were given plasmapheresis or anti-B cell treatment for acute ABMR.

Diagnosis of rejection

Surveillance ileal biopsies were routinely performed twice per week for the first 2 to 3 wk after transplantation and then once a week thereafter, with increased frequency in case of clinical indications. A diagnosis of acute ABMR was based upon the criteria, including: (1) clinical evidence of graft dysfunction; (2) histological evidence of tissue damage (vascular congestion, submucosal hemorrhage, neutrophilic margination, and platelet-fibrin thrombi in the lamina propria microvasculature)^[7]; (3) focal (5%-50%) or diffuse (> 50%) linear C4d deposition; and (4) circulating anti-HLA antibodies^[9,22,23]. A C4d staining was done on formalin-fixed paraffin-embedded tissue when acute ABMR was clinically or histologically suspected. The histological criteria for diagnosis of acute cellular rejection (ACR) were as described previously^[24]. A new rejection episode was defined by newly occurred clinical symptoms and histological evidence of acute rejection with at least 1 normal mucosal biopsy between rejection episodes. A determination of chronic rejection was based upon clinical symptoms and was further confirmed by a full-thickness specimen of partially or totally resected allografts to reveal evidence of vasculopathy and mesenteric lymphoid depletion with mesenteric sclerosis^[25].

Statistical analysis

Results are shown as means and ranges, unless otherwise stated. Categorical variables were assessed with the use of the χ^2 test or, when appropriate, Fisher's exact test. Continuous variables were analyzed with the use of the Student's *t*-test. Survival time was analyzed with the Kaplan-Meier method and differences were assessed by log-rank test. All data were analyzed using MedCalc for Windows, version 12.5 (MedCalc Software, Ostend, Belgium).

RESULTS

Diagnosis of acute ABMR after ITx

During the study period, 164 adults underwent 175 consecutive small bowel transplants; 11 (6.7%) patients underwent retransplantation. Donor characteristics, recipient profiles, and perioperative features are summarized in Table 1. We identified 18 cases (10.3%) that fulfilled all the criteria for acute ABMR proposed by the National Conference. Of these, 16 of 164 cases (9.8%) developed acute ABMR after primary transplantation and 2 of 11 cases (18.2%) developed acute ABMR after retransplantation (Figure 1). Recipient age at the time

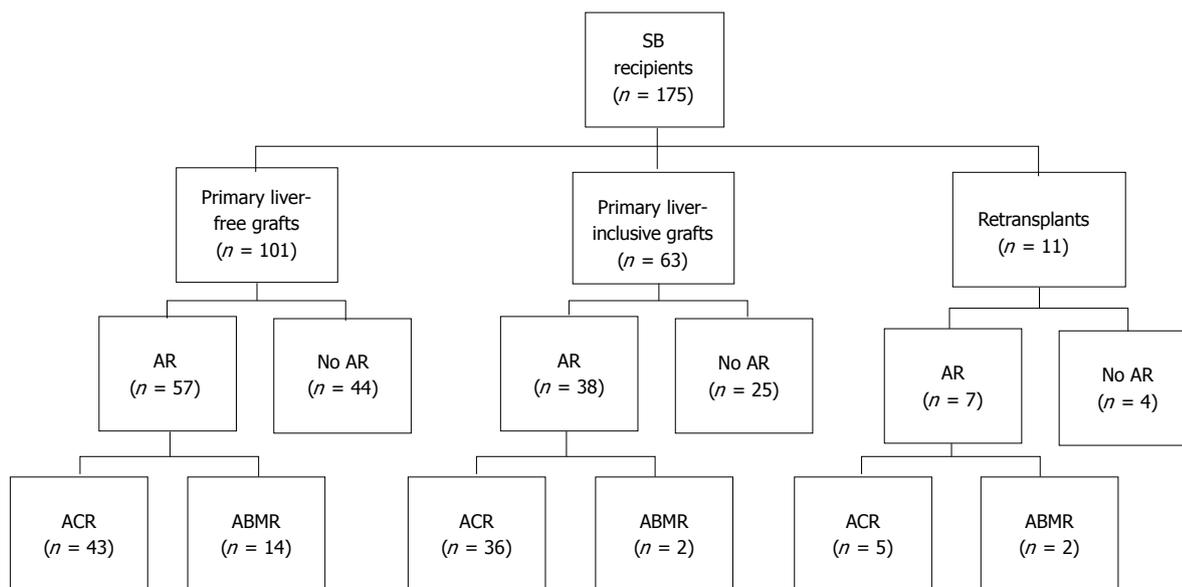

Figure 1 Patient distribution according to graft type and acute rejection type. SB: Small bowel; AR: Acute rejection; ACR: Acute cellular rejection; ABMR: Acute antibody-mediated rejection.

of transplantation was 25.4 ± 9.9 years old and thirteen cases (72.2%) were female. All patients were sensitized to HLA class I (median PRA 78.5%, range 11%-100%) and/or HLA class II antigens (median PRA 67.0%, range 1%-100%). A CDC-XM was positive in 14 (77.8%) recipients, in which anti-donor antibody titer was $\geq 1:8$ in 7 cases (50.0%). Three recipients (16.7%) underwent splenectomy at the time of transplantation (2 at primary transplantation and 1 at retransplantation). Recipients developed acute ABMR at a median time of 10.0 d (range, 4-162 d). Fourteen patients presented within 30 d after transplantation (early acute ABMR) and the remaining 4 presented beyond 30 d (late acute ABMR). Fifteen patients developed a single episode of acute ABMR and three developed repeat episodes of ABMR (Table 2).

In all cases, we established the diagnosis of acute ABMR based on the combination of clinical evidence of graft dysfunction, histological findings, and the presence of DSA. Six (37.5%) patients with acute ABMR occurring within a week displayed evidence of graft dysfunction by severe mucosal vascular congestion and diffuse mucosal hemorrhage during endoscopic examination. The other clinical presentation includes fever, abdominal pain or distention, increased stomal output or other non-specific symptoms. The prominent pathological findings in the cases with early ABMR were vascular congestion, focal hemorrhage with focal platelet-fibrin thrombi, and capillary neutrophilic infiltration in the lamina propria and the submucosa. The mucosal biopsies obtained from acute ABMR occurring within a week showed severe vascular congestion along with diffuse mucosal hemorrhage without any evidence of crypt and epithelial injury or apoptosis. These changes gradually returned to normal by 2 to 3 wk in most cases after treatment. Four cases with late ABMR exhibited less prominent vascular congestion and hemorrhage

but showed significant fibrin thrombi or neutrophilic margination (Table 2). There was no evidence of any significant vasculitis in the biopsies we evaluated. Seventeen cases showed a diffuse C4d deposition in the lamina propria and the submucosal capillaries (Figure 2). One case with a liver-inclusive transplant showed focal C4d deposition of the intestinal allograft but with significant vascular disturbance. Four of the 18 patients had pure acute ABMR without concomitant ACR within a year and the remaining 14 patients had concomitant ACR either before ABMR ($n = 3$), at the time of ABMR ($n = 4$), or after a diagnosis of ABMR ($n = 9$) (Table 2).

All 18 patients had DSA at the time of transplant: 10 to Class I HLA, 1 to Class II HLA only, and 7 to both Class I and Class II HLA. DSA was persistent in 3 cases at the time of the second episode of acute ABMR (Table 2). These antibodies were detected in fourteen cases by the purified HLA antigen-based ELISA and in the remaining four cases by the Luminex single-antigen bead assay.

Treatment, graft loss and patient death

Our treatment approach evolved over time and the regimen was individualized based on severity of illness, clinical course and response to therapy (Table 3). All patients were initially given intravenous steroids. Thirteen patients required additional OKT3 ($n = 10$), ATG ($n = 1$), Campath-1H ($n = 1$), or Campath-1H followed by OKT3 ($n = 1$) to reverse acute ABMR.

During the study period, post-transplant HLA antibodies were checked in 158 (90.3%) cases. *De novo* DSA was detected in twelve of the 18 patients (66.7%): 7 to Class II HLA, 5 to both Class I and Class II HLA. The presence of *de novo* DSA was markedly higher in the cases with acute ABMR compared to 7.6% (5 of 66) in the cases without rejection ($P < 0.0001$) or

Type of transplant: SB: An isolated small bowel; MV: A full multivisceral graft. ¹Patients with repeat ABMR; ²Patient with a history of ABMR after prior transplant; ³Patient with prior transplant. ST: Steroids; IVIG: Intravenous immunoglobulin; ACR: Acute cellular rejection; CHR: Chronic rejection.

21.6% (16 of 74) in the cases with ACR ($P < 0.001$). Graft failure occurred in 12 (66.7%) of the 18 patients with acute ABMR. The causes of graft loss were chronic rejection in 8 cases, severe ACR in 2, persistent ABMR in 1, and unknown etiology in 1 (Table 3). Nine cases underwent enterectomy due to rejection. Of those, *de novo* DSA was detectable in 7 cases prior to enterectomy and was persistent after graft removal. Two cases had undetectable levels of *de novo* DSA by the ELISA

assay before enterectomy but became detectable after enterectomy. The presence of a newly-formed DSA was closely associated with graft loss ($P < 0.0001$). Compared with no rejectors, intestinal graft survival was significantly lower in patients with acute ABMR ($P = 0.0001$) or ACR ($P = 0.0009$). Graft survival was lower in acute ABMR than in ACR but the differences between them did not reach statistical significance ($P = 0.088$) (Figure 3A). Patient survival was worse in acute ABMR

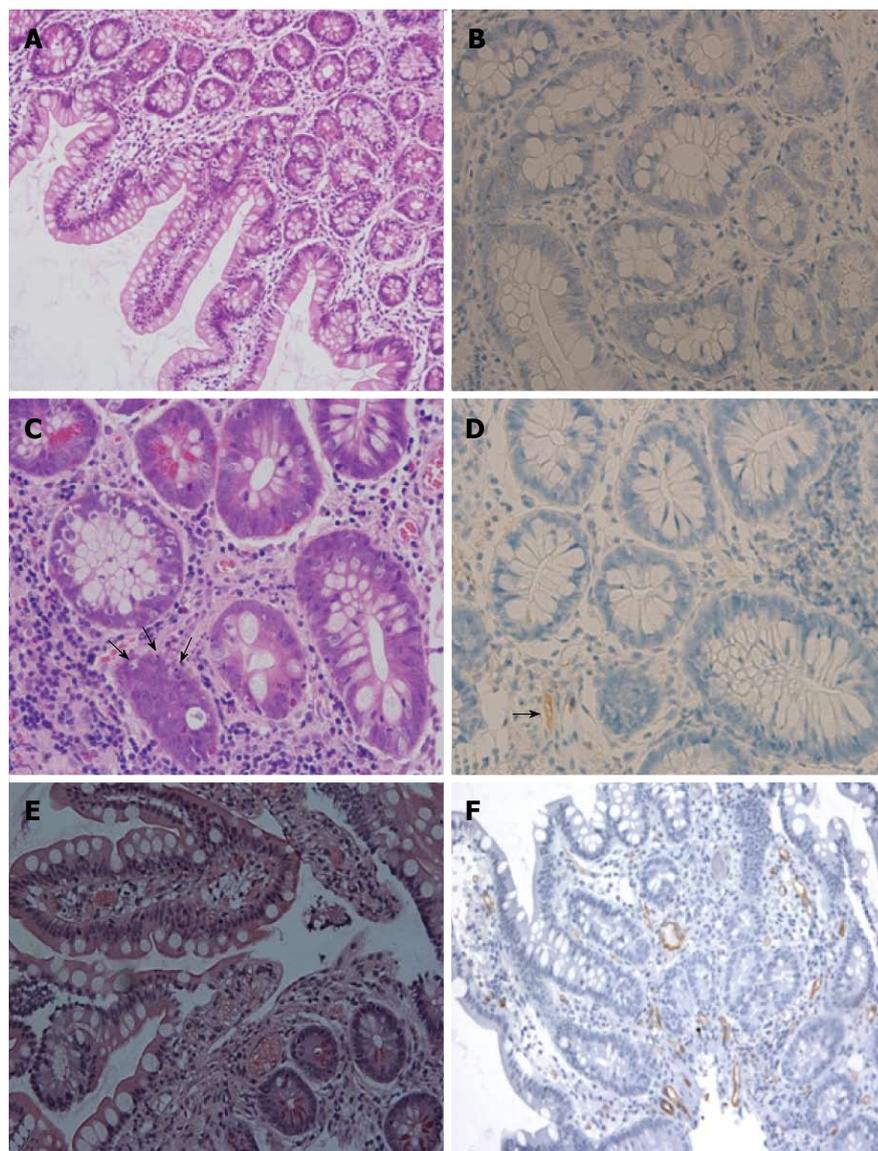

Figure 2 Histopathology of intestinal allograft. A and B: No rejection: normal mucosal architecture of small bowel biopsy after transplantation. No staining for C4d is seen in the capillaries of the lamina propria; C and D: Acute cellular rejection (ACR): There is mononuclear infiltration, crypt epithelial injury, and apoptotic bodies (arrows) in the lamina propria. Weak and focal staining for C4d (arrows) is sometimes present in a patient with ACR; E and F: Acute antibody-mediated rejection (ABMR): There is prominent hemorrhage and congestion with scattered fibrin thrombin in the lamina propria. Widespread and bright staining for C4d is present in the capillaries of the lamina propria. Magnifications: × 200 in A, E and F; × 400 in B, C and D. A, C, E: H and E; B, D, F: C4d.

or ACR than in no rejectors ($P = 0.0264$). There were no statistical differences in patient survival between ABMR and ACR (Figure 3B).

A total of five patients underwent repeat transplants, including a liver-inclusive graft in 4 and a liver-free intestinal graft in 1 patient. Of those, three patients had acute ABMR after primary transplantation and two patients had acute ABMR after retransplant. Four patients underwent repeat transplants after a diagnosis of acute ABMR and one with prior history of a liver-free graft developed acute ABMR after a liver-inclusive retransplant.

At an average follow-up of 32.3 mo (range, 13.3-76.4 mo), eight of the 18 (44.4%) patients died. The causes of patient death were sepsis in 4, massive gastrointestinal bleeding in 2, chronic liver failure in 1 and unknown etiology in 1 (Table 3). Patient 1 with a positive CDC XM developed acute ABMR in the intestinal allograft 4 d after a liver-inclusive intestine combined with kidney transplant. He responded well with a combination of steroids, IVIG and OKT3 therapies. One year after transplantation, he had progressively elevated liver enzymes with circulating

de novo DSA and he subsequently died due to chronic liver failure. In three patients undergoing liver-inclusive retransplants after primary graft loss, one patient died secondary to *Aspergillus* pneumonia, while the other three patients were alive with a well-functioning graft at the time of last follow-up. Two patients (#17 and #18) with a prior history of primary graft loss due to rejection developed acute ABMR after retransplantation. Patient 17 had acute ABMR 4 d after a liver-free retransplant and soon developed chronic rejection within a year with persistent *de novo* DSA and subsequently died due to massive lower GI bleeding. Patient 18 had acute ABMR 18 d after liver-inclusive retransplant, which was successfully treated with steroids and OKT3. The higher levels of preformed DSA gradually declined in this case after transplantation and she was well with functioning graft with no evidence of *de novo* DSA by the Luminex assay at the time of the last follow-up.

Risk factors for acute ABMR

In the univariate analysis, younger recipients at the time

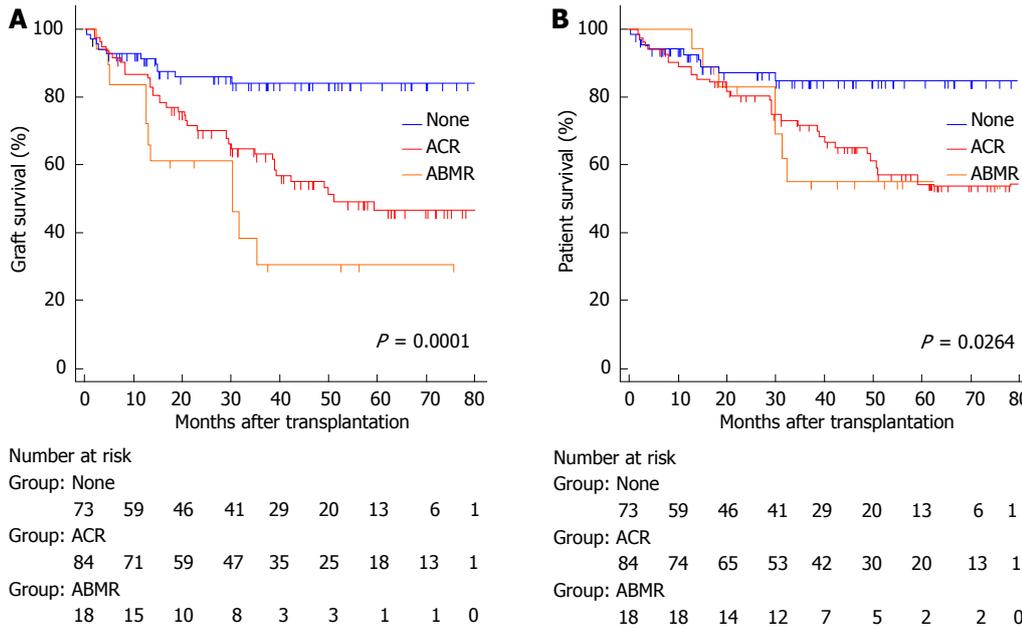

Figure 3 The Kaplan-Meier graft (A) and patient (B) survival for no acute rejection (none) (solid line), acute cellular rejection (dotted heavy line), and acute antibody-mediated rejection (dotted light line). The overall comparison was significantly different in graft (log-rank $P = 0.0001$) and patient survival (log-rank $P = 0.0264$). The patients with antibody-mediated rejection (ABMR) or acute cellular rejection (ACR) had significantly lower graft and patient survival than those without rejection. The graft survival was worse in ABMR than in ACR but the differences between them did not reach statistical significance ($P = 0.088$).

of transplant, liver-free graft, and the presence of DSA were closely related to acute ABMR. The presence of the spleen in recipients tended to be associated with acute ABMR but no statistical significance was observed ($P = 0.071$) (Table 4). In the multivariate analysis, only the presence of DSA and a liver-free graft were significantly associated with the development of acute ABMR (Table 5). Donor age, gender, cold ischemic time, cytomegalovirus donor and recipient serology, HLA mismatches, previous transplants, and induction therapy were not significantly associated with acute ABMR, and their inclusion in the multivariate model did not exclude liver-free grafts or the presence of DSA as independent risk factors.

DISCUSSION

We believe that the established diagnostic standards for acute ABMR in kidney or heart transplants can help identify acute ABMR after ITx. We found the incidence of acute ABMR of the intestinal allograft is 10.3%, on the basis of the presence of circulating DSA, evidence of C4d deposit, acute tissue injury, and clinical graft dysfunction. To our knowledge, this is the first largest series of investigation to date to retrospectively assess the incidence of acute ABMR after ITx. The most important finding in this study was that acute ABMR is closely associated with increased graft loss and poor outcomes. Our rate of intestinal graft acute ABMR is comparable to the incidence of acute ABMR reported in the kidney transplant that ranges from 7.7% to 41%, depending on the level of pre-transplant recipient sensitization status^[9,26,27]. Given the frequency and poor prognosis of acute ABMR after ITx, every effort should

be made to set up or eliminate this diagnosis in the setting of graft dysfunction to more specifically direct immunosuppressive management.

C4d deposition along graft capillaries has become a critical component to the diagnosis of acute ABMR in a kidney or heart transplant. However, the clinical relevance of a positive C4d staining in an intestinal allograft remains uncertain. Post-transplant microvascular lesions in a small intestinal allograft at early time periods might be related to higher pre-transplant PRA levels or a positive CDC-XM^[7]. Other studies concluded that C4d deposition had no clinical significance when assessing acute ABMR in a small bowel allograft^[28,29]. Unfortunately these studies either did not correlate with the HLA antibody levels or they did not detect DSA in small-sized heterogeneous populations. Therefore, the above studies did not have sufficient evidence to include or exclude C4d as a useful marker to detect acute ABMR in intestinal allografts. Our previous publications showed that a diffuse C4d deposition was very common in CDC-XM positive recipients with the presence of DSA, while focal and trace C4d deposition was often seen in CDC-XM negative recipients in the setting of no histological evidence of ACR or evidence of ACR but in absence of DSA^[18]. Our current study further demonstrates that a diffuse C4d deposition is strongly associated with vascular disturbances after ITx, indicating that it is a useful marker for a diagnosis of ABMR after ITx. Our results suggest that a diffuse C4d staining, in conjunction with the presence of DSA, clinicopathological findings and significant clinical improvement after initial treatment, strongly supports a diagnosis of acute ABMR. The clinical relevance of focal and weak C4d staining in an intestinal

allograft should be further evaluated in future studies. We suggest that a C4d staining be routinely included in intestinal biopsies in sensitized recipients or in the setting of appearance of a newly-formed DSA after ITx.

The rate of pretransplant sensitization in our current study was 30.3%, higher than 10%-15% in kidney or heart transplant recipients, indicating that intestinal recipients are an high immunological risk group. The causes of sensitization may be from previous operations, multiple blood transfusions, infections, pregnancies or retransplantation. Sensitization increases the risk of a positive CDC-XM and is associated with rejection and poor outcomes. Our results further showed that a positive CDC-XM significantly increases the risk of acute ABMR and is closely associated with graft loss, particularly in a liver-free transplant recipient. In the setting of anti-donor antibody titer ≥ 1:8, all four recipients lost grafts early on after a liver-free transplant. Similar to other solid organ transplants, our findings confirmed a close association between preformed DSA and acute ABMR, indicating that preformed DSA is a prerequisite for the occurrence of acute ABMR after ITx. In our series the majority of patients had preformed class I DSA prior to transplantation, often directed at the A, B locus, whereas the majority of *de novo* DSA post-transplant were against class II, which were often associated with late graft failure. The mechanisms underlying the difference between class I and class II in

this clinical setting is unknown. Based on our results, we suggest special attention should be paid to recipients with high immunological risk in terms of implementing pre-transplant desensitization strategies, avoiding positive cross-match transplantation, increasing maintenance immunosuppression, and frequently monitoring DSA post-transplant.

In our series, younger recipient age was associated with acute ABMR, but this significance no longer exist when we adjusted for other factors. Our analysis identified a liver-free transplant as an independent risk factor for the occurrence of acute ABMR after ITx. Our previous paper demonstrated that the liver is relatively insensitive to antibody-mediated damage and the inclusion of a liver graft with the intestine appears to be protective in recipients of high immunological risk^[30]. In contrast to a liver-free graft, no or only a single mild episode of rejection occurred in three highly sensitized recipients after a liver-inclusive transplant. Our findings further confirmed that the liver as a component of multivisceral transplants might ameliorate or prevent early and late intestinal allograft loss. A liver-inclusive transplant may offer a better long-term patient and graft survival in immunological high-risk recipients. As optimized approaches for depleting HLA antibodies have not yet been set up in ITx, the use of a liver-inclusive graft may be a valuable option in highly sensitized recipients, especially in the setting of retransplantation after primary graft loss due to rejection.

Despite the initial clinical improvement in many patients, long-term outcomes were dismal because of a high incidence of chronic rejection. In this series, although a combination of steroids and T-cell targeted OKT3 achieved the initial resolution after a diagnosis of acute ABMR, the majority of grafts failed due to subsequent severe ACR or chronic rejection. Clearly, additional studies are required to identify effective strategies to control acute ABMR. The antibody-directed regimens, such as

IVIg and anti-CD20, should be routinely implemented in highly sensitized recipients prior to transplantation. A new therapy, such as the proteasome inhibitor "bortezomab" and complement-targeted treatment with C1 or C5 inhibitor, has yielded encouraging preliminary results, but the long-term efficacy and safety remain to be seen.

Our study has several important limitations, including its retrospective nature, inconsistent antibody detection methods, and experience at a single institution. Although we identified 18 cases among 175 transplants over a 7-year period, the true incidence of acute ABMR may be higher after ITx. It is likely that less severe cases were unrecognized due to our evolving antibody detection methods, lack of standardized definition, and our unawareness of the importance of acute ABMR during the early study period. An additional important limitation of this study is that C4d staining of biopsies was not routinely performed in recipients with ACR to evaluate its sensitivity and specificity. Furthermore, the lack of consistent DSA monitoring post-transplantation limits our ability to assess sub-clinical acute ABMR. However, we sought to characterize a convincing series of cases to develop a preliminary definition that may serve as a foundation for future studies.

Our results indicate that acute ABMR is an important cause of intestinal graft dysfunction, particularly in a liver-exclusive transplant. After acute ABMR, patients are at an increased risk of developing refractory acute rejection and chronic rejection. Preventive and effective therapeutic approaches are needed to manage acute ABMR in intestinal transplant recipients.

ACKNOWLEDGMENTS

The authors would like to thank the surgical team (Kareem M Abu-Elmagd, Guilherme Costa, Geoffrey J Bond, Kyle Soltys, and George Mazariegos), the nursing staff at the Intestinal Rehabilitation and Transplant Center, the University of Pittsburgh Medical Center, for their excellent patient care. The authors thank Mr. Yinglun Wu for help with English grammar.

COMMENTS

Background

Antibody-mediated rejection (ABMR) is the major cause of kidney transplant failure. The incidence and clinical significance of acute ABMR after intestinal transplantation (IATx) remain unknown.

Research frontiers

ABMR has increasingly become an important area for research and clinical investigation. The aim of this study aimed to assess the incidence, risk factors and clinical outcomes of acute ABMR after ITx.

Innovations and breakthroughs

This is the first largest series of study to retrospectively examine the incidence of acute ABMR after ITx. The incidence of acute ABMR after ITx is 10.3% in the series. Both a liver-free graft and a high level of panel reactive antibody were identified as a significant independent risk factor for acute ABMR. Without appropriate management, acute ABMR was closely associated with increased

graft loss and poor clinical outcomes.

Applications

The results suggest that acute ABMR must be included in the differential diagnosis of acute rejection after ITx. The prevention of acute ABMR should include desensitization, avoiding a positive cross-match donor, and considering the liver as part of an intestinal graft in highly sensitized recipients. Future studies are required to develop the optimal approaches to managing acute ABMR in ITx recipients.

Terminology

Acute ABMR is identified on the basis of circulating donor-specific antibody, C4d deposition, tissue injury and clinical allograft dysfunction after ITx.

Peer-review

This is a well written, well designed retrospective review study on acute ABMR after intestinal transplantation, put through an electronic analysis of medical records of 18 patients diagnosed with ABMR out of 175 liver-free small bowel and modified multivisceral graft transplantations, during a 7-year period.

Abstract

AIM

To examine the risk of late-onset post-transplant lymphoproliferative disorder (PTLD) in the presence of persisting high Epstein-Barr virus (EBV) in EBV naïve pediatric heart transplant (HT) recipients.

METHODS

A retrospective review of the medical records of the 145 pediatric HT recipients who had serial EBV viral load monitoring at our center was performed. We defined EBV naïve patients whose EBV serology either IgM or IgG in the blood were negative at the time of HT and excluded passive transmission from mother to child in subjects less than 6 mo of age.

RESULTS

PTLD was diagnosed in 8 out of 145 patients (5.5%); 6/91 (6.5%) in those who were EBV seropositive and 2/54 (3.7%) in the EBV naïve group at the time of HT ($P = 0.71$). We found 32/145 (22%) patients with persistently high EBV load during continuing follow-up; 20/91 (22%) in EBV seropositive group vs 12/54 (22%) in EBV naïve group ($P = 0.97$). There was no significant association between pre-HT serostatus and EBV load after transplant ($P > 0.05$). In the EBV seropositive group, PTLD was diagnosed in 15% (3/20) of patients with high EBV vs 4.2% (3/71) of patients with low or undetectable EBV load ($P = 0.14$) whereas in EBV naïve patients 8.3% (1/12) of those with

high EBV load and 2.3% (1/42) with low or undetectable EBV load ($P = 0.41$). There was a highly significant association between occurrence of PTLD in those with high EBV load and duration of follow up (4.3 ± 3.9 years) after HT by Cochran-Armitage test for the entire cohort ($P = 0.005$). At least one episode of acute rejection occurred in 72% (23/32) of patients with high EBV *vs* 36% (41/113) patients with low or undetectable EBV after HT ($P < 0.05$).

CONCLUSION

There is an association between persistently high EBV load during post-HT follow up and the occurrence of late-onset PTLD in pediatric HT recipients irrespective of serostatus at the time of transplant. The occurrence of allograft rejection increased in patients with high EBV load presumably due to reduction in immunosuppression.

Key words: Pediatric heart transplantation; Epstein-Barr virus; Post-transplant lymphoproliferative disorder; Immunosuppression; Allograft rejection

Core tip: Post-transplant lymphoproliferative disorder (PTLD) after heart transplantation is a severe complication where there is still limited information is available. There are many publications on estimations of PTLD frequency in different settings and types of patient, as well as the factors associated with its appearance and prognosis. But, most studies do not take into account the length of follow-up which may be misleading given that patients are exposed to the risk of immunosuppression over a long period of follow-up. This study is unique that, it is a single center study span over a period of 18 years in which maintenance immunosuppression therapy and management of rejection episodes remained same throughout. Although, a single center study result cannot be generalized, however it adds to the existing literature for risk stratification of these patients based on whole blood Epstein-Barr virus (EBV) polymerase chain reaction (PCR) after accounting for the time since transplant and patients' pre-transplant EBV serostatus. This paper also highlights the risk of acute rejection after reduction or alteration in immunosuppression in patients with high EBV load by PCR without any effect on the occurrence of PTLD.

Persistent Epstein-Barr viral load in Epstein-Barr viral naïve pediatric heart transplant recipients: Risk of late-onset post-transplant lymphoproliferative disease. *World J Transplant* 2016; 6(4): 729-735 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/729.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.729>

INTRODUCTION

Post-transplant lymphoproliferative disorder (PTLD) is the most common malignancy occurring in 3.5%-9%

of pediatric HT recipients^[1-4]. It is characterized by uncontrolled proliferation of lymphoid lineage cells, the vast majority of which are B-cell lymphomas, in a context of posttransplant immunosuppression. In some situations, reducing the immunosuppression can reverse the proliferation, thus differentiating it somewhat from truly irreversible malignancies. Most but not all PTLD cases have a strong relationship with Epstein-Barr virus (EBV).

The development of PTLD is influenced by a variety of factors including the type, intensity, and cumulative amount of immunosuppression, and the EBV status of the donor and recipient. Children are at greatest risk for the development of PTLD since they are often seronegative at transplant and acquire a primary EBV infection post-heart transplant (HT) in the setting of immunosuppression. Nevertheless, the factors that account for whether or not a particular child develops EBV-associated PTLD are undetermined. Diagnosis and effective treatment of PTLD is hampered by our inability to determine which children are at risk of developing EBV-associated PTLD.

The onset of PTLD is usually preceded by an elevated EBV load in the peripheral blood which is highly sensitive but not a specific marker for development of PTLD in renal transplant recipients^[5,6]. Routine long-term post-HT EBV monitoring identifies a group of children who carry persistent viral loads for months to years after solid organ transplants^[5-8]. Patients with a persistently elevated level of circulating EBV may have an increased risk of PTLD^[2,9]. Previously, a single center study reported that a high EBV load did not predict PTLD in early post-heart and heart-lung transplant period^[10]. However, another single center study suggested that exposure to EBV and higher intensity immunosuppression was associated with increased risk of PTLD in pediatric HT recipients^[11]. A more recent study has shown that early onset PTLD in solid organ transplant recipients appears mainly as an EBV-driven disease especially favored by insufficient immunosurveillance^[12,13]. These contradictory findings leave the long-term clinical significance of chronic high EBV load unknown. We hypothesized that patients with persistently high EBV viral load at any time after their transplant in the setting of immunosuppression may be at increased risk for development of PTLD.

The objective of the study was to examine the risk of late-onset PTLD (> 1 year post-transplant) in the presence of persisting high EBV and to determine whether patients' serostatus at the time of HT changed the risk.

MATERIALS AND METHODS

All pediatric HT patients transplanted between 1995 and 2013 who had known EBV serology at the time of transplant were included in this retrospective descriptive study. For this study, we defined EBV naïve patients

whose EBV serology either IgM or IgG in the blood were negative at the time of HT and excluded passive transmission from mother to child in subjects less than 6 mo of age. Data collection included demographics, clinical data, pre-HT EBV serological status, serial post-HT EBV load, diagnosis of PTLD and acute rejection episodes during post-HT follow-up. The presence of EBV virus in whole blood was measured by quantitative polymerase chain reaction (PCR) using a cut-off of 1000 copies/mL according to our institution protocol.

Viral (EBV) load testing was done in whole blood using PCR every 2 wk for 3 mo, every month for 3 mo, every 3 to 6 mo for a duration of 1 year after HT, and thereafter annually. Additional EBV PCR levels were drawn if EBV PCR was rising, with any increased immunosuppression for treatment of allograft rejection, or if clinically indicated by symptoms such as protracted fever, gastrointestinal symptoms, unexplained elevated liver enzymes, lymphadenopathy, tonsillar hypertrophy, obstructive sleep apnea, unexplained anemia, pancytopenia, atypical lymphocytes or eosinophilia, persistent headache or focal neurological symptoms.

Our protocol for follow-up of patients based upon EBV PCR positivity included: (1) EBV PCR < 1000 copies/mL: No change in immunosuppression, routine follow-up as per above protocol; (2) EBV PCR 1000-9999 copies/mL: No change in immunosuppression, repeat EBV PCR every 2 wk; and (3) EBV PCR \geq 10000 copies/mL (> 2 consecutive tests and remains positive for > 12 mo): We reduced immunosuppression with a goal for tacrolimus trough level 3-5 ng/mL, cyclosporine trough level 50-75 ng/mL, and decreased mycophenolate mofetil/azathioprine dose to half of the initial dose and closely monitored for any signs of acute rejections. For this study analysis, we divided all patients into 3 groups based on EBV viral load as a continuous value anytime during post-TX follow-up: group I : Negative EBV or EBV PCR < 1000 copies/mL; group II : EBV PCR 1000-9999 copies/mL; and group III : EBV PCR \geq 10000 copies/mL (persistently positive for > one year). During follow-up, patients who had transiently increased EBV PCR in excess of 10000 but did not persist for a year were included in group II .

PTLD was defined according to the 2008 World health Organization (WHO) classification system, but early lesions such as lymphoid hyperplasia with scattered positive in situ hybridization using EBV encoded RNA detected by the Epstein-Barr early region (EBER) immunostaining assay^[14] was excluded for this study as PTLT. All biopsy proved polymorphic, monomorphic and classical Hodgkin lymphoma-type PTLD patients were evaluated by our oncology service and treatment was guided as per oncology protocol.

Acute Allograft rejection was defined as ISHLT grade 2R or higher or an episode of clinically significant decline in cardiac function treated with steroid bolus or anti-T cell therapies. Endomyocardial biopsy was performed per our institutional protocol for all patients and frequency of biopsy was not modified based on high EBV load or reduction of immunosuppression. However, patients

whose immunosuppression was decreased as a result of high EBV load were monitored closely clinically and by echocardiogram for any graft dysfunction.

All patients received basiliximab (simulect) and methyl prednisone for induction at the time of transplant as per our institution protocol since 2001. Between 1995-2000, our induction therapy was only methyl prednisone. Maintenance immunosuppression includes triple therapy of tacrolimus/cyclosporine, mycophenolate mofetil (MMF), and steroids. Steroids were withdrawn after one year routinely unless there are more than one rejection episode within first year after transplant. This study was approved by our institutional IRB.

Statistical analysis

Descriptive analyses of the continuous and categorical data were performed using mean, standard deviation, median, quartiles, frequency and proportion as appropriate. Fisher's exact test and χ^2 tests were used to test binary variables between two groups. Cochran-Armitage test and logistic regression were used to test the association between post-HT EBV load, duration of follow-up and incidence of PTLD. The statistical analyses were performed with SAS 9.3.

RESULTS

A total of 145 patients were followed from 1995 to 2013 for mean 4.3 ± 3.9 years (interquartile range 1.5 to 6.0 years) post-HT. Mean age at HT was 6.6 ± 6.3 years, median age 4.8 years with interquartile range 0.69 to 12.0 years. EBV was first detected at a median of 1 year (range 0.1 to 16 years) post-HT. Patients were then subgrouped based on age at transplant into 0-6 mo, 6 mo to 1 year, 1-7 years and 7-20 years vs EBV load as shown in Table 1. The proportions of high EBV load are 38.8%, 27.4%, 18.4% and 15.4% in age group 0-6 mo, 6 mo to 1 year, 1-7 years and 7-20 years, respectively. Cochran-Armitage test with square root transformation to age and the logistic regression showed that patients' age at HT was negatively associated with high EBV load ($P = 0.03$), which means patients with younger age had high risk for high EBV during follow up. One year old was chosen as the threshold for younger patients. χ^2 test showed that patients 1 year old or younger were more likely to have high EBV during follow up than patients older than 1 year old ($P = 0.01$). The relative risk for developing high EBV load in patients having transplant at 1 year old or younger is 2.16 (95%CI: 1.19-3.92) over patients having transplant at older age irrespective of their pre-HT EBV serological status.

The clinical characteristics of individual PTLD patient are described in Table 2. All patients were treated by reducing immunosuppression; five patients received rituximab, two patients received chemotherapy and one patient received chemotherapy plus radiation therapy. Three patients underwent tumor resection and all patients survived the treatment of PTLD. One patient died two years after treatment of PTLD due to non-cardiac cause.

Table 1 Outcomes (post-transplant lymphoproliferative disorder and number of rejections) by Epstein-Barr virus serological status at heart transplant

	Group I (EBV PCR negative or < 1000) (n = 66)	Group II (EBV PCR 1000-9999) (n = 47)	Group III (EBV PCR ≥ 10000) (n = 32)
EBV Naïve at HT	29/66 (44%)	13/47 (28%)	12/32 (37%)
Age at transplant			
0 up to < 6 mo	9	10	12
6 mo < 1 yr	3	5	3
1 yr up to < 7 yr	28	8	8
≥ 7 yr up to 20 yr	26	24	9
Post-HT Follow-up (yr)	4.5 ± 3.2	4.8 ± 4.2	4.6 ± 5.3
No of PTLD	1	3	4
No of total Rejections	40	42	48
Number of patients with ≥ 1 episodes of rejections	19	22	23

EBV: Epstein-Barr virus; PCR: Polymerase chain reaction; HT: Heart transplant; PTLD: Post-transplant lymphoproliferative disorder.

Table 2 Characteristics of individual patient diagnosed with post-transplant lymphoproliferative disorder

Patient (gender)	Year of HT	HT to PTLD (yr)	EBV serology at HT	EBV load at PTLD	Organ involved in PTLD	CD20 positivity	EBER status of PTLD	Histological diagnosis	Treatment
1 (M)	1995	16	Positive	< 10000	Retroperitoneal lymph node	Neg	Neg	Hodgkin Lymphoma	Chemotherapy
2 (F)	1996	14	Positive	< 10000	Cervical Lymph node	Neg	Neg	Diffuse large B-cell lymphoma	Chemotherapy
3 (M)	1999	12	Positive	> 10000	Retroperitoneal lymph node	Pos	Neg	Polymorphic PTLD	Rituximab
4 (M)	2001	3	Positive	> 10000	Pharynx	Neg	Pos	Intermediate between Hodgkin and large cell lymphoma	Chemotherapy plus Radiation
5 (F)	2009	3	Negative	> 10000	Cervical Lymph node	Pos	Pos	Polymorphic PTLD	Rituximab
6 (F)	2000	14	Positive	< 1000	Brain-Temporal Lobe	Pos	Pos	Polymorphic PTLD	Rituximab
7 (M)	2000	3	Negative	< 10000	Small intestine	Pos	Pos	Polymorphic PTLD	Rituximab
8 (F)	2005	6	Positive	> 10000	Retroperitoneal lymph node	Pos	Pos	Large B-cell Lymphoma	Rituximab

HT: Heart transplant; Neg: Negative; Pos: Positive; EBER: Epstein-Barr virus encoded small RNA; PTLD: Post-transplant lymphoproliferative disorder.

Figure 1 describes the distribution of patients' EBV serological status at the time of HT, EBV viral load by PCR post-HT, and number of patients who developed PTLD for the entire cohort. Out of 145 patients, 54 (37%) were EBV seronegative and 91 (63%) were EBV seropositive at the time of transplant and 22% from each group developed persistently high EBV viral load during follow-up after HT ($P = 0.97$). There were 6 cases (6.4%) of PTLD in EBV seropositive group vs 2 cases (3.9%) in EBV naive group ($P = 0.71$). In the EBV seropositive group, PTLD was diagnosed in 15 % (3/20) of patients with persistently high EBV vs 4.2% (3/71) of patients with low or undetectable EBV load ($P = 0.14$) whereas in EBV naive patients PTLD was diagnosed in 8.3% (1/12) who had persistently high EBV load and 2.3% (1/42) with low or undetectable EBV load ($P = 0.41$). There was no significant association between pre-HT serostatus and post-HT EBV viral load after transplant ($P > 0.05$).

For the entire cohort of 145 patients, we found 65/145 (44.8%) had negative or EBV < 1000 copies/mL (Group

I), 48/145 (33%) had EBV load between 1000-9999 copies/mL (Group II), and 32/145 (22%) patients had EBV load ≥ 10000 copies/mL (Group III) during follow-up irrespective of initial serological status at the time of transplant. PTLD was diagnosed in 8 out of 145 patients (5.5%) at a median of 4.4 years (mean 7.5 ± 6.5 years, interquartile range 2.7 to 13.7 years) after heart HT. PTLD was diagnosed in 12.5% (4/32) of patients with persistently high EBV vs 3.5% (4/113) of patients with low or undetectable EBV load ($P = 0.07$ by Fisher's exact test). High viral load could predict PTLD with sensitivity 50% (95%CI: 15.7%-84.30%), specificity 79.66% (95%CI: 71.8%-85.97%), positive likelihood ratio 2.45 (95%CI: 1.14-5.27), negative likelihood ratio 0.63 (95%CI: 0.31-1.26) and positive predictive value 12.5% (95%CI: 3.51%-2.88%). There is a significant association between persistently high EBV load during a sum of follow up over 11 ± 7 years after HT and the occurrence of PTLD by Cochran-Armitage test ($P = 0.005$).

There was at least one episode of acute rejection

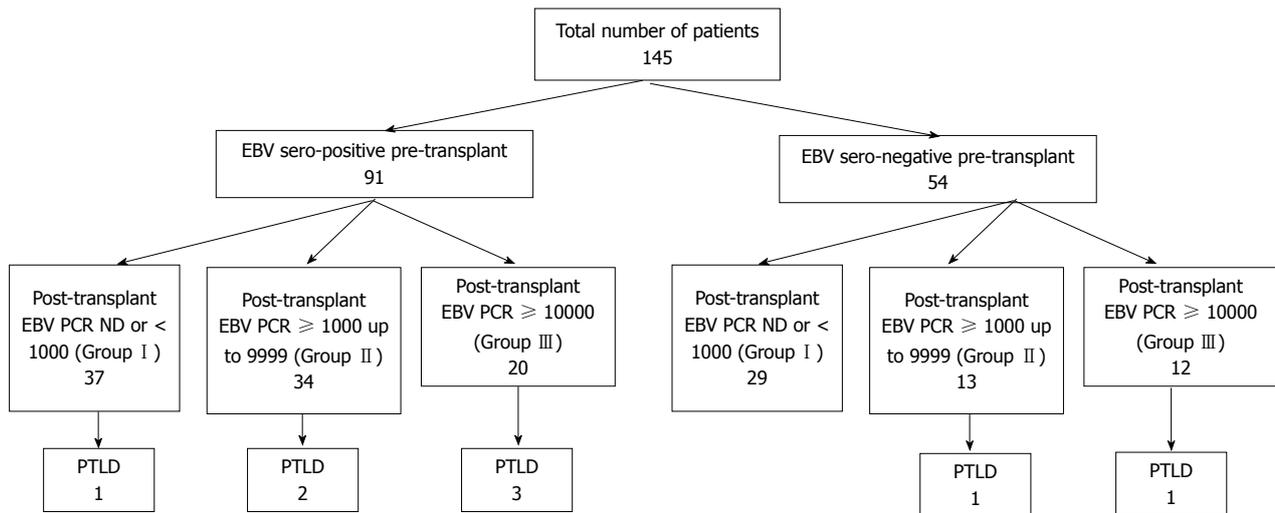

Figure 1 Patients' Epstein-Barr virus serostatus pre-heart transplant, post-transplant Epstein-Barr virus viral load as determined by whole blood polymerase chain reaction and incidence of post-transplant lymphoproliferative disorder for the entire cohort. EBV: Epstein-Barr virus; PTLD: Post-transplant lymphoproliferative disorder; PCR: Polymerase chain reaction.

(Grade 2R) in 23 patients with high EBV load after reduction of their immunosuppression (Table 1). On the other hand, 41 patients with low or negative EBV load who had no change in their immunosuppression had at least one episode of rejection. Thus, a larger proportion of patients 72% (23/32) with persistently high EBV load had acute rejections vs 36% (41/113) patients with low or negative EBV load ($P < 0.05$). Furthermore, there was an increase in frequency of total rejection episodes in patients with persistently high EBV load by 150% (48/32) vs 72.5% (82/113) in patients with low or negative EBV load ($P < 0.05$).

DISCUSSION

The incidence of PTLD in our study at 5.5% is similar with other series reported^[1]. The occurrence of PTLD is dependent on the transplanted organ type and patient-specific risk factors. The strongest risk factor for PTLD is the development of primary EBV infection after transplantation^[2,12,15,16]. Schubert *et al*^[2] have reported 8.2% incidence of PTLD in pediatric HT recipients and the EBV association was 83% as a risk factor for development of PTLD. EBV monitoring in peripheral blood using PCR has been reported to have variable sensitivity and lack of specificity as an indicator of risk for developing PTLD^[5,10,17-19]. Among pediatric HT recipients studied by Bingler *et al*^[20] those with high EBV load were more likely to develop late-onset PTLD, occurring as long as 8.4 years after HT. In this study, we showed that patients who underwent HT at younger age (Table 1) are at higher risk for development of high EBV load over time ($P = 0.05$) irrespective their serological status at the time of HT. This observation is of clinical importance because many potential risk factors for development of PTLD such as persistent EBV viremia and overall immunosuppression are a function of duration of follow-up and may not be observed in early post-HT period. The

occurrence of PTLD is highest in younger patients; age may not be an independent risk factor but may depend upon the likelihood of the recipient being exposed to long-term immunosuppression.

One of the limitations of the current study is the fact that we had incomplete data on the donor EBV status. Therefore, we could not determine whether high EBV load was the result of primary infection derived from community exposure or related to donor transmission. Asymptomatic high EBV load also predicts other adverse outcomes, such as graft dysfunction or acute rejection^[20,21]. Jabs *et al*^[21] showed that EBV viremia occurring immediately after renal transplant was associated with subsequent rejection episodes, and they speculate that T cell responses to viral infection might cross-react with the graft. In another study, Smith *et al*^[22] have showed that subclinical cytomegalovirus and EBV viremia occurring in the early post-transplant period was associated with higher incidence of allograft injury. The authors did not find evidence of significant viral replication in the renal allograft at 2 years after transplant, suggesting that graft dysfunction is not related to chronic infection^[22]. We found a higher rate of rejection episodes (mostly grade 2R) in pediatric HT recipients with persistently high EBV load compared to those patients with low or negative EBV PCR. The mechanisms of rejection are not clear from this study but may include viral cytopathic effects, increased expression of alloantigen, adhesion molecule expression by endothelial cells, or indirect inflammatory effects due to cytokine release, or a combination of multiple mechanisms leading to allograft injury.

In our practice, we do reduce maintenance immunosuppression in patients who have persistently raised EBV PCR ≥ 10000 copies/mL of whole blood. A link between EBV load and level of immunosuppression in adult HT patients was noted^[23]. We hypothesize that reduction of immunosuppression has probably contributed for higher allograft rejection episodes in patients with high

EBV load. Therefore, we recommend close monitoring for allograft rejection must be done after reduction of immunosuppressive therapy.

In this study, we have used methyl prednisone as induction therapy from 1995 through 2000 and basiliximab and methyl-prednisone as induction therapy from 2001 through 2013. Our standard maintenance immunosuppression (tacrolimus/cyclosporine, MMF or azathioprine and steroids) and consistent decrease in immunosuppression strategy in response to a high EBV support to the notion that it is overall immunosuppression exposure during the life time of the patient which compromises anti-tumor and anti-viral immunosurveillance capacity and thus facilitate development of PTLD. We have not used sirolimus or everolimus routinely and we cannot comment regarding the effect of proliferation signal inhibitors on EBV PCR or PTLD from this study.

This study must be viewed in light of some limitations. It was a single-center retrospective study and thus findings may not be generalizable. Some patients were transferred to another center and also transitioned to an adult HT program, thus complete follow-up data for a small portion of patients were not available. However, this is a well-studied patient population in which maintenance immunosuppression therapy and management of rejection episodes remained same throughout and we followed our standardized institutional protocol strictly.

In conclusion, there is an association between persistently high EBV load and the occurrence of late-onset PTLD in pediatric HT recipients especially considering cumulative incidences at different lengths of follow-up. Patients ≤ 1 year of age at the time of HT are more likely to have persistently high EBV PCR during follow up than patients > 1 year of age at the time of transplant irrespective of their EBV serological status. Reduction of immunosuppression in the face of persistently high EBV load did not change the proportions of patient who had late-onset PTLD but did increase the risk of allograft rejection significantly. Based on our findings, there is a need for research to better determine other factors that might be predictive of PTLD. Currently, there is a multi-center study sponsored by National Institute of Allergy and Infectious Diseases examining the role of viral (EBV) and immunological biomarker associated with development of PTLD after transplantation^[24]. This study will provide further insight to identify surrogate markers that can predict development of PTLD.

COMMENTS

Background

Post-transplant lymphoproliferative disorder (PTLD) is a significant complication after heart transplantation. Most but not all PTLD cases have a strong relationship with Epstein-Barr virus (EBV). This condition straddles the disciplines of transplantation, immunology, oncology, and virology. PTLD presents significant problems for the clinician because it is difficult to predict and has high morbidity and mortality rates. In addition, it has the potential for graft loss due to disease itself or the need to reduce immunosuppression, which increases the risk of graft rejection.

Research frontiers

The goal of this study is to review a single center experience of late-onset PTLD in the presence of persisting high EBV in pediatric heart transplant recipients.

Innovations and breakthroughs

This study showed that there is an association between persistently high EBV load during post-transplant follow up and the occurrence of late-onset PTLD in pediatric heart transplant recipients. The occurrence of PTLD is highest in younger patients; age may not be an independent risk factor but may depend upon the likelihood of the recipient being exposed to long-term immunosuppression. The incidence of allograft rejection increased in patients with high EBV load presumably due to reduction in immunosuppression.

Applications

Late-onset PTLD is less likely to be associated with patients' EBV serostatus at the time of transplant. Also, late-onset PTLD may be more likely extra-nodal and heterogeneous.

Terminology

Detection of persistently high EBV viral DNA by polymerase chain reaction (PCR) from the peripheral blood is associated with late-onset PTLD in pediatric heart transplant recipients.

Peer-review

The research is methodological well performed, clearly written, and the data is honestly presented.

Abstract

AIM

To identify the risk factors and the post-transplant psychological symptoms that affect adherence to therapy in a population of kidney transplant recipients.

METHODS

The study examined the psychological variables likely responsible for the non-adherent behavior using a psychological-psychiatric assessment, evaluation of the perception of patients' health status, and an interview regarding the anti-rejection drug therapy assumption. The study included 74 kidney transplant recipients.

RESULTS

Individuals with a higher level of education and more years since transplantation showed better mental balance. Regarding gender, women appeared to be less adherent to therapy. Further, the years since transplantation adversely affected the proper pharmacological assumption. Adherence to therapy did not significantly change with the mental health index.

CONCLUSION

The biopsychosocial illness model provides a conceptual

frame of reference in which biological, psychological, and social aspects take on the same importance in the adherence to treatment protocols. For effective management, it is necessary to understand the patients' personal experiences, their assumptions about the disease, health status perception, and mood, and to identify any "barriers" that could cause them to become noncompliant.

Key words: Transplantation; Adherence; Mental health; Psychological assessment; Psychiatric assessment

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Therapeutic Adherence after transplantation is of fundamental importance for the patient's short- and long-term well-being and assumes a set of adaptations to a new lifestyle. The authors in this study analyzed the psychological characteristics of a sample of transplant recipients and different temperament styles, yet not studied in other research on transplantation. The results suggested that different temperaments influence in different ways the treatment compliance and showed that the transplant experience change behaviors and quality of life based on the personality and temperament characteristics. In conclusion, post-transplant psychological support positively affects adherence to treatment, and coping strategies of the subject.

Psychological perspective of medication adherence in transplantation. *World J Transplant* 2016; 6(4): 736-742 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/736.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.736>

INTRODUCTION

The theme of therapeutic adherence (TA) plays a central role in research on education and health promotion^[1]. Adherence to immunosuppressive therapy after transplantation is of fundamental importance for the patients' well-being both short- and long-term and assumes a set of adaptations to a new lifestyle. The treatment effectiveness and transplant success not only depend on the correct choice of immunosuppressive drugs, but also on the patients' active participation in the therapeutic program that often includes psychological support and appropriate motivation^[2,3].

Non-adherence to therapy in transplant patients is one of the emerging causes of early and late graft loss. Patients with an organ transplant must take immunosuppressive drugs daily for the prevention of acute and chronic rejection. There is an obvious relationship between the discontinuity in the use of immunosuppressive drugs and the incidence of transplant failures in the medium and long term^[4]. Non-adherence to the transplant medication

regimen can lead to graft rejection, post-transplant mortality, increase in healthcare costs, and decrease in quality of life^[5,6]. One meta-analysis found non-adherence to medication across all organ transplants to be 22.6%^[7]. An estimated 50% of late acute rejections and 15% of graft losses are associated with non-adherence^[8]. An essential aspect to ensure full adherence to the treatment is the assessment of transplant recipient needs and his/her expectations while establishing a good therapeutic alliance^[9]. Many studies evaluating the relationship between the healthcare team and the patient highlighted the need for a relationship based on trust and clarity for the sharing of information regarding the treatment course^[10,11]. Even psychological and psychosocial aspects can alter the response to treatment^[12,13]: Mood disorders, high levels of anxiety, hostility, and the presence of "unstable" personality traits are associated with an increased risk of non-adherence to medical prescriptions in kidney transplant recipients^[14-16].

Adherence to therapy thus is a complex variable and influenced by many factors: Socio-demographics, psychological characteristics, transplant recipient self-efficacy, factors related to immunosuppressive therapy, and the doctor-patient relationship. The aim of this study is to identify the risk factors and post-transplant psychological symptoms that affect adherence to therapy in a population of kidney transplant recipients.

MATERIALS AND METHODS

The study examined the psychological variables that are likely responsible for the non-adherent behavior using a psychological-psychiatric assessment, evaluation of the perception of patients' health status, and an interview regarding the anti-rejection drug therapy assumption. The psychological-psychiatric assessment involved the use of the following tests:

The Symptom Checklist-90-Revised (SCL-90-R) evaluated psychological symptoms. It is a relatively brief self-report psychometric instrument (questionnaire) published by the Clinical Assessment division of the Pearson Assessment and Information group. It is one of the most widely used measures of psychological distress in clinical practice and research and is designed to evaluate a broad range of psychological problems and symptoms of psychopathology. According to the overview given by the publisher, the SCL-90-R is normed on individuals 13 years and older. It consists of 90 items and takes 12-15 min to administer. The following primary symptom dimensions are assessed: Somatization (SOM), obsessive-compulsive (OBS), interpersonal sensitivity (INT), depression (DEP), anxiety (ANX), hostility (HOS), phobic anxiety (PHOB), paranoid ideation (PAR), psychoticism (PSY), and a category of "additional items" that helps clinicians assess other aspects of the patient's symptoms^[17,18]. A large number of studies have been conducted demonstrating the reliability, validity, and utility of the instrument^[19-22].

Personality study has provided an analysis of the

Table 1 Demographic data (*n* = 74 kidney transplant responders)

Years since transplantation procedure, mean ± SD (range)	5.39 ± 3.74 (1.00-14.00)

Retired	12.01%

temperament variables by the TEMPS-A (Temperament Evaluation of Memphis, Pisa and San Diego Autoquestionnaire). The features of temperament as well as its intensity may exert a constructive or destructive impact on the quality of life^[23]. The TEMPS-A contains 110 items (109 in the version for males) measuring affective temperament traits occurring throughout life of the subject, as represented by five dimensions: Depressive (DT), cyclothymic (CT), hyperthymic (HT), irritable (IT), and anxious (AT). Questions about the various types are grouped together. The TEMPS-A measures the severity of the temperament traits ranging from 0 to 1. The calculation of points for each temperament is done by dividing the sum of points obtained in a given subscale by the number of questions contained therein^[24,25].

Quality of life was examined with the Short Form Health Survey (SF-36) that assesses the degree of self-perceived psychological well-being. The SF-36 consists of eight subscales: Vitality, physical functioning, bodily pain, general health perceptions, physical role functioning, emotional role functioning, social role functioning, and mental health. Subscales are presented as scores between 0 and 100; a lower score indicates more disability and a higher score less disability. The two considered variables in this study were the physical index score (PIS) and mental index score (MIS). The validity and reliability of the SF-36 has been confirmed in patients with renal disease^[26,27].

Therapeutic adherence was studied through the Basel Assessment of Adherence to Immunosuppressive Medication instrument (BAASIS), which was developed to assess adherence to immunosuppressive medication in adult transplant patients. The instrument measures patients' taking, skipping, timing (± 2 h from the prescribed time, TM), and dose reduction of drugs. The recall period is limited to four weeks. The BAASIS comprises four questions with a 6-point scale for responses ranging from never (0) to every day (5). In addition, the BAASIS has a visual analogue scale (VAS) ranging from 0% (medication never taken as prescribed) to 100% (medication always taken as prescribed)^[28,29].

The current study included 74 kidney transplant recipients (32 females, 43.25%), with a mean age of 48.3 \pm 13.6 years (range 22-75). Demographic data regarding years since transplant procedure (first transplantation), occupation, level of education are presented in Table 1. All

patients underwent a standardized immunosuppressive protocol with tacrolimus, mycophenolate mofetil, and steroids. The basic psychological-psychiatric assessment excluded the presence of lifetime psychiatric disorders (axis I) according to the Diagnostic and Statistical Manual for Mental Disorders (5th ed., DSM-5) or concomitant use of drugs that could influence cognitive and emotional aspects^[30]. All patients provided written informed consent after the procedures were fully explained by a trained physician (MD, psychiatrist) or a psychologist.

The data were examined for normality and transformed if necessary. Pearson's R correlation test was performed using the "Statistical Package for Social Sciences" (SPSS, Version 17). The *P* value of less than 0.05 (*P* < 0.05) was considered statistically significant. In addition, we applied multivariate linear regression analysis to predict the outcome variable (BAASIS total score, BT) from predictor variables (patterns of personality and demographic characteristics).

RESULTS

The current study included 74 kidney transplant recipients (32 females, 43.25%), with a mean age of 48.3 \pm 13.6 years (range 22-75). Demographic data regarding years since transplant procedure (first transplantation), occupation, level of education are presented in Table 1. All patients underwent a standardized immunosuppressive protocol with tacrolimus, mycophenolate mofetil, and steroids. Correlations by the Pearson coefficient between results of the SCL-90-R, SF-36 (physical and mental index score), and demographic characteristics of the sample are shown in Figure 1. Individuals with a higher level of education (E) and with more years of transplantation (YT) showed higher mental balance (E/MIS *r* = 0.61; YT/MIS *r* = 0.48). Specifically, the level of education was negatively correlated with anxious, obsessive-compulsive, and depression aspects (E/OBS *r* = -0.81; E/DEP *r* = -0.67; E/ANX *r* = -0.59).

Correlations by the Pearson coefficient between results of the BAASIS, SF-36 (physical and mental index score), and demographic characteristics of the sample are shown in Figure 2. Regarding gender, women (female sex, FS) appeared to be less adherent to therapy in our study (FS/BT *r* = 0.46), while years of transplantation adversely affected the proper pharmacological assumption (YT/BT *r* = 0.34). In addition, as the index of subjective physical well-being increases, compliant behavior increases as well (PIS/BT *r* = -0.47), especially with regards to the treatment assumption of correct timing (PIS/TM *r* = -0.27). Adherence to therapy was not significantly correlated with the mental health index (MIS/BT *r* = -0.01).

Correlations by the Pearson coefficient between the results of the TEMPS-A, BAASIS of the sample are shown in Figure 3. The temperament variables measured with the TEMPS-A were correlated with treatment adherence. Specifically, the cyclothymic, irritable, and depression personality adversely affected adherent behavior (BT/CT

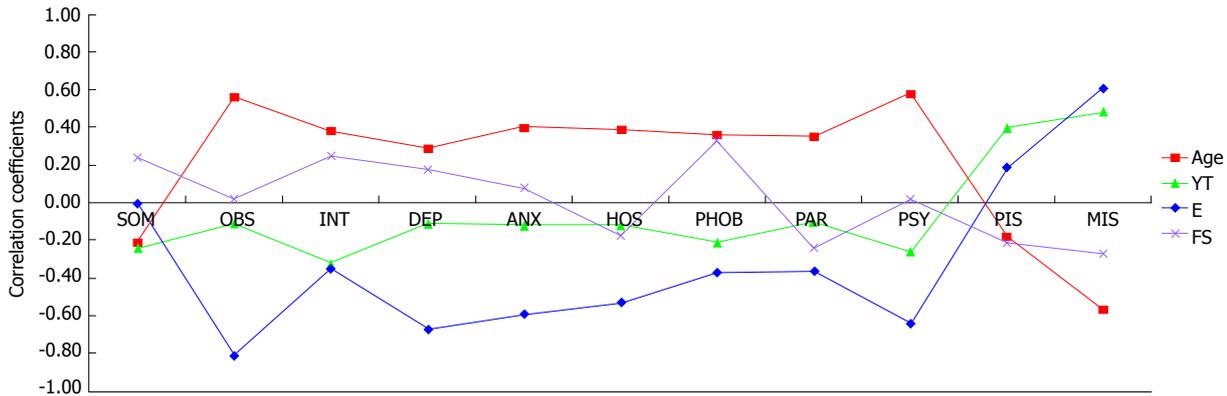

Figure 1 Correlations between symptom Checklist-90-R, short form health survey, and demographic characteristics. SF-36: Short form health survey; SOM: Somatization; OBS: Obsessive-compulsive; INT: Interpersonal sensitivity; DEP: Depression; ANX: Anxiety; HOS: Hostility; PHOB: Phobic anxiety; PAR: Paranoid ideation; PSY: Psychoticism; PIS: Physical index score of SF-36; MIS: Mental index score of SF-36; YT: Years since transplant procedure; E: Education; FS: Female sex. Correlation coefficients (r) < 0.3 indicate weak correlation, ≤ 0.7 moderate correlation, > 0.7 strong correlation.

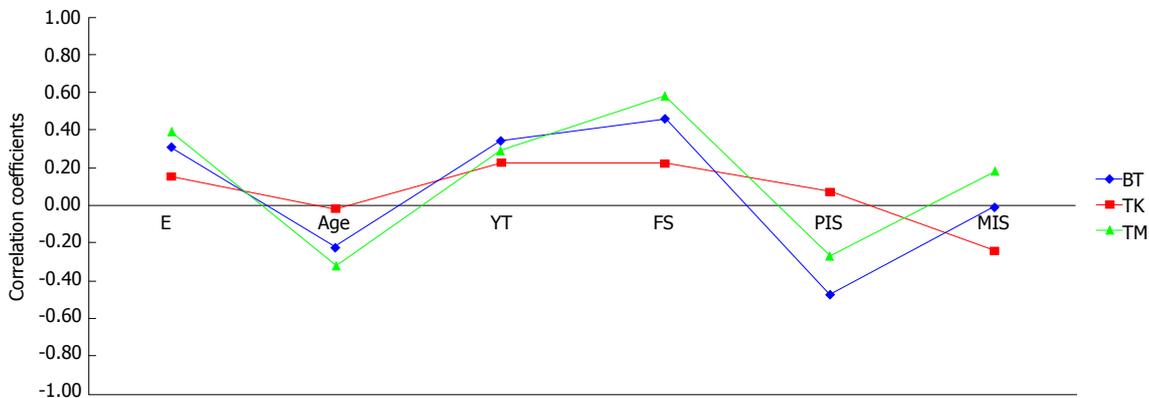

Figure 2 Correlations between basal assessment of adherence to immunosuppressive medication instrument, short form health survey, and demographic characteristics. BAASIS: Basal assessment of adherence to immunosuppressive medication instrument; BT: BAASIS total score; TK: BAASIS taking dimension; TM: BAASIS timing dimension; SF-36: Short form health survey; PIS: Physical index score of SF-36; MIS: Mental index score of SF-36; E: Education; YT: Years since transplant procedure; FS: Female sex. Correlation coefficients (r) < 0.3 indicate weak correlation, ≤ 0.7 moderate correlation, > 0.7 strong correlation.

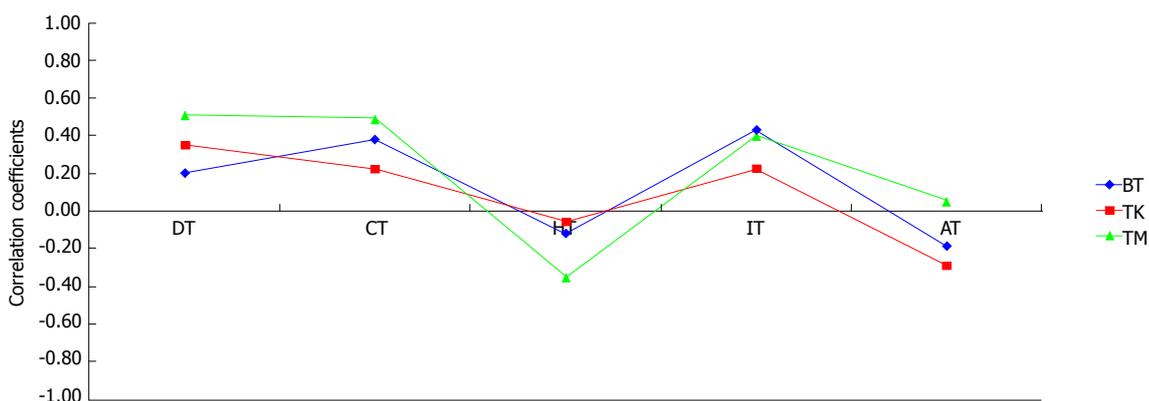

Figure 3 Correlations between temperament evaluation of memphis, pisa and san diego autoquestionnaire and basal assessment of adherence to immunosuppressive medication instrument. BAASIS: Basal assessment of adherence to immunosuppressive medication instrument; DT: Depressive temperament; CT: Cyclothymic temperament; HT: Hyperthymic temperament; IT: Irritable temperament; AT: Anxious temperament; BT: BAASIS total score; TK: BAASIS taking dimension; TM: BAASIS timing dimension. Correlation coefficients (r) < 0.3 indicate weak correlation, ≤ 0.7 moderate correlation, > 0.7 , strong correlation.

$r = 0.39$; BT/IT $r = 0.44$; BT/DT $r = 0.21$); however, a moderate positive correlation was found between the timing scale of the BAASIS and depressive temperament

variable (TM/DT $r = 0.52$), suggesting time management difficulties for patients with a depressive personality.

Multivariate linear regression analysis showed high

associations between predictor variables (sex and years since transplant procedure, cyclothymic temperament, and anxious temperament) and outcome variable (BAASIS total score), whereas no consistent associations between other predictor variables (age, irritable temperament, IT) and outcome variable (BAASIS total score) were detected (Tables 2 and 3).

DISCUSSION

Similar studies on the subject have revealed significant psychological and behavioral differences between adherent and non-adherent transplanted patients, differences that express a greater vulnerability of the latter and which lead to consider that, next to drug therapy, psychological therapy is required^[5,31]. Still not considered in other studies on the transplant topic is the temperament. "Temperament has been temporarily defined as a biologically determined, hereditary core of the personality, being stable and relatively unchangeable throughout life, which determines the basic level of reactivity, mood and energy of given individual"^[24].

Based on these assumptions, this study has allowed us to analyze different temperament styles and suggested that different temperaments can influence in different ways the treatment compliance and quality of life of transplant recipients.

In this study, the biopsychosocial illness model (BIM) provided a conceptual frame of reference within which biological, psychological, and social aspects took on the same importance in explaining the adherence to treatment protocols^[32]. For good treatment management, it is necessary to understand the patients' personal experiences, their beliefs about the disease, health status perception, and mood, and to identify any "barriers" that could make them noncompliant. The analysis of the variables that are responsible for the behavior of not adhering to the treatment regimen should provide suggestions for psychological support and psychiatric treatment. Treatment adherence towards the prescribed medication is critical for the safe and successful delivery of efficacious interventions, especially for complex tasks such as the management of transplant patients^[33,34].

The study revealed that years of transplantation positively affected mental health, but on the other hand,

Table 3 Linear model of temperament predictors on basal assessment of adherence to immunosuppressive medication instrument total score

CT: Cyclothymic temperament; IT: Irritable temperament; AT: Anxious temperament; Linear model with 95% bias corrected and accelerated confidence intervals (in parentheses).

adversely affected therapeutic adherence, while the level of education was positively correlated with good mental balance. Studies examining the non-pharmacological risk factors that influence therapeutic adherence thus need further confirmation^[5,35]. Another finding that requires careful reflection concerns the long-term negative impact that the cyclothymic and anxious personalities could have on adherent behavior, while the presence of post-transplant psychological symptoms (mental health index) did not affect treatment adherence^[36-39]. This finding could be related to the notion that while people with mental problems feel the need to be cared for and are more willing to properly follow the treatment protocol, patients with mood swings (cyclothymic temperament) and those in an alert and apprehensive state (anxious temperament) are not prepared to calmly accept the rigorous therapeutic protocol and require constant attention by healthcare staff^[40]. Thus, the quality of care is not just about the correct prescription but also about the patients' active participation through an assessment of their expectations and preferences. Patients adopt adherent behavior when they accept the type of care in terms of the therapeutic project^[41]. Helpful in this regard is cognitive behavioral therapy aimed at increasing transplant recipients' awareness^[42].

Immediately after transplant, patients must be assisted to increase the capacity for self-efficacy and resilience necessary to achieve the correct lifestyle for maintaining the graft. In a next step, it would be desirable to establish a cognitive and psychosocial rehabilitation plan to improve coping strategies and strengthen the patients' resources in order to positively influence the final outcome of the transplant process. These efforts therefore must operate simultaneously at several levels on the basis of an integrated strategy that organizes and coordinates the various types of treatment-medication, psychotherapy, assistance-and the operators' different functions, in an intervention program formulated on the basis of the characteristics and needs of each individual patient^[43,44].

The authors would thank Professor Sabina De Geest for

providing the BAASIS questionnaire used in this research.

COMMENTS

Background

Adherence to immunosuppressive therapy after transplantation is of fundamental importance for the patients' well-being both short- and long-term and assumes a set of adaptations to a new lifestyle. I pazienti trapiantati devono assumere quotidianamente farmaci immunosoppressori per la prevenzione del rigetto acuto e cronico (infezioni, complicanze secondarie). The treatment effectiveness and transplant success not only depend on the correct choice of immunosuppressive drugs, but also on the patients' active participation in the therapeutic program that often includes psychological support and appropriate motivation. Adequate adherence to doctor's orders is a resource for both patients and the health care system and society, as it reduces the costs for therapies, for minor complications associated with the disease, the health care interventions, morbidity and mortality. However various social, cultural, financial and psychological aspects affect adherence to immunosuppressive therapy.

Research frontiers

Although most research has focused on adherence to drug treatment, the concept of adherence must include other behaviors related to health protection involving the doctor-patient relationship, the service delivery system and change their living habits. The communication characteristics of the doctor, the kind of language used and the setting are essential to strengthen the motivation and awareness of the need for a cure. Future programs should provide the ability to support the transplanted in transplant experience, helping him to properly follow treatment, help him to learn cognitive and behavioral strategies of self-regulation.

Innovations and breakthroughs

Studies of the Italian population have revealed significant differences in psychological and personality traits among transplant patients adherent and non-adherent to therapy, differences that express a greater vulnerability of the latter and which lead to consider that, next to drug therapy, you are required psychological therapy. This study also allows to analyze different temperament styles, yet not studied in other research on transplantation and suggests that different temperaments influence in different ways the treatment compliance.

Applications

The data in this study suggested that psychological and psycho-educational support to the transplanted patient could yield favorable outcomes about adherence to immunosuppressive therapy. Furthermore, this study also provided readers with important informations about psychological problems that could highlight on transplanted subject.

Terminology

TA is the patient's ability to be able to follow precisely the prescribed cure. Specifically, the concept of adherence to therapy includes the compliance and persistence: Compliance reflects the acceptance of the patient to medical prescription (number of daily dose), the persistence instead indicates the time period between the start and the interruption of the treatment. BIM provided a conceptual frame of reference within which biological, psychological, and social aspects took on the same importance in explaining the adherence to treatment protocols. You must operate simultaneously at several levels in an intervention program formulated on the basis of the characteristics and needs of each individual patient.

Peer-review

Studies concerning the influence of temperament to the therapeutic adherence are scarce. The authors in this study analyzed the psychological characteristics of a sample of transplant recipients followed as outpatients at a transplant center. The results showed that the transplant experience change behaviors and quality of life based on the personality and temperament characteristics.

Abstract

AIM

To explore the effect of primary liver disease and comorbidities on transplant length of stay (TLOS) and LOS in later admissions in the first two years after liver transplantation (LLOS).

METHODS

A linked United Kingdom Liver Transplant Audit - Hospital Episode Statistics database of patients who received a first adult liver transplant between 1997 and 2010 in England

was analysed. Patients who died within the first two years were excluded from the primary analysis, but a sensitivity analysis was also performed including all patients. Multivariable linear regression was used to evaluate the impact of primary liver disease and comorbidities on TLOS and LLOS.

RESULTS

In 3772 patients, the mean (95%CI) TLOS was 24.8 (24.2 to 25.5) d, and the mean LLOS was 24.2 (22.9 to 25.5) d. Compared to patients with cancer, we found that the largest difference in TLOS was seen for acute hepatic failure group (6.1 d; 2.8 to 9.4) and the largest increase in LLOS was seen for other liver disease group (14.8 d; 8.1 to 21.5). Patients with cardiovascular disease had 8.5 d (5.7 to 11.3) longer TLOS and 6.0 d (0.2 to 11.9) longer LLOS, compare to those without. Patients with congestive cardiac failure had 7.6 d longer TLOS than those without. Other comorbidities did not significantly increase TLOS nor LLOS.

CONCLUSION

The time patients spent in hospital varied according to their primary liver disease and some comorbidities. Time spent in hospital of patients with cancer was relatively short compared to most other indications. Cardiovascular disease and congestive cardiac failure were the comorbidities with a strong impact on increased LOS.

Key words: Length of stay; Hospital stay; Comorbidity; Liver transplantation

Core tip: Time patients spent in hospital in transplant admission and in later admissions after liver transplantation may reflect the success of liver transplantation. By analysing a linked United Kingdom Liver Transplant Audit - Hospital Episode Statistics database between 1997 and 2010, we found that average transplant length of stay (LOS) was 24.8 d, and mean LOS of all admissions in the first two years after transplantation was 24.2 d. Primary liver disease and comorbidities had a significant impact on LOS. Patients transplanted for cancer has shorter LOS compared to other indications. Cardiovascular disease and congestive cardiac failure were associated with increased LOS.

INTRODUCTION

The short-term and long-term survival after liver

transplantation has been improving over the last few decades. However, length of stay (LOS) is another outcome that reflects the success of liver transplantation. Transplant LOS (TLOS) has also been one of the main outcomes in investigating health care resource use in organ transplantation. Identifying variables predicting longer LOS will help clinicians plan hospital resources in advance, and maximise the resource utilisation. LOS in transplant admission can also reliably reflect the cost of liver transplant admission^[1].

There are several studies report risk factors predicting longer transplant LOS^[2-9]. Recipient factors (e.g., age, sex, liver disease severity, retransplantation, pre-transplant nutritional status, pre-transplant renal support), donor factors (e.g., age, weight, non-local donor centre) and early post-transplant complications and graft dysfunction have been shown to be associated with prolonged transplant LOS. LOS also varies between liver transplant centres^[4,5]. Nevertheless, primary liver disease and comorbidities have rarely been investigated in terms of their effects on LOS. Moreover, the previous studies were based on only single or few centres, and the cohort sizes were often limited. In this study, we used a national clinical database linked to an administrative hospital database in England to investigate LOS in a larger national cohort of liver transplant patients.

LOS in later admissions after liver transplantation may reflect quality of life after liver transplantation and represent the success of liver transplantation. Moreover, it can reflect the healthcare resource use in the maintenance period after liver transplantation. To the best of our knowledge, there has not been any study in this topic.

In this study, we aim to investigate the effect of primary liver disease and pre-transplant comorbidities on TLOS as these two important factors have rarely been studied. The secondary aim is the effect of these factors on LOS in later admissions (LLOS) in the first two years after liver transplantation.

MATERIALS AND METHODS

The linked UKLTA-HES database

Records from the United Kingdom Liver Transplant Audit (UKLTA) database linked at a patient level to Hospital Episode Statistics (HES) records were used in this study. The UKLTA database prospectively collects liver transplant-specific data for all patients undergoing liver transplantation in the United Kingdom for audit purposes^[10]. The HES database is an administrative hospital database of all admissions to National Health Service (NHS) hospitals in England^[11]. A HES record contains the tenth revision of the International Classification of Diseases (ICD-10) diagnosis codes^[12], procedure codes, admission method as well as length of hospital stay based on date of admission and date of discharge. The linkage process was based on hierarchical deterministic linkage criteria, including NHS number, sex, date of birth, postcode, date of transplant and a

procedure code for liver transplantation or a diagnosis code relevant to liver disease. A detailed description of the linkage process has been published elsewhere^[13].

This linked database contained records of patients receiving a first liver transplant in England between 1st April 1997 and 31st March 2010. We excluded linked records of paediatric liver transplantation (younger than 17 years), multi-organ transplantation, living-donor liver transplantation and domino liver transplantation. To avoid the interference from the short LOS in patients who died early after transplantation, the patients who died within the first two years after liver transplantation (718 patients) were also excluded from the primary analysis. However, a sensitivity analysis for the whole cohort was also performed. At least two years follow-up was available for all included patients.

LOS information

LOS information was obtained from the HES database. TLOS was calculated from date of transplant to date of discharge, while LOS of a later admission was calculated from date of admission to date of discharge. LOS of all later admissions in the first two years after transplantation (LLOS) was defined as a sum of LOS of every admission in any NHS hospital in England that had an admission date within the first two years from the date of transplant.

Statistical analysis

Unadjusted TLOS and LLOS of patients in each primary liver disease group and of patients with each comorbidity were compared using unpaired two-tailed Student's *t*-test and analysis of variance (ANOVA) as appropriate. Primary liver diseases were categorised into ten indication groups according to Roberts *et al*^[14], including one group with less common indications grouped together as the other liver diseases group. Eight comorbidities were identified from ICD-10 diagnosis codes in HES based on the adaptation of the Royal College of Surgeons Charlson Score for liver transplantation^[15]. Cardiovascular comorbidity comprises of a history of myocardial infarction, peripheral vascular disease and cerebrovascular disease.

Multivariable linear regression analysis was performed to determine the effects of the individual variables on TLOS and LLOS, taking into account other baseline characteristics, severity of liver disease and transplant centres. Variables included in the model were 10-group primary liver disease, all eight comorbidities, recipient age, sex, serum bilirubin, creatinine, sodium and international normalised ratio (INR) of prothrombin time (factors reflecting the severity of liver disease), liver transplant centre and time period of liver transplantation. Serum bilirubin and creatinine were log-transformed before inputting into the model to improve the linearity of the relationship between these factors and LOS. The comorbidities and sex were included as binary variables, while primary liver disease groups, transplant centre and time period of liver transplantation

were entered as categorical variables. The remaining variables were included as continuous variables.

LOS may not only depend on disease and patient factors, such as type and severity of liver disease and comorbidities, but also on hospital policy that may change over time. Therefore, we included the information about individual transplant centre and time period of liver transplantation in the models.

The ten primary liver disease groups were mutually exclusive. In the multivariable models, coefficients of primary liver disease groups were compared to cancer group as a reference group because it was one of the most common and shortest LOS groups. To make the comparison easier to interpret, we also presented adjusted mean LOS, which reflects LOS for these groups after taking other variables into account. The adjusted mean TLOS and LLOS for patients in each of the primary liver disease groups were calculated based on the prediction from multivariable linear regression models and presented along with their 95% confidence intervals (CI). This represents the LOS according to primary liver disease groups with an average case-mix profile of other variables in the model.

To ensure that patients with missing values were not excluded from the analyses, missing values were imputed with ten plausible data sets using multiple imputation with chain equations technique^[16]. The ten completed data sets were individually analysed, and estimates were then pooled to give final estimates using Rubin's rules^[17]. However, all of the variables in the model had missing values for less than 5% of the patients. All statistical analyses were performed using Stata version 11.2 (StataCorp, College Station, TX, United States). A *P*-value of less than 0.05 was considered statistically significant.

Sensitivity analysis

The primary analysis included only patients who survived the first two years after transplantation as the patients who died early after transplantation would shorten the average of LOS. A sensitivity analysis for TLOS was performed using the whole cohort including patients who died in the first two years after transplantation (4490 patients).

RESULTS

Demographic characteristics

The data used in this study were from 3772 adult patients who had a first liver transplant in England from April 1997 to March 2010 and survived the first two years after liver transplantation. The median (interquartile range: IQR) age was 52 (42 to 59) years, and 58.7% of the patients were male. The most common indication for liver transplantation was alcoholic cirrhosis (20.0%), followed by cancer (13.9%) and primary biliary cirrhosis (13.4%). The most common comorbidity was diabetes mellitus with a prevalence of 20.8%, followed by chronic

Results are numbers (percentages) or medians (interquartile ranges). INR: International normalised ratio; UKELD: United Kingdom End-stage Liver Disease.

pulmonary disease (9.1%) and chronic renal disease (6.6%) (Table 1). In terms of pre-transplant status, 74.0% of the patients were at home, while 16.0% were in hospital but not ventilated, and 10.0% were hospitalised and ventilated at the time of transplantation. Some 4.7% of the patients received a liver graft from donation after cardiac death.

Overall LOS

Overall, patients spent an average of 24.8 d (95%CI: 24.2 to 25.5) in hospital during their transplant admission, and 24.2 d (22.9 to 25.5) in later admissions in the first two years after transplantation (Table 2).

LOS according to primary liver diseases

Primary liver disease groups were significant predictors of both TLOS and LLOS (Table 2). Using cancer group as a baseline, the multivariable analysis demonstrated that patients in acute hepatic failure (6.1 d longer), other liver disease (5.9 d longer), metabolic and non-

alcoholic fatty liver disease (4.3 d longer) and hepatitis C cirrhosis (3.9 d longer) groups had significantly longer TLOS than the baseline. As for LLOS, other liver disease (14.8 d longer) and primary sclerosing cholangitis (8.4 d longer) were significantly associated with longer LLOS than the baseline (Table 3).

Figure 1 presents the same above results using adjusted means for TLOS and LLOS, and further illustrates that patients with acute hepatic failure, hepatitis C cirrhosis, metabolic and non-alcoholic fatty liver disease and other liver disease had longer than average TLOS and LLOS, although not all significantly so. Whereas, patients with liver diagnosis of cancer, primary biliary cirrhosis, alcoholic cirrhosis and autoimmune hepatitis and cryptogenic cirrhosis groups had shorter than average TLOS and LLOS. Of note, primary sclerosing cholangitis was associated with shorter TLOS, but significantly longer LLOS (Figure 1).

LOS according to comorbidities

Patients with atherosclerotic cardiovascular disease had the longest unadjusted TLOS at 33 d, and those with chronic renal disease had the longest unadjusted LLOS at 32 d (Table 2). The multivariable linear regression analysis demonstrated that cardiovascular disease and congestive cardiac failure were significantly associated with longer TLOS. Patients with cardiovascular disease spent an average of 8.5 d longer in transplant admission than those without the comorbidity, and those with a history of congestive cardiac failure spent 7.6 d longer than those without, confirming what previously observed in unadjusted LOS (Table 3).

Patients with cardiovascular disease spent significantly longer time in hospital in the first two years after transplantation than those without the comorbidity (6.0 d longer). Those with chronic renal disease and chronic pulmonary disease spent 4.8 d and 4.3 d longer than those without the comorbidities, respectively, albeit not statistically significant (Table 3).

Sensitivity analysis of TLOS including patients who died in the first two years after liver transplantation

After including 718 patients who died within the first two years after transplantation, the sensitivity analysis of 4490 patients found that primary liver disease, cardiovascular disease and congestive cardiac failure remained statistically significant in predicting TLOS. In terms of primary liver disease groups, patients in other liver disease group had the longest TLOS, followed by acute hepatic failure group. Cardiovascular disease were associated with 8.7 d longer TLOS than those without the comorbidity, while patients with congestive cardiac failure had 7.7 d longer TLOS than those without, which were similar to those in the primary analysis (Table 4).

DISCUSSION

Liver transplant recipients spent in total 49 d in hospital during the first two years after transplantation,

¹A coefficient for primary liver disease groups represents a difference in days between LOS in the primary liver disease group and the reference group (cancer); ²A coefficient for comorbidities represents a difference in days between LOS of patients with and without the comorbidity. The multivariable model was adjusted for primary liver disease group, comorbidities, recipient age, sex, log bilirubin, log creatinine, INR, sodium, transplant centre and time period of transplantation. TLOS: Transplant length of stay; INR: International normalised ratio.

cardiovascular disease and cardiac failure also had longer TLOS than those without these comorbidities, and patients with cardiovascular disease spent longer time in later admissions than those without.

In terms of primary liver disease, acute hepatic failure, hepatitis C cirrhosis and other liver disease were associated with longer TLOS. Patients with acute hepatic failure are mostly intubated and ventilated and on renal replacement therapy^[18]. Therefore, it is not unexpected that they required more time to recover from the liver transplant operation. Hepatitis C cirrhosis may be related to more complications after liver transplantation, and this is probably the reason why patients transplanted for this indication spent longer time in transplant admission. The group of patients with other liver disease is the most heterogeneous group of patients with a wide range of liver diagnoses, consisting mainly of Budd-Chiari syndrome, secondary biliary cirrhosis and polycystic liver disease. Thus, the reason why these patients had longer LOS needs further investigation.

Patients with primary sclerosing cholangitis had relatively shorter TLOS, but relatively longer LLOS. These discrepancies may be a result of a higher rate of recurrent disease, vascular complications or conditions related to ulcerative colitis that need admissions for interventions or procedures^[19]. Nevertheless, the reasons for readmissions can be either transplant-related or non-transplant-related, and they were not explored in this study.

With respect to comorbidities, common comorbidities, such as diabetes, chronic pulmonary and renal disease, showed no impact on TLOS, while less common comorbidities, such as cardiovascular disease and congestive cardiac failure, were found to have an impact on TLOS. Cardiovascular disease, which is the grouping of three comorbid conditions in the same disease spectrum (myocardial infarction, peripheral vascular disease and cerebrovascular disease), was significantly associated with longer TLOS as was congestive cardiac failure. We have shown elsewhere that a previous history of cardiovascular disease and cardiac failure were also associated with

higher 90-d mortality^[15]. This study further showed that these groups of high-risk patients also used more health resources during their transplant admission. This is probably because of a higher risk of cardiac complications following a hemodynamically stressful liver transplant operation in these already compromised patients.

A previous single-centre study carried out in the United States with only 83 patients found that multi-vessel coronary artery disease is associated with higher mortality, increased LOS and post-operative vasopressor requirements^[20], which is in line with the results found in our national cohort in England. In addition, we demonstrated that the LOS in later admissions in the first two years in patients with atherosclerotic cardiovascular disease was also longer, particularly in those who survived the first two years. This reflects that these patients with cardiovascular comorbidity have a higher mortality risk and require more healthcare resources during transplant admissions as well as the early period after liver transplantation.

Our results have a number of implications for clinical practice. First, LOS of the transplant admission and of later admissions can be an alternative marker of outcomes after liver transplantation, especially in the era that graft and patient survival after liver transplantation have been excellent. LOS in later admissions after liver transplantation may also reflect the quality of life and functional status of a patient after transplantation. A successful liver transplantation should return a patient back to the healthy status with as few admissions after transplantation as possible. Second, the ability to estimate LOS may be beneficial to the pre-transplant counselling process as it can help to inform patients and their relatives what to expect after liver transplantation. Third, another benefit of estimating LOS is that it would help clinicians and hospitals plan their resource utilisation and bed management. For example, patients transplanted for cancer spent, on average, a total of 44 d in the first two years after transplantation, whereas patients who were transplanted with an indication in other liver disease group, such as Budd-Chiari syndrome, had a total LOS that was 50% longer (66 d) (Figure 1). Fourth, our results can improve economic evaluations of liver transplantation as it provides more accurate estimates of LOS for patients with comorbidities.

We note a number of limitations of this study. Firstly, we have not explored the reasons for later admissions. It may be beneficial to understand the indication for readmissions in particular groups of patients, and this may warrant further research. Secondly, this study includes only patients who had a first liver transplant. It is known that the outcomes of retransplantation are much different to those of first liver transplantation^[21]. Retransplantation has also been shown to be associated with longer transplant LOS^[4].

Conclusion

We have shown that the time patients spent in hospital after liver transplantation is linked to primary liver

disease and comorbidities. LOS was relative short for patient who had a liver transplant for cancer whereas the opposite was true for patients with atherosclerotic cardiovascular disease and congestive cardiac failure.

ACKNOWLEDGMENTS

The authors would like to thank all liver transplant centres for providing data to the United Kingdom Liver Transplant Audit. We would also like to thank all those involved in collecting and handling liver transplant data at the National Health Service Blood and Transplant. COMMENTS

Background

Time patients spent in hospital after transplantation is directly related with health care resource use and partly reflects the success of liver transplantation. Identifying factors predicting longer length of stay will help clinicians and hospitals to plan and maximise the resource utilisation.

Research frontiers

Several recipient and donor factors have been found to be associated with prolonged transplant length of stay. However, primary liver disease and comorbidities have rarely been investigated in this issue. Length of stay in later admissions after transplantation also reflects quality of life after liver transplantation and can represent the success of liver transplantation. This has never been investigated in liver transplantation.

Innovations and breakthroughs

Based on the United Kingdom national liver transplant cohort, the authors demonstrated that transplant length of stay was affected by primary liver disease and comorbidities. Patients with acute hepatic failure, hepatitis C cirrhosis, atherosclerotic cardiovascular disease and a history of congestive cardiac failure stayed longer in hospital in their transplant admissions, while patients with primary sclerosing cholangitis spent more time in subsequent admissions in the first two years after liver transplantation.

Applications

Estimating length of stay will help clinicians and hospitals plan their health care resource utilisation including bed management. Moreover, knowing the estimated length of stay will be beneficial to the pre-transplant counselling process. It can help inform patients and relatives what they expect after liver transplantation. Finally, in the era that graft and patient survival after liver transplantation have been excellent, length of stay of the transplant admission and of later admissions can be a surrogate of outcomes after liver transplantation. Length of stay in later admissions after liver transplantation also specifically reflects the quality of life of patients after transplantation and the success of liver transplantation as it should return a patient back to the healthy status with as few admissions after transplantation as possible.

Terminology

Transplant length of stay (TLOS) was calculated from date of transplant to date of discharge, not including time patients spent in hospital in the pre-

transplant period. Length of stay in later admissions was a sum of length of stay of every admission in any National Health Service hospital in England that had an admission date within the first two years from the date of transplant. Cardiovascular comorbidity comprises of a history of myocardial infarction, peripheral vascular disease and cerebrovascular disease coded in the administrative hospital database in any previous admission in the preceding year before the transplant. Congestive cardiac failure is defined by a history of congestive cardiac failure coded in the administrative hospital database in any previous admission in the preceding year before the transplant. Other liver disease is a group of indications for liver transplantation that is consisted of less common indications grouped together. It is the most heterogenous group of indications, including mainly Budd-Chiari syndrome, secondary biliary cirrhosis and polycystic liver disease.

Peer-review

This study investigated the time after surgery after liver transplantation. The aim was clear, and methods were appropriate.

Abstract

AIM

To evaluate cardiac magnetic resonance imaging (CMR) as a non-invasive tool to detect acute cellular rejection (ACR) in children after heart transplant (HT).

METHODS

Thirty pediatric HT recipients underwent CMR at the time of surveillance endomyocardial biopsy (EMB) and results were compared to 14 non-transplant controls. Biventricular volumes, ejection fractions (EFs), T2-weighted signal intensities, native T1 times, extracellular volumes (ECVs) and presence of late gadolinium enhancement (LGE) were compared between patients and controls and between

patients with International Society of Heart and Lung Transplantation (ISHLT) grade \geq 2R rejection and those with grade 0/1R. Heart rate (HR) and brain natriuretic peptide (BNP) were assessed as potential biomarkers.

RESULTS

Significant ACR (ISHLT grade \geq 2R) was an infrequent event in our population (5/30, 17%). Ventricular volumes, EFs, LGE prevalence, ECVs, native T1 times, T2 signal intensity ratios, HR and BNP were not associated with the presence of \geq 2R ACR.

CONCLUSION

In this pilot study CMR did not reliably identify ACR-related changes in pediatric HT patients.

Core tip: After heart transplantation the diagnosis of significant acute cellular rejection (ACR) changes management and is associated with adverse outcome. Endomyocardial biopsy is the gold standard for the detection of ACR but has important limitations. This prospective trial examined the use of cardiac magnetic resonance imaging (CMR) for the diagnosis of ACR in pediatric heart transplant recipients. Significant rejection was a rare event in our cohort and was not associated with changes in CMR parameters in this pilot study.

Magnetic resonance imaging of the transplanted pediatric heart as a potential predictor of rejection. *World J Transplant* 2016; 6(4): 751-758 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/751.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.751>

INTRODUCTION

Acute cellular rejection (ACR) is an immune-mediated process leading to allograft damage and decreased graft survival. It is a serious and potentially lethal complication after heart transplant (HT). The gold standard for the detection of rejection is an endomyocardial biopsy (EMB). However, EMB is an invasive procedure, exposes the patient to ionizing radiation and carries a small but important risk of serious complications^[1-4].

Cardiac magnetic resonance imaging (CMR) has been proposed as a non-invasive method for the detection of rejection in adults after HT. However, CMR measurements used in adults for the detection of rejection or myocardial inflammation, including T2-weighted imaging^[5,6], native T1 times and extracellular volume fractions (ECVs) derived from T1 mapping^[7], myocardial thickness,

ventricular volumes and ejection fraction (EF)^[8,9] have not been systematically evaluated in pediatric HT recipients with EMB-proven ACR.

In this pilot study we sought to assess the utility of parameters of ventricular function and myocardial tissue characterization for the non-invasive detection of ACR in children and adolescents after HT.

MATERIALS AND METHODS

Patients and study design

This single center, prospective, cross-sectional study was approved by the institutional research ethics board and included pediatric (age < 18 years) HT patients who were scheduled for a clinically-indicated EMB between April 2010 and March 2011. All consecutive and eligible patients without contraindications to contrast-enhanced CMR during the study period were invited to participate. In patients who underwent more than one CMR/EMB procedure during the study period only the first set of investigations was analyzed for this study. Following written informed consent, CMR was performed immediately prior to cardiac catheterization and EMB. Control subjects were asymptomatic relatives of patients diagnosed with arrhythmogenic right ventricular cardiomyopathy (ARVC) who had normal echocardiograms, electrocardiograms (ECGs), signal-averaged ECGs as well as CMR scans and who were negative for ARVC-associated mutations if testing had been performed. Control subjects did not receive gadolinium as part of their CMR study. Heart rate (HR) was obtained from the average HR during the short axis CMR cine acquisition for ventricular volumetry.

Standardized immunosuppression post-transplantation for all patients included the use of thymoglobulin for induction (1-5 doses depending on risk factors), tacrolimus and mycophenolate mofetil. Perioperative steroids were discontinued 6 mo post-HT until 2007 and thereafter were discontinued at 5 d post-HT. Routine surveillance for rejection included serial echocardiograms, ECGs and cardiac catheterization with decreasing frequency over time post-transplantation.

EMB

At the authors' institution right ventricular EMBs are obtained at 1, 6 and 12 mo and then annually up to 5 years post-HT; thereafter only if there is clinical or echocardiographic suspicion for rejection. During the EMB five or six tissue samples were obtained from the right ventricular surface of the interventricular septum, stained with hematoxylin and eosin and evaluated using light microscopy. Samples were graded by a hospital pathologist who was blinded to the CMR and biochemistry results (below) and reported according to the International Society of Heart and Lung Transplantation (ISHLT) Standardized Cardiac Biopsy Grading Criteria^[10]. Congruent with clinical practice grades 2R and 3R were classified as significant ACR and grades 0R and 1R as

non-significant ACR. Tissue samples were also evaluated for the presence of antibody-mediated rejection (AMR) by C4d immunohistochemical staining.

CMR

CMR was performed using a 1.5 Tesla scanner (Magnetom Avanto, Siemens AG Healthcare Sector, Erlangen, Germany) and a phased-array multi-channel surface receiver coil.

Ventricular volumetry and late gadolinium enhancement

A stack of multiphase short axis slices was acquired using the steady state free precession technique for left and right ventricular volumes, as described previously^[11,12]. Ventricular volumes were extracted from the cine short axis stack in end-diastole and end-systole in the routine clinical fashion using commercially available software (QMass, version 7.2, Medis, Leiden, The Netherlands). Ventricular volumes were reported as indexed to recipient body surface area. EFs for both ventricles were calculated using end-diastolic and end-systolic volumes. The presence of late gadolinium enhancement (LGE) was determined qualitatively on standard long-axis (4-chamber, 2-chamber and 3-chamber) and short-axis slices using phase-sensitive inversion-recovery acquisitions > 10 min after the administration of 0.2 mmol/kg gadopentetate dimeglumine (Magnevist®, Bayer, Leverkusen, Germany).

T1 mapping and extracellular volumes

We previously described our T1 mapping approach for these patients in detail^[13]. In short, a modified Look-Locker inversion recovery sequence (MOLLI) with inversion pulses of 100 msec and 150 msec, respectively, as well as 3 and 5 single-shot images after these inversion pulses was used to measure native and post-contrast longitudinal relaxation T1 times of myocardium and blood. Images were acquired in diastole at a single mid-ventricular short axis slice orientation before and > 10 min after administration of contrast (same injection as described above for LGE). Breathholds were used in cooperative patients and all other patients were scanned during free breathing. Longitudinal relaxation times (T1 times) were measured using commercially available software (CVI42, Circle Cardiovascular Imaging, Calgary, AB, Canada). Contours were drawn in the interventricular septum, the left ventricular (LV) free wall and in a region encompassing the entire LV myocardium. T1 times in the blood pool were measured in the LV cavity. The ECV was calculated using pre- and post-gadolinium T1 times of blood and myocardium as well as the patient's hematocrit, obtained at the time of the scan^[14].

T2-weighted imaging

An ECG-gated turbo spin-echo readout sequence without fat saturation pulse preceded by a double inversion recovery dark-blood preparation and the following parameters was obtained in a single midventricular short axis slice^[15]: Inplane spatial resolution 1.6 mm, slice

thickness 6-10 mm, TE 59 ms. Imaging was performed in diastole during every other or every third heartbeat, depending on the HR, to achieve a TR of at least 1000 ms. The scanner's body coil was used for a homogeneous signal reception within the field of view. Myocardial signal intensity was measured around the circumference of the short axis slice and normalized to that of skeletal muscle using a dedicated module within the CVI42 software^[16].

Brain natriuretic peptide levels

A blood sample was drawn upon insertion of the peripheral intravenous cannula needed for the CMR and analyzed for brain natriuretic peptide (BNP) levels (Modular Analytics, Roche Diagnostics, Laval, QC, Canada).

Statistical analysis

CMR data from transplant patients were stratified according to the presence (grade \geq 2R) or absence (grade 0R or 1R) of significant ACR. Most variables were not normally distributed and results are thus presented as medians, 10th and 90th percentiles. Medians between groups were compared using a non-parametric Wilcoxon two-sample test or the Kruskal-Wallis test where appropriate. A *P*-value < 0.05 was considered statistically significant. All analyses were performed using SAS for Windows 9.4 (SAS Institute Inc., Cary, NC, United States). Statistical review of the study was performed by a biomedical statistician (FD).

RESULTS

Patient demographics and non-imaging biomarkers of rejection

The CMR studies from 14 non-transplant pediatric controls and 30 pediatric HT recipients were included in this study. The EMBs from 25 HT patients (83%) showed no significant ACR (ISHLT grades 0R or 1R) while 5 (17%) demonstrated significant rejection (ISHLT 2R). No patient had ISHLT grade 3R ACR. None of our HT patients were identified as having AMR. There were no statistically significant differences between the transplant groups with < 2R and \geq 2R ISHLT rejection with respect to age at CMR or for time since transplant (Table 1). Patients with grade 2R rejection were younger than the controls and "no rejection" groups at the time of CMR but this difference was not statistically significant. HR and BNP were significantly increased in both groups of HT patients compared to controls but there were no statistically significant differences between the "no rejection" and "rejection" HT groups.

Ventricular function, volumes and mass

Biventricular end-diastolic volumes were decreased in the rejection group compared to the controls but not in the group without rejection (Figure 1). LVEF was decreased and LV mass increased only in the "no rejection" group compared to controls (Table 2). However, no significant

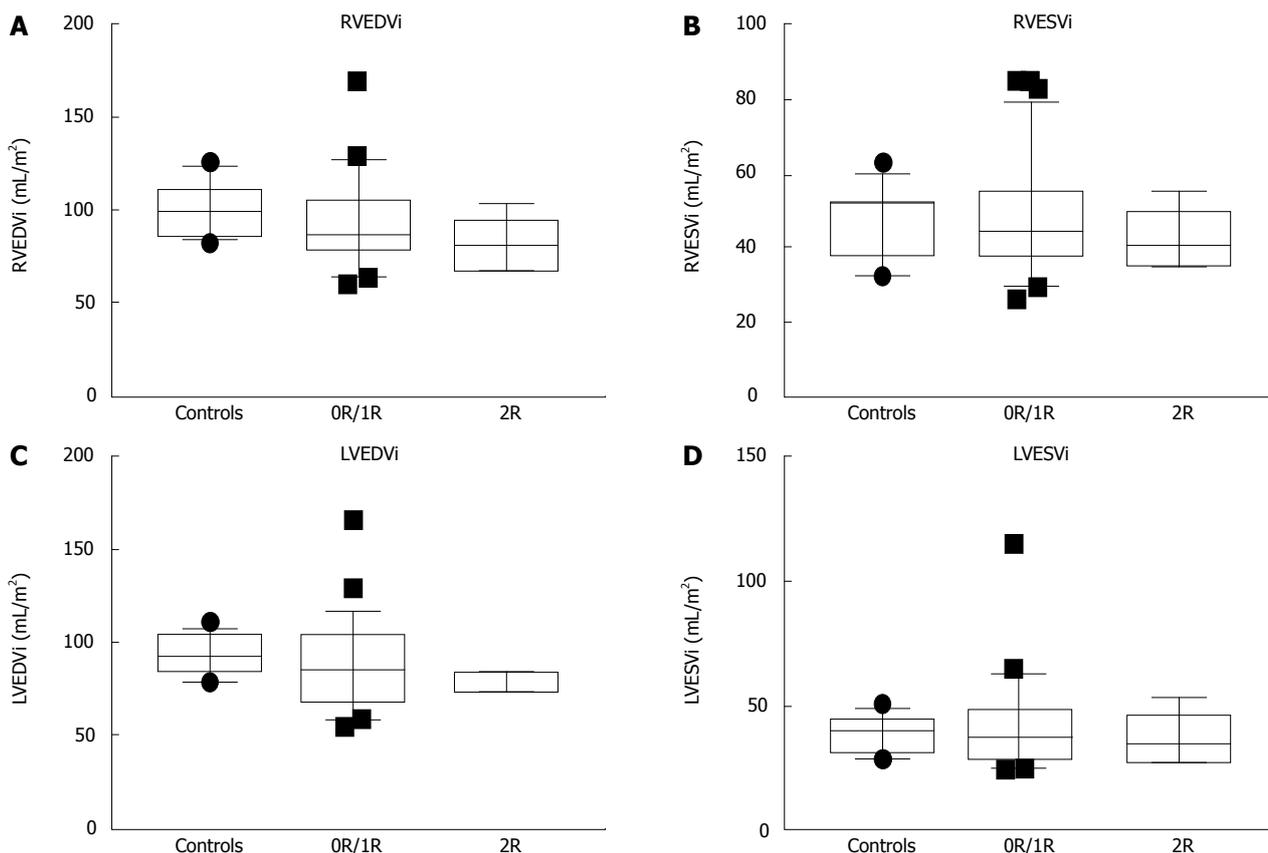

Figure 1 Box and whiskers plots for end-diastolic and end-systolic ventricular volumes of controls and transplant patients without (OR/1R) and with (2R) significant rejection. A: Right ventricular end-diastolic volume indexed to body surface area (RVEDVi); B: Right ventricular end-systolic volume indexed to body surface area (RVESVi); C: Left ventricular end-diastolic volume indexed to body surface area (LVEDVi); D: Left ventricular end-systolic volume indexed to body surface area (LVESVi).

Age at CMR (yr)	12.8 (9.2, 15.3)	13.6 (2.2, 17)	7.7 (1.6, 17.5)
HR	71 (57, 84)	96 ^b (82, 126)	108 ^d (101, 130)
BNP	9.2 (5, 12.9)	38.7 ^f (5, 81.6)	59.9 ^e (14.9, 202)

Data shown as number (percentage) or median (10th, 90th percentiles). Significantly different compared to controls, ^b*P* = 5.76E-05, ^d*P* = 0.005, ^f*P* = 0.005, ^e*P* = 0.03. There were no significant differences between the transplanted rejection groups. HR: Heart rate in beats per minute; BNP: Brain natriuretic peptide in ng/L; CMR: Cardiac magnetic resonance imaging.

differences between HT patients with and without clinically important rejection were observed with regards to ventricular volumes, ejection fractions, LV mass or LV mass/volume ratio. The absence of a significant change in ventricular volumes with rejection may be confounded by the increase in ventricular size with age (Figure 2). There was no significant association between BNP and CMR parameters.

Native T1 times, myocardial extracellular volume fraction and LGE

The MOLLI sequence for T1 mapping became available to us after study enrollment had begun and therefore this data was available only in a subgroup of patients (Table 3). With regards to patient demographics there were no significant differences between this patient subset and the entire cohort. There were no significant differences in native T1 times and ECV fraction between patients with < 2R and ≥ 2R ISHLT rejection. LGE was not observed in any of the HT patients. Native T1 times and ECV were not quantified and LGE imaging was not obtained in controls who did not receive contrast.

Myocardial T2-weighted imaging

The global ratios of myocardial:skeletal muscle T2 signal intensities on a mid-ventricular short axis slice were similar between groups and did not differ between controls (median 1.37, 10th percentile 1.29, 90th percentile 1.67) and transplant patients with no rejection (median 1.3, 10th percentile 1.02, 90th percentile 1.6) or with rejection (median 1.3, 10th percentile 1.12, 90th percentile 1.47). There were no significant differences between transplant patients with < 2R and ≥ 2R ACR rejection.

Table 2 Ventricular volumes, function and mass

	Controls	No rejection (OR/1R)	Rejection (2R)
Number	14	25	5
RVEDVi (mL/m ²)	98.5 (85.7, 120.4)	86.6 (64.1, 124.4)	80.6 ^a (68.1, 102.7)
RVESVi (mL/m ²)	50.5 (33.9, 56.1)	44.1 (30.7, 77)	41 (34.9, 55.4)
RVEF (%)	53.4 (48, 60)	50 (41, 57)	47.4 (40, 56)
LVEDVi (mL/m ²)	93 (79.2, 104)	85.2 (58.9, 112)	74.1 ^c (73.7, 85)
LVESVi (mL/m ²)	40.3 (29.8, 45)	37.5 (24.6, 60.9)	33.8 (27.2, 52)
LVEF (%)	58.8 (53.2, 63)	54 ^e (46, 64)	56 (36, 63)
LV mass (g/m ²)	53.5 (45.8, 61)	61.5 ^b (50, 84.6)	66.1 (48, 80)

Data shown as median (10th, 90th percentiles) except for number. Significantly different compared to controls, ^a*P* = 0.03, ^c*P* = 0.02, ^e*P* = 0.05, ^b*P* = 0.003. There were no significant differences between the transplant rejection groups. RVEDVi: Right ventricular end-diastolic volume indexed to recipient body surface area; RVESVi: Right ventricular end-systolic volume indexed to recipient body surface area; RVEF: Right ventricular ejection fraction; LVEDVi: Left ventricular end-diastolic volume indexed to recipient body surface area; LVESVi: Left ventricular end-systolic volume indexed to recipient body surface area; LVEF: Left ventricular ejection fraction; LV mass: Left ventricular mass indexed to recipient body surface area; CMR: Cardiac magnetic resonance imaging.

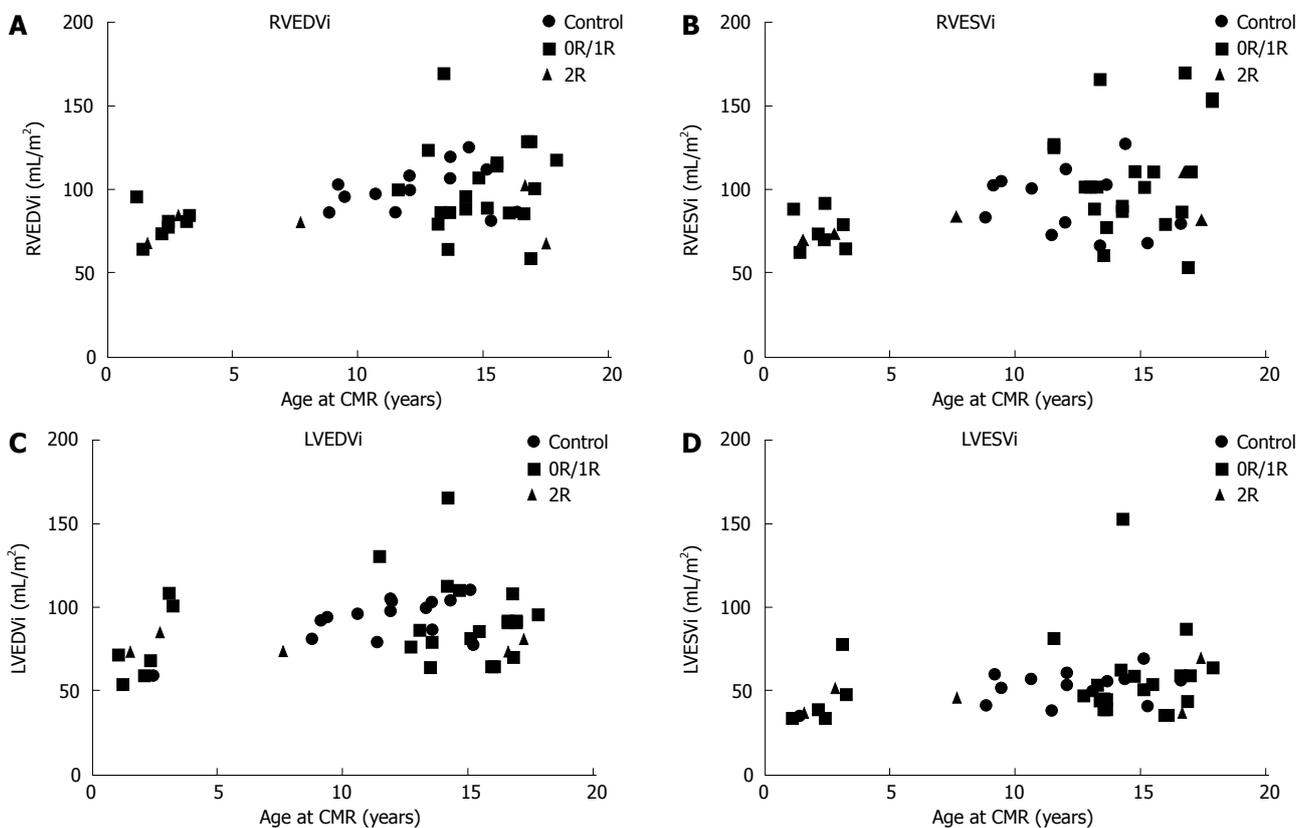

Figure 2 Ventricular volumes plotted as a function of age for controls and transplant patients without (OR/1R) and with (2R) significant rejection. A: Right ventricular end-diastolic volume indexed to body surface area (RVEDVi); B: Right ventricular end-systolic volume indexed to body surface area (RVESVi); C: Left ventricular end-diastolic volume indexed to body surface area (LVEDVi); D: Left ventricular end-systolic volume indexed to body surface area (LVESVi).

DISCUSSION

Despite a growing body of evidence in adult HT patients and important information from animal experiments the role of CMR for the detection of ACR in children has not been explored^[17-19]. CMR tissue characterization overcomes important limitations of EMB such as the potential of containing scar from a previous EMB in the

histological sample and the fact that specimens are collected from the RV surface of the interventricular septum and may not be representative of the remainder of the myocardium^[17]. The current study compared descriptors of myocardial edema, expansion of the myocardial extracellular space, presence of patchy myocardial scarring as well as ventricular size and function between controls and HT recipients as well

Table 3 T1 and extracellular volume data for heart transplant patients

	No rejection (0R/1R)	Rejection (2R)
Number	18	4
Female (%)	8 (44)	1 (25)
Days post-transplant	485 (13, 1818)	142 (12, 800)
Age at CMR (yr)	13.2 (1.4, 16.9)	5.3 (1.6, 16.8)
Native T1 (ms)		
IVS	1008 (963, 1067)	976 (967, 1026)
LV free wall	988 (903, 1018)	978 (924, 1016)
Entire LV	991 (930, 1031)	978 (944, 1020)
Hematocrit	0.37 (0.26, 0.44)	0.35 (0.29, 0.38)
ECV		
IVS	0.3 (0.26, 0.34)	0.29 (0.26, 0.33)
LV free wall	0.27 (0.24, 0.34)	0.28 (0.25, 0.31)
Entire LV	0.29 (0.26, 0.33)	0.29 (0.27, 0.32)

Data shown as number (percentage) or median (10th, 90th percentiles). There were no significant differences between the groups. ECV: Extracellular volume; IVS: Interventricular septum; LV: Left ventricle.

as between HT patients with < 2R and \geq 2R ISHLT rejection. However, in contrast to the experience in adult HT populations for several of these parameters, we were unable to demonstrate an association of any of them with ACR in pediatric HT recipients^[17,19].

None of the 30 patients in our study displayed patchy myocardial scarring as evidenced by LGE. This finding is in contrast to studies in adult HT recipients which found myocardial scarring on LGE imaging in a sizeable proportion (although this was not correlated with rejection)^[19,20]. The reason for this discrepancy remains unclear, but may be related to the younger age of the donor hearts used for pediatric HT^[21,22]. While LGE reflects patchy myocardial scarring of a certain size native T1 and ECV are regarded as measures of expansion of the extracellular matrix. Both are elevated in states of increased myocardial fibrosis or edema. Acute rejection is characterized histologically by inflammation of the myocardium while chronic or repeated episodes of rejection have been associated with fibrotic remodeling^[7,23,24]. Native T1 and ECV have been explored as markers of ACR in a pilot study in adults after HT but an association with rejection has yet to be demonstrated^[8]. In the current study, albeit in a limited number of patients, ECV and native T1 times did not distinguish between < 2R and \geq 2R ISHLT rejection. T2-weighted imaging is an established approach to detect tissue edema in inflammatory conditions and in the heart it is used as a marker for myocardial edema in myocarditis^[6]. Studies that employed T2 signal intensity for the non-invasive detection of rejection have yielded mixed results in adult HT patients^[5,9,25]. Our early results did not reveal increased signal intensity on T2-weighted imaging in patients with ACR. T2 mapping is another approach to myocardial edema which has yielded promising results in adult ACR^[19,26-28], but this technique was not available to us at the time of the study. When discussing the lack of agreement between CMR markers and histological

indicators of ACR, important shortcomings of EMB as the gold standard for the detection of ACR must be considered. Marie *et al*^[26] found T2 mapping CMR to be "positive" for significant rejection several weeks before a follow-up EMB confirmed it suggesting a lack of sensitivity for EMB.

Ventricular size, LV myocardial mass, and function did not distinguish between patients with < 2R and \geq 2R ISHLT rejection in our study. An increase in indexed right ventricular end-diastolic volume has emerged as a potential predictor of rejection in adults^[19], but the trend in our patients was in the opposite direction for both right and left ventricular end-diastolic volumes. The use of ventricular volumes as a biological marker is potentially problematic for two reasons: Firstly, there is often a size mismatch between the donor and the recipient which can be up to two-fold in children. This mismatch is fairly random and quite possibly obscures any association between ventricular size and the presence of rejection. Secondly, indexing to body surface area, although standard practice, is a crude strategy for normalizing ventricular volumes in children. Z-scores are more reliable in ensuring comparability across a spectrum of ages, body sizes and genders, but universally accepted Z-scores for CMR volumes are missing.

Another potential sign of inflammation is myocardial swelling as evidenced by increased LV "mass". Studies in adults have shown an increase in LV wall thickness during episodes of rejection^[28,29]. However, an increase in LV mass in HT patients also occurs unrelated to rejection due to myocardial hypertrophy either as an adverse effect of medications^[30], myocardial TNF- α expression^[31] or hypertension. In our study there was no significant difference between HT patients with and without \geq 2R ACR with regards to LV mass.

With regards to non-CMR parameters, higher HRs were noted in the HT recipients as compared to controls due to denervation during the transplant operation. However, in our small cohort HR did not differ significantly between patients with and without significant rejection. An elevated BNP has also been proposed as a marker for rejection in pediatric cardiac transplant patients^[32] and, although elevated in the transplant patients, there was no significant difference between the transplant rejection groups.

The most important limitation of this pilot study is the small number of patients with \geq 2R rejection which may have obscured associations of EMB with CMR parameters. The number of patients with available T1 mapping data, in particular, was very small. The small numbers may have also augmented the effects of potential confounders, for example donor:recipient size mismatch in HT patients, and thereby affected the comparability of ventricular volumes. The relatively low prevalence of ACR in the current era is related to improved immunosuppression regimes and, consistent with contemporary outcomes^[33], none of the patients in our study had severe grade 3R rejection. The incidence of moderate (grade 2R) ACR (17%) was similar

to the 13%-23% found by others^[8,19,20]. T1 relaxometry and T2-weighted imaging were based exclusively on measurements in a single mid-ventricular short axis slice. Many experts now recommend a wider representation of all regions of the LV in tissue characterization. Since many of the measures we assessed are associated with intramyocardial edema, which is rare in 2R rejection, it is perhaps unsurprising that the studied CMR parameters were unchanged. It is possible that, rather than detecting acute rejection, CMR may have a greater role in identifying long-term changes in the myocardium perhaps associated with cardiac allograft vasculopathy.

Studies in adults have produced mixed results with regards to the use of CMR as a screening tool for rejection and our pilot study did not identify CMR parameters altered by the presence of 2R rejection. However, myocardial tissue characterization by CMR is undergoing continuous refinement. Given the conceptual association between ACR and myocardial inflammation and the multiple disadvantages of EMB, CMR should continue to be evaluated for its ability to non-invasively detect rejection. Larger trials producing sizable cohorts of patients with clinically-significant rejection episodes and including T2 relaxometry are recommended.

COMMENTS

Background

Cardiac magnetic resonance imaging (CMR) has been proposed as a non-invasive method for the detection of rejection in adults after heart transplant (HT). However, CMR measurements used in adults for the detection of rejection or myocardial inflammation have not been systematically evaluated in pediatric HT recipients with biopsy-proven acute cellular rejection (ACR). In this pilot study, the authors sought to assess the utility of parameters of ventricular function and myocardial tissue characterization for the non-invasive detection of ACR in children and adolescents after HT.

Research frontiers

CMR tissue characterization overcomes important limitations of endomyocardial biopsy (EMB) such as the potential of containing scar from a previous EMB in the histological sample and the fact that specimens are collected from the RV surface of the interventricular septum and may not be representative of the remainder of the myocardium.

Innovations and breakthroughs

CMR has shown potential utility in adult heart transplant recipients. However, in this pilot study CMR did not reliably identify ACR-related changes in pediatric heart transplant patients.

Applications

Given the multiple disadvantages of EMB, CMR should continue to be evaluated for its ability to non-invasively detect rejection. Larger trials producing sizable cohorts of patients with clinically-significant rejection episodes and including T2 imaging are recommended.

Terminology

EMB: Invasive procedure used to sample the endomyocardium of the right ventricle to diagnose rejection; ACR: Damage created by T-cell mediated immune response directed by the recipient against the transplanted organ; T1- and T2-weighted imaging: MRI sequences that are used to differentiate tissues based mainly on their composition of fat and water.

Peer-review

The authors have produced an interesting study evaluating the use of CMR scanning as a means to diagnose acute cellular rejection in paediatric HT recipients.

Abstract

AIM

To explore the benefits and harms of corticosteroid (CS) minimization following renal transplantation.

METHODS

CS minimization attempts to improve cardiovascular risk factors (hypertension, diabetes, dyslipidemia), to enhance growth in children, to ameliorate bone disease and to lead to better compliance with immunosuppressive agents. Nevertheless, any benefit must be carefully weighed against the reduction in net immunosuppression and the potential harm to renal allograft function and survival.

RESULTS

Complete CS avoidance or very early withdrawal (*i.e.*, no CS after post-transplant day 7) seems to be associated with better outcomes in comparison with later withdrawal. However, an increased incidence of CS-sensitive acute rejection has been observed with all CS minimization strategies. Among the prerequisites for the safe application of CS minimization protocols are the administration of induction immunosuppression and the inclusion of calcineurin inhibitors in maintenance immunosuppression regimens.

CONCLUSION

Transplant recipients at low immunological risk (primary transplant, low panel reactive antibodies) are

thought as optimal candidates for CS minimization. CS avoidance may also be undesirable in patients at risk for glomerulonephritis recurrence or with severe delayed graft function and prolonged cold ischemia time. Thus, CS minimization is not yet ready for implementation in the majority of transplant recipients.

Key words: Acute rejection; Corticosteroid withdrawal; Corticosteroid minimization; Corticosteroid avoidance; Immunosuppression; Renal transplantation

Core tip: Although corticosteroids have been traditional components of immunosuppressive regimens in renal transplantation, corticosteroid minimization strategies are developed in an attempt to mitigate their many side-effects. The benefit from this approach must be balanced against the risk of acute rejection due to insufficient immunosuppression and the potential harm to allograft survival. We present an overview of these strategies and their impact on clinical outcomes analyzing the key clinical trials performed. Furthermore, we focus on patient selection according to the immunological risk and the induction immunosuppression, the principal factors that determine the success of corticosteroid withdrawal and avoidance protocols.

Vlachopoulos G, Bridson JM, Sharma A, Halawa A. Corticosteroid minimization in renal transplantation: Careful patient selection enables feasibility. *World J Transplant* 2016; 6(4): 759-766 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/759.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.759>

INTRODUCTION

Corticosteroids (CS) have been ubiquitously included in immunosuppressive regimens since the early days of renal transplantation (Tx). They have significantly contributed to the successful transformation of a highly experimental intervention into a universally adopted clinical treatment. However, their use is associated with a plethora of adverse events due to their non-specific mode of action. The negative impact of CS on cardiovascular disease risk factors such as hypertension, diabetes mellitus, and dyslipidemia is well known. Non-cardiovascular adverse events such as growth retardation, impaired wound healing, subcapsular cataract, bone problems (osteoporosis, fractures, avascular necrosis) and cosmetic effects leading to patient non-compliance are equally established^[1-4]. An increasing interest in minimizing the exposure to CS in transplant recipients with stable allograft function has been manifested by renal transplant clinicians to reduce the morbidity burden associated with their use. In the United States, CS avoidance regimens were administered to 23% of

all first renal transplant recipients in 2004^[5]. Among the remaining 77% who were discharged on CS, roughly 10% had CS withdrawn during the first post-transplant year. Nonetheless, this policy has to be carefully balanced against the risk of acute rejection due to insufficient immunosuppression and should not jeopardize renal allograft function and survival.

MATERIALS AND METHODS

Definitions

Strategies for CS minimization can be categorized as: (1) CS avoidance; and (2) CS withdrawal following a period after Tx. The latter can be further divided as early withdrawal (weeks or months after Tx, usually 3-6 mo after Tx) or late withdrawal (at least 6 mo after Tx). Overlapping between these categories has been reported in the literature leading to a degree of uncertainty over the exact terminology. For instance, very early withdrawal (< 2 wk) has been classified under both CS avoidance and CS withdrawal strategies. For the purpose of this manuscript, we will include very early withdrawal under the CS avoidance strategy. The overall efficacy of CS minimization regimens depends on the extent to which the rest of the immunosuppressive agents can suppress the alloimmune response and on the immunological risk stratification. In general, induction immunosuppression is required for the safe application of CS minimization as well as the inclusion of calcineurin inhibitors in maintenance immunosuppression. Patients at low immunological risk (first transplant, non-sensitized) are considered as ideal candidates for the implementation of CS minimization^[6].

Data from studies on CS minimization have produced conflicting results regarding benefit vs harm. Clinical heterogeneity across these studies is moderate to high, especially regarding the spectrum of induction and maintenance immunosuppression agents used. Some studies have reported reductions in cardiovascular risk factors such as dyslipidemia^[7], but there is no clearly proven reduction of the burden of cardiovascular disease. On the other hand, although CS avoidance or withdrawal studies resulted in increased rates of acute rejection, the impact on allograft survival appears to be neutral. Given the current dilemma over the efficacy vs safety profile of CS minimization strategies, our institution has continued on the traditional strategy of rapid CS tapering after Tx to the lowest possible dose. We reserve CS avoidance or withdrawal for highly selected cases at low immunological risk who present compelling contraindications to CS such as severe osteoporosis. We will try to elaborate on the potential advantages and disadvantages of our protocol focusing on the comparison with the CS minimization practices mentioned above. Our goal is to identify the optimal management strategy, which will allow for the maximum benefit of different patient subsets without compromising safety and will likely improve Tx outcomes.

Table 1 Characteristics of the multi-center, randomized Astellas Corticosteroid Withdrawal Study with a follow-up time of 5 years^[8]

	CS withdrawal at day 7 arm (n = 191)	Standard CS arm (n = 195)	P-value
Baseline demographic, immunological risk and immunosuppressive therapy data			
Age (mean ± SD, yr)	46.6 ± 12.2	46.2 ± 12.7	NS
Female gender (%)	30.9	36.4	NS

CS: Corticosteroid; HLA: Human leukocyte antigens; MMF: Mycophenolate mofetil; NS: Not significant; PRA: Panel-reactive antibodies; SD: Standard deviation; TAC: Tacrolimus.

RESULTS

Low CS dose as maintenance therapy

We advocate the immunosuppressive protocol, which involves the administration of three daily intravenous pulses of 500, 250 and 250 mg methylprednisolone intraoperatively and on postoperative days 1 and 2 respectively. We attempt to rapidly taper CS dose to 20 mg oral methylprednisolone per day by 2-4 wk following Tx. Thereafter, we further reduce CS dose with the aim of 4 mg methylprednisolone per day at 3 mo in the absence of acute rejection. This dose is continued indefinitely. Data from randomized clinical trials (RCT) argue that maintenance CS treatment has still a dominant place in the management of renal transplant recipients. In the RCT with the longest follow-up to date (Astellas Corticosteroid Withdrawal Study), Woodle *et al*^[8] assigned 386 renal transplant recipients with PRA (panel reactive antibodies) \leq 25% to either very early CS withdrawal at one week post-transplant or CS continuation tapered to 5 mg prednisolone per day at 6 mo (Table 1). All patients received induction immunosuppression; 68% of them with the lymphocyte-depleting agent anti-thymocyte globulin (ATG) and 32% with anti-interleukin-2 receptor monoclonal antibodies. Maintenance immunosuppressive regimen consisted of tacrolimus and mycophenolate mofetil (MMF). After a follow-up of 5 years, no difference was found in the rate of patient death, death-censored allograft loss and moderate/severe acute rejection. Total biopsy-confirmed acute rejection was lower in the CS continuation arm (10.8% vs 17.8%, $P = 0.04$). This result was driven by the increased rates of mild, CS-sensitive acute rejection in the very early CS withdrawal

arm. It is interesting that biopsy-proven acute rejection rates were numerically lower with ATG induction than with anti-interleukin-2 receptor monoclonal antibodies in very early CS withdrawal patients, but that did not reach statistical significance (14.4% vs 24.2%, $P = 0.09$). Serum creatinine and creatinine clearance estimated by the Cockcroft-Gault equation were similar between the two arms at 5 years. However, chronic allograft nephropathy (CAN) incidence at 5 years was more than double (9.9% vs 4.1%, $P = 0.028$) with very early CS withdrawal compared to a continuation. This finding raises an important concern. Although very early CS withdrawal seems to be non-inferior to CS continuation at 5 years concerning patient and allograft survival, it is unknown if the increased incidence of CAN would negatively influence those outcomes beyond that time-point. Clinical trials with extended follow-up time to 10 years are needed to resolve this issue. The effect of very early CS withdrawal on cardiovascular risk factors was mixed. No significant difference was found in hypertension, new-onset diabetes mellitus, total cholesterol and low-density lipoprotein (LDL) levels; very early CS withdrawal led only to improvement in serum triglycerides. As far as it concerns non-cardiovascular adverse events, very early CS withdrawal reduced bone fractures and avascular necrosis but it was paradoxically associated with more frequent subcapsular cataract.

A meta-analysis of 34 studies, which included 5637 patients, produced broadly similar results^[9]. It was found that acute rejection risk was significantly increased with CS avoidance or withdrawal regimens compared to maintenance CS (relative risk: 1.56, 95%CI: 1.31-1.87, $P = 0.0001$). No statistically significant differences

were found for patient or allograft survival, but allograft function was modestly better with maintenance CS (weighted mean difference in creatinine clearance: 3.05 mL/min, 95%CI: 1.45-4.66). In contrast to the abovementioned RCT, occurrence of hypertension, new onset diabetes mellitus and hypercholesterolemia was reduced with CS avoidance or withdrawal regimens. However, the effect on hard cardiovascular endpoints cannot be estimated because included studies underreported cardiovascular events. In conclusion, acute rejection rates are constantly lower when CS maintenance regimens are used. Patient and allograft survival seems not to be influenced by CS minimization, but it is unknown if this remains the same with longer follow-up. Although CS minimization may permit some improvement in cardiovascular risk factors, data are not consistent about it.

CS avoidance

The rationale behind CS avoidance or very early withdrawal is that acute rejection may be triggered more easily with CS withdrawal within weeks or months after Tx. However, it invariably requires the use of potent induction immunosuppression and the selection of low immunological risk recipients. Attempts to use CS avoidance regimens in the absence of induction immunosuppression resulted in unacceptably high acute rejection rates^[10]. In a three-arm multicenter RCT, which included 336 renal transplant recipients with PRA \leq 20%, Vincenti *et al.*^[11] used basiliximab as an induction agent and compared no CS at all vs CS withdrawal by day 7 vs standard CS. Maintenance immunosuppression consisted of cyclosporine and enteric-coated mycophenolate sodium. Biopsy-proven acute rejection rates were significantly higher with complete CS avoidance and very early CS withdrawal regimens (31.5% vs 26.1% vs 14.7%) at a follow-up of 12 mo. No difference was found for patient and allograft survival as well as for median 12-mo estimated glomerular filtration rate. A prospective RCT, which included 300 patients, compared very early CS withdrawal at day 2 with standard CS^[12]. It also used basiliximab for induction, but maintenance was a calcineurin inhibitor and mycophenolate mofetil or sirolimus. It found absolutely no difference in patient and allograft survival, acute rejection, incidence of CAN and allograft function between the two arms at 3 years. A lower frequency of new-onset diabetes mellitus was noted in the very early CS withdrawal group.

Induction with a lymphocyte-depleting agent (rabbit anti-lymphocyte globulin, rALG) was explored in the clinical context of CS avoidance for the first time by Laftavi *et al.*^[13]. They randomized 60 renal transplant recipients to either very early CS withdrawal at day 7 or CS continuation. Maintenance immunosuppression involved tacrolimus and MMF. No difference in acute rejection and allograft function was demonstrated with very early CS withdrawal at a follow-up time of 12 mo. However, increased interstitial fibrosis was found in protocol biopsies at 12 mo in the group of very early CS

withdrawal. In a case series of 1241 renal transplant recipients with an impressive follow-up time of 10 years, the results of CS withdrawal at day 5 were reported^[14]. All patients received induction immunosuppression with Thymoglobulin while maintenance immunosuppression comprised of a calcineurin inhibitor (tacrolimus or cyclosporine) and a secondary agent (MMF or sirolimus). Despite acute rejection rates of 25% for cadaveric donor Tx and 31% for living donor Tx at 10 years, patient and allograft survival was comparable to that reported in national registry databases. A beneficial effect of very early CS withdrawal was shown for new-onset diabetes mellitus, subcapsular cataract, and avascular necrosis. Till now, induction with lymphocyte-depleting agents seems to be the optimal option for consolidating the benefits of CS avoidance strategies without putting renal allografts at risk of acute rejection. It is not surprising that approximately 90% of United States renal transplant recipients with a steroid-free regimen on discharge have received induction with a lymphocyte-depleting agent^[15]. Anti-interleukin-2 receptor monoclonal antibodies have been used in the remaining 10% of the patients.

The monoclonal lymphocyte-depleting antibody alemtuzumab has lately emerged as a promising CS-sparing agent. In a comparative, multicenter RCT, 852 unselected (both low and high immunological risk) renal transplant recipients were administered either induction with alemtuzumab (followed by reduced-dose tacrolimus and MMF without CS) or with basiliximab (followed by standard-dose tacrolimus, MMF, and CS)^[16]. According to the preliminary results, alemtuzumab halved biopsy-proven acute rejection at 6 mo. Patient and allograft survival were not different between the two groups. Long-term follow-up results of this study are eagerly awaited. In a direct comparison of alemtuzumab with basiliximab (both arms were subjected to CS withdrawal by day 5) in a cohort of 335 low-risk patients, the rate of biopsy-confirmed acute rejection was lower with alemtuzumab (10% vs 22%, $P = 0.003$) at 3 years^[17]. The major studies on CS avoidance are summarized in Table 2. Lastly, an important question is whether patients on CS avoidance regimens should be put in CS maintenance after treatment of an acute rejection episode. A retrospective study found that allograft survival is not affected by the introduction of CS maintenance or not but the lack of CS maintenance is a risk factor for a subsequent second acute rejection^[18].

CS withdrawal

Early CS withdrawal: Initial attempts to apply early CS withdrawal under cyclosporine-based maintenance immunosuppressive regimens did not meet success^[19,20]. The advent of more potent maintenance immunosuppressants like tacrolimus and MMF renewed researchers' interest in assessing the feasibility of early CS withdrawal (Table 3). Vanrenterghem *et al.*^[21] studied CS withdrawal 3 mo after Tx in 556 low immunological risk patients enrolled

in a multicenter RCT. Maintenance immunosuppression consisted of tacrolimus and MMF. In the follow-up time of only 6 mo, it was shown that acute rejection rates were higher in the CS withdrawal arm during months 3-6. Mean total cholesterol and LDL were reduced in the CS withdrawal arm at the same period. Pascual *et al.*^[22] summarized RCTs in CS withdrawal between 3 and 6 mo in a systematic review including 9 studies with 1820 patients. They concluded that patient and allograft survival is not affected by early Cs withdrawal up to 3 years after Tx. Total acute rejection rates were higher with early CS withdrawal in cyclosporine-treated patients. Although reduction of total cholesterol levels was observed with early CS withdrawal, no significant difference was found for any of the other cardiovascular or non-cardiovascular adverse events. It is worth mentioning that induction immunosuppression was not used in any of the included studies. Overall, evidence about the benefit-risk ratio of early CS withdrawal is weaker than that of CS avoidance and follow-up times are shorter. It is unknown if induction with lymphocyte depleting agents or anti-interleukin-2 receptor monoclonal antibodies were used in any of the studies, it would have any meaningful impact on the results.

Late CS withdrawal: It appears that late CS withdrawal (more than 6 mo and possibly years after Tx) represents the least favorable method of the CS minimization strategies. It is apparent that certain CS-related complications would already have been established by that time. For instance, it is well known that a rapid deterioration in osteoporosis occurs within the first post-transplant year^[23]. Moreover, acute rejection risk is clearly increased upon late withdrawal of immunosuppressants as dictated by cases of non-compliant patients^[3]. In a single-center RCT, Smak Gregoor *et al.*^[24] examined the

effect of CS withdrawal at 6 mo after Tx in 212 renal transplant recipients. Biopsy-proven acute rejection was manifested in 4% of CS withdrawal patients vs 1.4% of controls (*P* > 0.05). Patient and allograft survival was not different after a follow-up of 2 years. Allograft function was also not different. CS withdrawal resulted in reduced mean blood pressure but had no effect on other metabolic risk factors. Interestingly enough, a prospective, observational study from the Collaborative Transplant Study group reported that in renal transplant recipients with CS withdrawal more than 6 mo from Tx, patient and allograft survival was better than retrospectively matched controls over a follow-up time of 7 years with no difference in acute rejection rates^[25]. The reduction was also noted in the incidence of cardiovascular parameters. However, the lack of randomized design remains a significant limitation of this study.

DISCUSSION

Challenges and opportunities of CS minimization strategies

The beneficial effects of CS minimization in selected, low-risk patients have prompted researchers to attempt CS minimization in renal transplant recipients at higher immunological risk. However, available data are sparse (Table 4). In a small RCT, 21 patients with PRA > 20% or retransplantation were assigned to either alemtuzumab and tacrolimus monotherapy without CS or Thymoglobulin with standard tacrolimus, MMF and very early CS withdrawal at day 5^[26]. Biopsy-proven acute rejection rates were quite high at one year; 18.2% with alemtuzumab vs 37.5% with Thymoglobulin. In a more recent, head to head comparison of alemtuzumab with ATG (both

arms underwent CS withdrawal by day 5) in a cohort of 139 high-risk patients, there was no difference in biopsy-proven acute rejection at 3 years (18% vs 15%, *P* = 0.63)^[17]. The inference is that CS minimization is not yet ready for prime time in immunologically high-risk patients. It has been hypothesized that CS minimization may increase post-transplant glomerulonephritis recurrence. In a major retrospective study, it was found that recurrence rate was indeed higher with rapid CS discontinuation compared to CS maintenance for all glomerulonephritis types (hazard ratio 4.86, 95%CI: 2.34-10.07, *P* < 0.0001)^[27]. The analysis also showed no difference in patient, allograft, and death-censored allograft survival. Pediatric patients are a subgroup in which CS minimization may be of special interest due to growth retardation that is associated with chronic CS use (Table 4). In a multicenter RCT, Grenda *et al*^[28] assessed the effect of CS withdrawal at day 4 (together with dadizumab induction and tacrolimus, MMF) vs standard tacrolimus, MMF, and CS in a cohort of 196 children. Growth was significantly enhanced at 6 mo by CS withdrawal. Patient survival, allograft survival and allograft function were not different.

The effect of CS withdrawal on total cholesterol and triglycerides was positive. Similar results were obtained by Höcker *et al*^[29] who evaluated CS withdrawal ≥ 1 year after Tx in 42 moderate- to high-risk children (maintenance immunosuppression was cyclosporine and MMF).

In contrast to the perceived benefits of CS minimization in younger transplant recipients, this strategy may not be suitable for elderly patients. Although acute rejection rates may be lower in the elderly, it has been suggested that acute rejection may be more severe and lead to a compromised death-censored allograft survival^[30]. Furthermore, the potentially beneficial effect of CS minimization in cardiovascular disease risk factors in the elderly may not be relevant due to their limited lifespan. For these reasons, it seems that CS minimization in the elderly may result in poor outcomes and should not be exercised except with extreme caution. Finally, CS minimization may not also be suitable for transplant recipients with delayed graft function (DGF) and prolonged cold ischemia time. The ischemic injury in these allografts is strongly associated with the development of acute rejection^[31]. Therefore, it is

prudent to avoid CS minimization in this patient subgroup if possible.

Based on current evidence, we believe that the majority of renal transplant recipients should continue to receive indefinite CS maintenance immunosuppression. However, selected patients can be good candidates for CS minimization protocols. The optimal patient phenotype to undergo CS minimization is that of a young transplant recipient (including children) who has no prior transplants and is unsensitized to HLA alloantigens. A primary disease that caused end-stage renal disease should not be glomerulonephritis. Any severe perioperative ischemic insult to the allograft should discourage the application of CS minimization. As such, CS minimization may be contraindicated with DGF, prolonged cold ischemia time, and donation after cardiac death. Available data indicate that the preferred CS minimization strategy is probably either complete CS avoidance or very early CS withdrawal. ATG (or alemtuzumab) may be preferable to anti-interleukin-2 receptor monoclonal antibodies as induction agents in this clinical scenario whereas maintenance immunosuppression should better contain the calcineurin inhibitor tacrolimus instead of cyclosporine.

In conclusion, CS maintain their position as important components of the therapeutic armamentarium in renal transplantation. A movement towards CS elimination from induction and maintenance immunosuppression regimens has developed to reduce the myriad side effects associated with chronic CS use. CS minimization strategies have resulted in an increased incidence of acute rejection compared to CS continuation. However, these acute rejection episodes are considered mild and amenable to treatment. Moreover, they do not seem to have detrimental effects on patient survival, allograft survival or allograft function at a follow-up until 5 years. Nonetheless, an observed trend towards increased fibrosis is alarming and calls for the conduction of RCTs with longer follow-up to determine the true consequences of CS minimization. Although CS minimization protocols have been associated with a reduction of adverse effects (especially improvement of dyslipidemia), these results are not always reproducible, and it is unclear if they could clinically translate to less cardiovascular events. At present, the implementation of CS minimization cannot be universally recommended to renal transplant recipients.

COMMENTS

Background

Due to their immunosuppressive properties, corticosteroids (CSs) have been extensively used for the prevention and treatment of rejection in solid organ transplantation. However, myriad side-effects have been associated with CS. Recent research attempts to minimize CS use in renal transplantation in an effort to reduce the burden of their side-effects without compromising allograft and patient survival.

Research frontiers

The choice of the induction immunosuppression agent - and of maintenance immunosuppression to a lesser degree - is an extremely important aspect of

CS minimization strategies and the focus of many studies. Studies with follow-up times of more than 5 years and with data on interstitial tissue fibrosis are needed.

Innovations and breakthroughs

Alemtuzumab appears to be a very promising induction agent potentially allowing the combination of CS avoidance with lower doses of tacrolimus and mycophenolate mofetil. Long term results of the 3C study may provide valuable insights on this topic.

Applications

In the United States, CS avoidance regimens were administered to 23% of all first renal transplant recipients in 2004. Although they cannot yet be recommended to the majority of renal transplant recipients, selected patient groups such as primarily those with low immunological risk and low risk for glomerulonephritis recurrence may benefit more from CS minimization.

Terminology

CS avoidance: Either no CS use at all or CS use only until day 7 after transplantation (Tx). CS withdrawal: CS tapering following a period after Tx. It is divided as early withdrawal (weeks or months after Tx, usually 3-6 mo after Tx) or late withdrawal (at least 6 mo after Tx).

Peer-review

This review paper is a well written paper of the impact of corticosteroid minimisation on kidney transplant and has valuable information.

Abstract

AIM

To review negative pressure wound therapy (NPWT) as an

important addition to the conventional methods of wound management.

METHODS

A systematic review, performed by searching the PubMed, EMBASE and Cochrane Library databases, showed 11 case reports comprising a total of 22 kidney transplantation (KT) patients (range, 1 to 9), who were treated with NPWT. Application of NPWT was associated with successful healing of wounds, leg ulcer, lymphocele and urine leak from ileal conduit.

RESULTS

No complications related to NPWT were reported. However, there was paucity of robust data on the effectiveness of NPWT in KT recipients; therefore, prospective studies assessing its safety and efficacy of NPWT and randomised trials comparing the effectiveness of NPWT with alternative modalities of wound management in KT recipients is recommended.

CONCLUSION

Negative pressure incision management system, NPWT with instillation and endoscopic vacuum-assisted closure system are in investigational stage.

Key words: Negative pressure; Wound therapy; Kidney transplantation; Wound infection; Wound dehiscence

Core tip: Systematic review of the safety and efficacy of negative pressure wound therapy (NPWT) in kidney transplant (KT) recipients revealed 11 case reports, which have shown the effective role NPWT in the management of wound dehiscence, lymphocele, urine leak from ileal conduits and leg ulcers. Because of the lack of robust evidence on the safety and efficacy of NPWT in KT patients, prospective multicentre studies recruiting large number of patients is recommended to examine the role

of NPWT in the treatment of wound-related complications in KT recipients. The efficacy of negative pressure incision management system, NPWT with instillation and endoscopic vacuum-assisted closure system remain in investigational stage.

Shrestha BM. Systematic review of the negative pressure wound therapy in kidney transplant recipients. *World J Transplant* 2016; 6(4): 767-773 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/767.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.767>

INTRODUCTION

Kidney transplantation (KT) represents the best treatment modality for patients with end-stage renal disease, providing the best outcomes for survival, quality of life and cost-effectiveness^[1]. Immunosuppressive agents administered to prevent rejection and prolong transplant survival, not only increase susceptibility to infections, but also delay wound healing. Post-operative wound infection leading to cavitation and dehiscence continue to remain serious problems resulting in extended hospital stay, readmissions, repeated surgical interventions and protracted recovery, thereby imposing extra cost to the healthcare delivery system^[2]. The wound complication rate after KT ranges between 2% to 47%. The risk factors for these complications are advancing age, diabetes mellitus, body mass index, kidney failure, type of surgical incision, re-operation, operator's experience, and immunosuppressive drugs including sirolimus and steroids^[3-6]. The wound-related complications can present as superficial infection, haematomas, lymphocele, and partial or full-thickness wound dehiscence leading to incisional hernias^[7].

Negative pressure wound therapy (NPWT), also referred to as, vacuum-assisted closure therapy (VACT), topical negative pressure therapy or microdeformational wound therapy has been evaluated over last two decades and is considered as an useful adjunct to the management of diverse range of lesions including open abdominal wounds, open fractures, post-traumatic wounds, split-thickness skin grafts and after clean surgery in obese patients^[8-13]. Application of any new form of treatment in KT patients is associated with concerns on the part of clinicians, particularly when robust evidence supporting their safety and efficacy are lacking. A systematic review of the published literature was carried out to evaluate the effectiveness and safety of NPWT in KT recipients presenting with wound-related complications.

MATERIALS AND METHODS

Literature search

A systematic electronic literature search was performed

in PubMed, EMBASE and Cochrane Library databases from inception to March 2016. The search terms "renal transplantation", "kidney transplantation", "negative pressure wound therapy", "vacuum-assisted closure", "wound", and "topical negative pressure therapy" were used. EndNote software (Version X7.5, BLD 9325; Thomson Reuters, Philadelphia, PA, United States) was used to compile pertinent references.

Renal transplantation technique

KT is performed by using classical Gibson's muscle-cutting incision, where the iliac vessels and urinary bladder are accessed extraperitoneally. The renal vessels are anastomosed to the iliac vessels and the ureter to the bladder by the techniques described previously^[14]. Wound infection leading to muscular dehiscence exposes the kidney to the external environment, which predisposes to infection around the kidney, haemorrhage from mycotic aneurysms of the vascular anastomoses, lymph leak, urine leak, and dehiscence of muscle layers leading to incisional herniation.

Principles of NPWT

The beneficial effect of negative sub-atmospheric pressure on the wound results in gradual closure of wound edges by micro- and macrodeformation of the wound surface, and by suction of infectious material and interstitial fluid, reduces tissue oedema. Decompression of tissue increases blood flow and tissue oxygenation, thereby accelerates the wound healing cascade including, angiogenesis, neurogenesis, granulation tissue formation, cellular proliferation, differentiation and migration of appropriate cellular components at the site of healing^[15-20].

Glass *et al*^[21] in a systematic review, evaluated the molecular basis for the promotion of wound healing by NPWT and observed an increase in the expression of cytokines, chemokines and growth factors, which reflected mechanoreceptor and chemoreceptor transduction in response to stress and hypoxia. There was reduction of expression of matrix metalloproteinase-1, -2, -9 and -13, with no changes on the activity of tissue inhibitor of metalloproteinase-1^[21].

The NPWT device comprises of black polyurethane ether foam dressing or white polyvinyl alcohol foam, which is tailored to fit into the dimension of the wound. A tube with multiple perforations is placed within the foam for the evacuation of the wound discharge. The tube together with the foam is then covered with an occlusive drape, which helps to maintain uniform negative pressure. The effluent of the wound is collected in a canister, which is attached to the vacuum pump with an adjustable negative pressure, ranging from 50 and 125 mmHg (Figure 1A and B). At the interval 48-72 h, the soiled dressing is replaced with fresh dressing at the bedside, when progress of healing is assessed. The device can be used in preparation for secondary suture, a skin graft, flap or until full closure of the wound has taken place^[22,23]. The oldest and most popular device in clinical practice is the vacuum-assisted

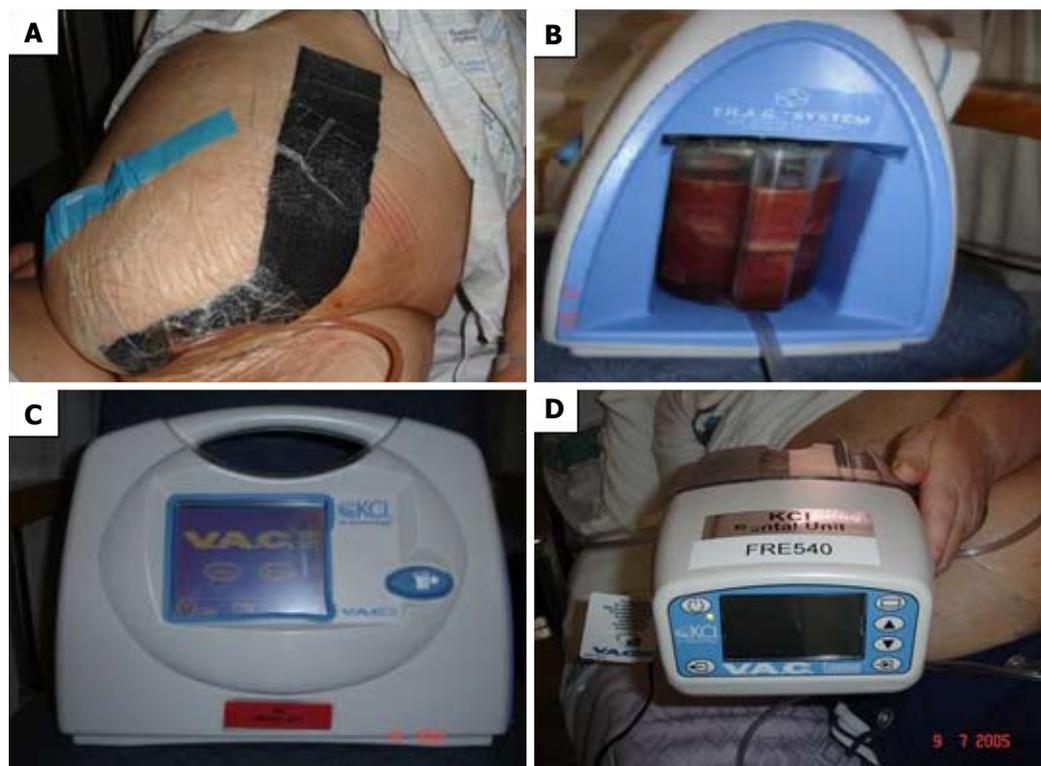

Figure 1 Negative pressure wound therapy device and its components. A: Black polyurethane foam dressing and tubing in the wound; B: Canister containing exudates; C: Standard suction device; D: Portable suction device.

closure (VAC® KCI, San Antonio, Texas) system (Figure 1C and D)^[24].

The contra-indications for the applications of NPWT are excessive pain with NPWT, presence of pus or excessive bleeding and intolerance. The success of NPWT is assessed by the reduction in wound size by at least 10% per week or 50% improvement over 4 wk period, which indicates high probability of success of the therapy^[25].

RESULTS

The literature search identified 11 case reports comprising of a total of 22 KT patients (range, 1 to 9) (Table 1), who were treated with NPWT^[26-36]. Comparison between NPWT and other methods of wound treatment in KT patients has not been reported in any study.

In 2003, Hodzic *et al*^[32], for the first time, reported successful outcome of application of NPWT for 15 d in 2 KT patients prior to secondary suture of wounds. Successful treatment of an infected and dehisced laparotomy wound following liver and KT in a patient by employing NPWT was reported by Zanus *et al*^[26], where associated complications included acute pancreatitis, abdominal compartment syndrome and wound infection by multi-drug resistant organisms. The patient required 14 successive laparotomies and NPWT for 6 mo for complete closure of the wound^[26]. Similarly, Markić *et al*^[34] have described successful treatment with application of NPWT in 2 KT patients who developed infected and dehisced wounds. NPWT was

applied for 2 and 3 wk, respectively, which was followed by secondary sutures^[34].

The occurrence of ureteric complications significantly delays the recovery following KT and the incidence of such complication ranges between 1.2% and 8.9%^[37]. Urinary leak rate of 11% requiring re-implantation was reported by Surange *et al*^[38] in a series of KT into ileal conduits. Two cases of urine leak and wound dehiscence following KT into ileal conduits were managed successfully by Heap *et al*^[28] with the application of NPWT. Secondary suture of the wounds was carried out after two and three months in these patients. The renal function was restored in both patients leading to 141 µmol/L and 75 µmol/L of serum creatinine, respectively, at the end of 3 mo^[28]. On the other hand, Ortiz *et al*^[27], had negative experience of NPWT in a KT recipient with peri-renal collection and wound infection. They concluded that NPWT had encouraged and prolonged urine leak, which had healed after 5 d of discontinuation of NPWT^[27]. Iesari *et al*^[36] had applied VAC device in a KT patient who had developed spontaneous rupture of urinary bladder due to gangrenous cystitis and extensive wound dehiscence associated with multidrug resistant *Acinetobacter baumannii* infection. There was significant urine leak following VAC therapy, hence this was discontinued and topical homologous platelet-rich gel was used resulting in complete wound healing^[36].

Infection caused by virulent organisms after skin grafts and reconstructive surgery in KT recipients not only lead to failure of treatment, but also can be life-

NPWT: Negative pressure wound therapy.

threatening. Thodis *et al*^[29] treated soft tissue infection caused by *Vibrio vulnificus* with NPWT, which involved the leg in a KT recipient. Autologous platelet concentrate spray further enhanced granulation tissue formation leading to complete epithelialization of the wound after 4 wk^[29]. In a similar situation, Devries *et al*^[31] were unsuccessful in treating soft tissue infection on the leg of a KT recipient, that culminated in amputation. As the patient was on sirolimus, wound healing could have been compromised by the same drug^[5,31,39].

Lymphocele following KT can cause significant morbidity due to infection and compression of ureter and blood vessels. The reported incidence of lymphocele ranges between 0.6% to 49%^[40]. Franchin *et al*^[35] have described successful management of a large deep-seated lymphocele infected with *Staphylococcus haemolyticus*, *Escherichia coli* and *Enterococcus faecalis*, with the application of NPWT. Following surgical drainage, the wound had completely dehisced and transplanted kidney exposed. The cavity was packed with foam dressing and device was applied. A negative pressure of 80 mmHg was maintained. The dressing was changed every 5 d. After 45 d, the lymphocele had sealed and skin closed^[35].

In a prospective study reported by Shrestha *et al*^[30], 9 KT patients had developed wound infection with cavitation and wound dehiscence. This was associated with significant amount of discharge from the wound, which failed to respond to standard method of treatment. Treatment with NPWT for a median of 9 (range 3-30) d led to cessation of discharge from the wound. Of the 9 patients, 4 patients were managed on an outpatient with portable NPWT device, where the treatment was discontinued after a median of 5.5 (range 3-7) d. The median hospital stay since the employment of NPWT was significantly shorter (5, range 2-12 d) compared to the standard method of treatment prior to application of NPWT (11 d, range, 5-20 d; $P = 0.003$). The wound healed completely in all 9 cases after the therapy^[30].

Recently, Bozkurt *et al*^[33], for the first time, employed Prevena incision management system (Kinetic Concept Inc. San Antonio, Texas, United States) to the clean closed surgical wound for 5 d after a KT and observed complete healing of the wound with no skin or device-

related problems.

DISCUSSION

All infected wounds with associated collections require surgical drainage for early healing. Fleischmann *et al*^[41] from Germany, in 1993, for the first time described the benefit of exposing wounds to sub-atmospheric pressure, which promoted wound debridement and healing. He applied this method in 15 patients with compound fractures and observed enhanced proliferation of the granulation tissue with no associated bone infection leading to complete healing of fractures^[41]. In 1997, Louis Argenta and Michael Morykwas introduced NPWT therapy, for the first time, in the treatment of bed sores and slow healing wounds. Since then, NPWT has been extended to treat various types of wounds resulting from surgery, trauma, infection, congenital deformities and tumours^[42-44]. The experience of NPWT gained over the past two decades has encouraged clinicians to treat patients globally in both hospital and domiciliary environments^[44-46].

This systematic review has confirmed the available evidence on the safety and efficacy of the application of NPWT in KT recipients limited to case reports. On the other hand, the reported experiences do support NPWT in the management of complex wounds following KT, including urine leak from KT in ileal conduits and lymphoceles. The theoretical risk of haemorrhage and urine leak from transmission of suction pressure on the vascular and ureteric anastomoses cannot be ignored. Prolonged urine leak had occurred in two reported cases after KT where NPWT was applied. Discontinuation of NPWT had led to resolution of urine leak. In author's single KT patient with a urine leak from the ureterovesical junction, treatment with NPWT led to persistence of urine leak for 1 wk. Resolution of the urine leak occurred 2 d after discontinuation of NPWT therapy. Successful outcomes of NPWT in the management of wound infections in cardiac and liver transplant recipients have been described previously^[47,48].

Development of enterocutaneous fistula during the course of NPWT is always a concern, which is particularly

applicable in deep wounds after KT, where thin layer of peritoneum lies between the bowel and the foam dressing. Occurrence of enterocutaneous fistula has been observed after NPWT in open abdominal wound. However, the evidence in support of the occurrence of this complication after NPWT is weak^[49-51].

Shrestha *et al*^[30], in their largest reported series of 9 patients, observed benefit of NPWT on wound healing, reduced hospital stays and convenience of wound management. The management of 4 patients on an outpatient basis with the NPWT device *in situ*, was convenient to the patient and saved hospital cost significantly^[30].

Comparison of NPWT with standard treatment modalities

There is no data available comparing the safety and efficacy of NPWT over conventional methods of wound management in KT recipients. However, there are several randomised trials and meta-analyses, which have assessed the effectiveness of NPWT for skin grafts and surgical wound healing by primary and secondary intentions and in chronic wounds compared with several conventional treatment methods. With regards to healing of surgical wound by primary intention, the evidence for the effect of NPWT for reducing surgical site infections, time to complete healing and wound dehiscence remains unclear^[52]. A Cochrane Database Systematic Review assessed the effect of NPWT for the treatment of chronic wounds in comparison with five different comparators, which did not show that NPWT significantly increased the healing rate. The trials did have methodical flaws, therefore need for better quality research was recommended^[53]. Similarly, a recent Cochrane review did not show clinical effectiveness of NPWT over alginate dressings in the treatment of open infected groin wounds and a silicone dressing in the treatment of excised pilonidal sinus when they were allowed to heal by secondary intention^[54].

NPWT with instillation

NPWT with instillation (NPWTi) is a recent advancement, which is being assessed in the management of complicated surgical wounds. The wound is covered with normal saline (0.9%) and left for 10-20 min for diffusion to take place. Then, 2-4 h of negative pressure at -125 mmHg is applied. A panel of experts in the first International Consensus Guidelines for NPWTi have recommended its use in high risk patients with multiple comorbidities including diabetes, contaminated traumatic wounds, and wounds complicated by invasive infection or extensive biofilm. Available evidence suggest achievement of better outcomes with the addition of NPWTi to standard of care in properly selected cases, compared to standard care alone^[55,56]. As majority of KT recipients often have associated co-morbidities, NPWTi may be an option in this group of patients.

Negative pressure incision management

Colli *et al*^[57] employed the negative pressure incision

management system in clean closed incisions, for the first time, in 10 patients after cardiac surgery and observed normal wound healing in patients where complications were expected after surgery. Bozkurt *et al*^[33], have reported their experience of using Prevena incision management device in a KT recipient. A recent meta-analysis of NPWT for closed surgical incisions, (including 10 studies, 1311 incisions in 1089 patients) showed significant reduction in wound infection (RR = 0.54) and seroma formation (RR = 0.48), when NPWT was compared with standard care. The reduction in wound dehiscence was not significant. The numbers needed to treat were 3 (seroma), 17 (dehiscence) and 25 (infection). Due to heterogeneity between the included studies, no general recommendations could be made yet^[58]. However, this device has a potential for its use in immunosuppressed and obese patients undergoing KT.

Endoscopic vacuum-assisted closure system

Endoscopic vacuum-assisted closure system (E-VAC) has developed as an important alternative in patients with upper gastrointestinal leaks not responding to standard endoscopic or surgical treatment procedures. Leak from oesophageal and gastric anastomosis sites and perforations resulting from endoscopic procedures were successfully closed using the E-VAC therapy^[59,60]. Application of this device in KT recipients remains to be explored.

This systematic review has shown successful healing of wounds, leg ulcer, lymphocele and urine leak from ileal conduit following application of NPWT in KT recipients and there was no report of complications associated with NPWT. However, there is lack of robust evidence on safety and efficacy of NPWT in KT patients. Based on available evidence on the application of NPWT in KT recipients, NPWT can be considered as a valuable adjunct in the management of infected and dehisced wounds following KT. The safety and efficacy of NPWT, negative pressure incision management system, NPWT with instillation and E-VAC system, and efficacy of NPWT in comparison with standard methods of wound management, need to be examined prospectively by including large number patients in multicentre studies.

COMMENTS

Background

Negative pressure wound therapy (NPWT) is a useful adjunct to the conventional methods of management of infected wounds with deep cavitation in the kidney transplant (KT) recipients. A systematic review was performed to assess the safety and efficacy of NPWT in KT recipients, which showed 11 case reports including 22 KT recipients who were treated with NPWT showing beneficial outcomes.

Research frontiers

There are no randomised trials comparing the safety and efficacy of NPWT with alternative modalities of wound management, hence multicentre prospective study by including large number of patients is recommended.

Innovations and breakthroughs

The negative pressure incision management, NPWT with instillation, and

endoscopic vacuum-assisted closure system are the new developments in this field, which need to be applied and examined in the RT recipients.

Applications

NPWT has been applied in the treatment of abdominal wounds, leg ulcers, lymphoceles and urine leak from ileal conduit in RT recipients successfully.

Terminology

Negative pressure wound therapy (NPWT), also referred to as, vacuum-assisted closure therapy (VACT), topical negative pressure therapy (TNPT) or microdeformational wound therapy.

Peer-review

The authors made a comprehensive review on NPWT on KTx recipients. It provides useful information for clinicians.

Abstract

AIM

To identify the outcome measures that have been used in randomized controlled trials (RCTs) of exercise training in solid organ transplant (SOT) recipients and to link these outcomes to the International Classification of Functioning, Disability and Health (ICF) framework.

METHODS

Electronic literature searches of MEDLINE, EMBASE, CINAHL, Cochrane, Scopus, and Web of Science were performed. We sought RCTs that investigated the effect of exercise training in SOT recipients. Reference lists of all eligible publications were searched for other appropriate studies not identified by the electronic search. A complete list of outcome measures used in the RCTs was generated and each of these was linked to an ICF category.

RESULTS

Four hundred and thirteen articles were retrieved, of which 35 met our inclusion criteria. The studies included were designed to compare the effects of exercise training programs to usual care or to another exercise training program and reported on recipients of heart ($n = 21$), kidney ($n = 9$), lung ($n = 3$) or liver ($n = 2$) transplant. Of the 126 outcome measures identified, 62 were used as primary outcome measures. The most commonly occurring primary outcomes were aerobic capacity using the peak VO_2 ($n = 13$), quality of life using the short-form-36 ($n = 8$), and muscle strength ($n = 7$). These

outcome measures were linked to 113 ICF categories and the majority of outcomes fall into the body function domain ($n = 93$).

CONCLUSION

There is little standardization in outcome measures used in RCTs of exercise interventions in SOT recipients. The ICF framework can be used to select a core set of outcomes that cross all domains of ICF and that would be appropriate to all SOT recipients.

Core tip: Over 30 randomized controlled trials (RCTs) have been conducted to examine the effectiveness of exercise training on outcomes in solid organ transplant recipients. However, the synthesis of findings across studies has been limited by the lack of similar outcomes. We identified 126 unique outcomes used in RCTs of exercise training and categorized them according to the International Classification of Functioning, Disability and Health framework. Most commonly, outcomes fell into the domains of body structure and body function, whereas there were a limited number of outcomes examining activities and participation. This review highlights the need for a core set of outcomes for RCTs in exercise training for this population.

Janaudis-Ferreira T, Mathur S, Konidis S, Tansey CM, Beaufrepaire C. Outcomes in randomized controlled trials of exercise interventions in solid organ transplant. *World J Transplant* 2016; 6(4): 774-789 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/774.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.774>

INTRODUCTION

As the acute morbidity and mortality associated with solid organ transplantation continues to improve, interventions that improve quality of life and long-term health outcomes are needed. Exercise training has several important health benefits for solid organ transplant (SOT) recipients, such as improving maximal aerobic capacity (VO₂ peak), body composition and quality of life^[1]. Exercise and physical activity also have potential effects for mitigating long-term complications post-transplant and side-effects of immunosuppressant medication such as reducing blood pressure, controlling blood glucose^[2], managing weight gain^[3], improving muscle^[4] and bone strength^[5], and reducing fatigue^[6-8]. A limitation of the current literature on exercise for SOT is the inability to combine outcomes from studies due to the wide range of reported outcomes. In a

systematic review of exercise training in SOT recipients conducted in 2012 by Didsbury *et al*^[1], the authors included 15 randomized controlled trials (RCTs) with 28 unique outcomes. The majority of outcomes were related to cardiovascular parameters (VO₂ peak, blood pressure, cholesterol), with fewer studies examining body composition, frailty indicators or quality of life. The authors were therefore hampered in their ability to conduct meta-analyses, which limited the conclusions of their comprehensive review.

The inability to synthesize data from studies in the field of SOT is of particular concern, as this is a small population and studies on exercise training are often conducted at single transplant centres with relatively small sample sizes. In order to gain greater statistical power to draw conclusions, studies need to be combined using knowledge synthesis approaches, which require common outcomes. Inconsistencies in the reporting of outcomes can affect the conclusions of systematic reviews and may contribute to reporting bias^[9]. Therefore, in order to facilitate standard reporting of key outcomes across studies, the development of core outcomes sets for clinical trials is gaining more attention^[10,11].

The International Classification of Functioning, Disability and Health (ICF) is an established framework developed by the World Health Organization and is commonly used in rehabilitation. The ICF is designed to describe health and health-related status from biological, personal and societal perspectives^[12]. The framework classifies human function into four domains: Body functions; body structures; activities and participation; and environmental factors^[12]. These domains match well with the goals of exercise training and physical rehabilitation programs; specifically to identify, measure and treat physical impairments (body function and structure); to reverse or normalize activity limitations; and to enhance participation in all settings^[13]. Using the ICF to map the outcomes of the current literature on exercise training in SOT recipients will assist in classifying the breadth of outcomes that have been used in the studies to date and also in identifying any domains that are understudied in this population. This information can provide a starting point for developing a core set of standard outcomes^[10] for clinical trials of exercise and physical rehabilitation in SOT recipients.

The objectives of this systematic review were to identify the outcome measures that have been used in RCTs of exercise training in SOT recipients and to link these outcomes to the ICF framework.

MATERIALS AND METHODS

Data sources and search strategy

This systematic review is in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) statement^[14]. A librarian designed and performed electronic literature searches of Medline from inception until May 2016. The search was then adapted for EMBASE, CINAHL, Cochrane, Scopus, and Web of Science and run on these databases.

Search terms included organ transplantation, transplant recipients, graft recipient, heart, lung, kidney, pancreas, liver, exercise, exercise therapy, rehab, rehabilitation, resistance training, physical education, training, physical activity, and physical exertion (Table 1). The searches were limited to RCTs, published in English, and in humans. One investigator (Stacey Konidis) also conducted hand searches of the reference lists of all the studies that met the inclusion criteria to identify additional relevant articles.

Criteria for including studies in the review

We selected all RCTs that investigated the effect of exercise training in SOT recipients. We included trials that compared the effects of exercise training programs to standard care as well as trials that compared two or more different exercise training programs in SOT recipients. In the case of multiple publications of the same study, we considered all of them if the outcomes measures were different. We excluded studies that did not have an isolated exercise intervention group (*i.e.*, those that examined the effect of a drug combined with exercise). We also excluded non-English articles and conference abstracts. One investigator (Stacey Konidis) reviewed the study titles and abstracts to determine potential study eligibility. When this investigator was uncertain, a second reviewer (Tania Janaudis-Ferreira) was consulted. Two investigators independently reviewed the full texts of the articles to determine eligibility (Stacey Konidis and Tania Janaudis-Ferreira).

Data extraction and synthesis

Two reviewers (Stacey Konidis and Cecile Beaurepaire) performed the data extraction and tabulation. A third reviewer (Tania Janaudis-Ferreira) double-checked the extracted data. Outcome measures were abstracted using a standard form and imported into a spreadsheet, sorted into primary and secondary outcomes and

classified according to four domains of the ICF (body functions, body structures, activities and participation, and environmental factors). Information about the exercise interventions and patient populations were also retrieved. Considering the purpose of this review, study quality or risk of bias assessments of the included studies were not deemed to be necessary.

RESULTS

Literature search

The electronic and hand searches led to the identification of 522 articles. After excluding 109 duplicates, there were 413 articles left for title and abstract screening. Following the study title and abstract screening, 366 were considered to be unrelated to the objectives of the review. Of the 47 articles that remained for full-text analysis, 12 were excluded. This left a total of 35^[2-5,15-45] articles for inclusion in this review. The study flow and reasons for exclusion are shown in Figure 1.

Review of studies and outcome domains assessed

The studies included were designed to compare the effects of exercise training programs to usual care or to another exercise training program and reported on transplantation of heart (*n* = 21), kidney (*n* = 9), lung (*n* = 3), and liver (*n* = 2). A total of 1313 patients were randomized in the 35 studies. Description of the exercise programs and other details about the studies is presented in Table 2.

Table 3 outlines the outcome measures that were used in each study. In total, there were 126 outcome measures. Of the 126 outcome measures, 62 were used as primary outcome measures in at least one study. The most commonly occurring primary outcomes were peak VO₂ (*n* = 13), SF-36 (*n* = 8), and muscle strength (*n* = 7).

Each outcome measure was linked to an ICF

¹Does not add to 1313 since some patients included in more than one study; ²Same patients as Braith 1996; ³Same patients as Karolopat 2007; ⁴Same patients as Hermann 2011; ⁵Same patients as Nytrøen 2012; ⁶Same patients as Dall 2014. BMD: Bone mineral density; HR: Heart rate; BP: Blood pressure; HRQOL: Health-related quality-of-life; CVD: Cardiovascular disease; BMI: Body mass index; METs: Metabolic unit of task; HRR: Heart rate reserve; HRR1: Heart rate recovery; CRI: Chronotropic response index; CRP: C-reactive protein; IL-6: Interleukin-6; TNF-α: Tumor necrosis factor-α; sICAM-1: Intercellular adhesion molecule-1; 6MWD: 6 minute walk distance; FVC: Forced vital capacity; HRV: Heart rate variability; BRS: Baroreflex sensitivity.

domain and the list is shown in Table 4. The majority of outcomes fell into the body function domain ($n = 93$). Fourteen outcome measures were linked to the activities and participation, 5 to body structures, 2 to environmental factors and 2 described outcomes were unclassified in the ICF. Frailty indicators such as grip strength ($n = 1$), fatigue ($n = 0$) or gait speed (6-minute-walk) ($n = 3$) were rarely used. Ten multi-dimensional questionnaires were used in the studies

reviewed.

DISCUSSION

Physical rehabilitation in SOT patients strives to minimize the impairments associated with prolonged chronic illness, allowing individuals to improve their ability to carry out daily tasks and activities and to participate in life roles. When selecting outcome measures to use in clinical trials

Table 3 List of outcome measures by study

b440		Respiratory compensation point	0	Heart	
b440		Ventilatory reserve and capacity	0	Lung	
Functions of the respiratory system (respiration rate)		b4400	CO ₂ production	0	Heart
		b4400	Oxygen uptake at anaerobic threshold	0	Lung
		b4400	Peak ventilation	2	Heart, kidney
	b4400	Peak VO ₂	13	Heart, kidney, liver, lung	
	b4400	Ventilatory equivalent for carbon dioxide and oxygen	1	Heart	
	Functions of the respiratory system (respiratory muscle functions)	b445	Respiratory muscle force/strength	1	Heart, lung
		Functions of the cardiovascular system (general physical endurance)	b4550	Rating of perceived exertion	0
Functions related to the digestive, metabolism and the endocrine system	b530		Body mass index	4	Heart, kidney, liver
	b530	Body weight/mass	3	Heart, kidney, liver, lung	
	b530	Fat mass/body fat	3	Heart, kidney, liver	
	b530	Fat-free mass	1	Heart	
	b530	Hip girth	0	Kidney	
	b530	Hip-waist ratio	0	Heart	
	b530	Lean tissue mass	2	Heart, kidney, liver	
	b530	Percent body fat	2	Heart, kidney, liver	
	b530	Visceral fat scale	0	Heart	
	b530	Waist girth	0	Kidney	
	General metabolic functions, unspecified	b5400	Basal metabolic rate	0	Heart
		b5400	Metabolic age	0	Heart
	General metabolic functions, other, specified	B5408	Maximal metabolic units	1	Kidney
		Functions related to metabolism and the endocrine system	b540-559	Enzyme levels	0
b540-559	Fetuin A		0	Kidney	
b540-559	Oxidative stress-induced lipid peroxidation		0	Heart	
b540-559	Serum insulin		1	Heart	

	b540-559	Serum metabolic and/or hematologic profile	1	Heart
	b540-559	Vitamin B ₁₂	0	Kidney
	b540-559	Glycemic control parameters	0	Heart, kidney
	b540-559	Muscle metabolic enzyme activity	1	Heart
	b545	Body water	0	Heart
	b545	Homeostasis model assessment	0	Heart
Functions of the genitourinary and reproductive functions (urinary functions)	b610-639	Glomerular filtration rate	1	Kidney
Neuromusculoskeletal and movement-related functions (muscle power functions)	b730	Peak workload/power output	1	Heart, kidney, lung
	b730	Muscle strength	7	Heart, kidney, liver, lung
	b730-b749	Muscle vasodilation	1	Heart
	b740	Muscle endurance	1	Heart
Body structure Structures related to movement - additional musculoskeletal structures related to movement (bones)	s7700	Bone mass	0	Heart
	s7700	Bone mineral content	1	Heart, kidney, liver
	s7700	Bone mineral density	3	Heart, kidney, liver, lung
	s7700	Total bone calcium	0	Heart
	s7702	Muscle composition (fibre types)	1	Heart
Activities and participation participation	d410	STS-60	0	Kidney
Mobility - walking and moving	d450	Daily steps	0	Lung
	d450	Daily walking time	1	Lung
	d450	6 Minute Walk Distance	3	Heart, liver, lung
	d450	Anaerobic threshold	1	Heart, lung
Mobility - walking and moving	d450-469	Daily physical activity	0	Heart
	d450-469	Movement intensity	0	Lung
	d450-469	Self-reported activity level	0	Kidney
	d450-469	Time spent in moderate intense activities	0	Lung
	d450-469	Duke Treadmill Score	0	Heart
	d450-469	Exercise duration	1	Heart, kidney
Managing diet and fitness	d5701	Caloric intake	0	Heart
	d5701	Nutritional intake	1	Liver
Major life areas (work and employment)	d840-859	Employment status	1	Kidney
Environmental factors	e1108	Smoking status	0	Kidney
Products or substances for personal consumption, other specified				
Drugs	e1101	Immunosuppression use	0	Kidney
Questionnaires		DASI	0	Kidney
		Quality of Life Profile for Chronic Diseases Questionnaire	1	Lung
		SF-36	8	Heart, kidney, liver, lung
		St. George's Respiratory Questionnaire	1	Lung
		State-Trait Anxiety Inventory	1	Heart
		Beck Depression Inventory	1	Heart
		Hospital Anxiety and Depression Scale	2	Heart
		Visual Analog Scale (change in HRQoL)	0	Heart
		WHOQOL-BREF	2	Heart, kidney
Not covered by ICF		Chronic Liver Disease Questionnaire	1	Liver
		Incidence of morbidity	0	Kidney, lung
		Adherence to training and follow-up	2	Kidney

¹Count Primary: Count of studies that used this measure as a primary measure. RR-interval: Inter-beat interval (heart rate); CVD: Cardio-vascular disease; STS-60: Sit-to-stand 60; SF-36: Short-form 36; HRQoL: Health-related quality of life; WHOQOL-BREF: A shorter version of the original World Health Organization Quality of Life Questionnaire; DASI: Duke Activity Status Index.

of SOT recipients, it is important to capture changes across all domains that are relevant to the primary goals of the physical rehabilitation intervention. We have used the ICF categories to classify the outcome measures used in RCTs of exercise interventions after SOT. From this systematic review, we have learned that the outcome measures used in these RCTs vary widely. This finding is in line with the results of similar systematic reviews conducted in

other populations (e.g., individuals with critical illness, post-surgery and stroke)^[11] Some of the studies focused on multiple primary outcomes and others used just two or three. In total, 62 different primary outcomes were used with the most common being peak VO₂ (*n* = 13) and the SF-36 (*n* = 8). Most of the outcomes used fell into the body functions domain (*n* = 93) with very few in the activities and participation domain (*n* = 14). Few

studies included outcomes that are also considered frailty indicators. These are important outcomes as frailty is present in many SOT recipients and can have a negative impact on transplant outcomes^[6-8].

As we did, Disbury *et al*^[1] found that the most commonly used outcome measure was VO₂ peak. However, this is an expensive test that requires complex equipment as well as expertise from a professional to interpret the results. Functional exercise capacity tests that are more relevant to patients' activities and participation in daily life and less costly to administer should be considered.

Disbury *et al*^[1] were unable to merge data on health-related quality-of-life (HRQoL) measures since so many different questionnaires were used. We found that 11 of the RCTs analyzed used multi-dimensional questionnaires as an outcome measure with several using more than one. These questionnaires each cover many different ICF categories. For instance, Cieza and Stucki^[46] have linked individual questions from the short-form-36 (SF-36) questionnaire to ICF domains and found that this questionnaire incorporates at least 21 ICF codes. Linking individual items on HRQoL questionnaires could help researchers select a questionnaire that covers many ICF codes and that would be most suited to be part of the core set of outcome measures recommended, thus making it possible to meaningfully merge data from multiple studies.

A core set of outcome measures to be used in all of these populations would be helpful to minimize and standardize the number of outcomes used in this patient group. While it is important to conduct a comprehensive assessment, the use of a large number of outcome measures can be burdensome for both patients and evaluators. Ideally, the core set of variables should cover all four domains of the ICF, *i.e.*, they need to cover all aspects of the health condition. Furthermore, the core set of variables needs to include outcomes that are common to all organ groups. Many of the issues that affect physical function and exercise capacity are common across the transplant types despite each SOT having its own unique characteristics and challenges^[47]. Some of the pre-transplant issues that limit physical function are specific to the failing organ, but the physiological changes associated with severe chronic disease, deconditioning and nutritional depletion are common to all groups^[48]. Post-transplant issues that limit physical function vary depending on the phase of recovery, but include things such as extended hospital and intensive care stay, prolonged sedentary time, immunosuppressant medications and episodes of organ rejection^[48]. Outcome measures that relating to these commonalities and to increasing physical function would be suitable for inclusion in the core set of variables. However, there are some organ specific issues that may be important to address differently among the groups (*e.g.*, the effects of exercise in the denervation of the heart after transplant or the effects of exercise on early onset of diabetes after

kidney transplant) and researchers should be encouraged to include secondary outcomes to address them.

The selection of outcome measures should reflect the length of time since the transplant and whether the course of recovery has been complicated. For example, the main goal of physical rehabilitation for acute phase post-transplant is usually to improve basic mobility and activities of daily living while rehabilitation for long-term recipients is generally focused on improving their exercise capacity and levels of physical activity to prevent cardiovascular complications. When considering appropriate outcomes, is also important to take into account their psychometric properties^[49]. Knowing the validity of the outcomes in the transplant population can help researchers with sample size calculations for interventional studies and justify the use of the selected primary outcomes.

None of the studies reviewed included an economic evaluation of the exercise programs and the potential cost savings if SOT recipients experience less long-term cardiovascular disease and fewer hospital readmission related to frailty and physical disability. Although robust economic studies can be challenging, they may be important to convince healthcare funders that exercise programs can be cost-effective and have a positive impact on transplant outcomes and survival. Exercise programs also need to be more readily available for transplant recipients as lack of availability of post-transplant exercise programs has been identified for example in Canada^[50].

Limitations

A limitation of this systematic review is the inclusion of only RCTs. There are other studies on exercise training in SOT recipients that use different research designs, especially observational studies using pre-post designs that were not included. We chose this strategy because RCTs are of the highest quality of study design. We assumed that investigators conducting RCTs have chosen their outcomes carefully and that this group of studies is representative of all rehabilitation trials in transplant recipients. We have also limited our search to studies published in English, which may have reduced our sample size.

There is little standardization in outcome measures used in RCTs of exercise interventions in SOT recipients. Outcome measures for clinical trials should also be selected based on their psychometric properties, stage post transplantation and severity of impairments of the patient population. Further research is needed to develop consensus on a standardized core set of outcomes to measure the effectiveness of such interventions. The ICF framework can be used to select appropriate outcomes that cross all domains and that would be appropriate to all SOT recipients.

COMMENTS

Background

Over 30 randomized controlled trials (RCTs) have been conducted to examine

the effectiveness of exercise training on outcomes in solid organ transplant (SOT) recipients. However, the synthesis of findings across studies has been limited by the lack of similar outcomes across studies. The objectives of this systematic review were to identify the outcome measures that have been used in RCTs of exercise training in SOT recipients and to link these outcomes to the International Classification of Functioning, Disability and Health (ICF) framework.

Research frontiers

Between 1996 and 2015 more than 30 RCTs were published on the effects of exercise training in SOT recipients. Taken together, the results of these RCTs show that exercise training improves maximal aerobic capacity, muscle strength, body composition, cardiopulmonary variables and quality of life. There is little evidence for the effect of exercise in physical activity and participation in SOT recipients. In a systematic review of exercise training in SOT recipients conducted in 2012 by Didsbury *et al.*, the authors included 15 RCTs with 28 unique outcomes. The majority of outcomes were related to cardiovascular parameters (VO₂ peak, blood pressure, cholesterol), with fewer studies examining body composition, frailty indicators or quality of life. The authors were therefore hampered in their ability to conduct meta-analyses, which limited the conclusions of their comprehensive review.

Innovations and breakthroughs

There are numerous studies examining the role of exercise training to improve outcomes following SOT. Exercise training has several important health benefits for SOT recipients, such as improving maximal aerobic capacity (VO₂ peak), body composition and quality of life. A limitation of the current literature on exercise for SOT is the inability to combine outcomes from studies due to the wide range of reported outcomes.

Applications

This systematic review suggests that there is a need to develop consensus on a standardized core set of outcomes to measure the effectiveness of exercise interventions in SOT. A standardized core set of outcomes would facilitate standard reporting of key outcomes across studies.

Terminology

The ICF is an established framework developed by the World Health Organization and is commonly used in rehabilitation. The ICF is designed to describe health and health-related status from biological, personal and societal perspectives. The framework classifies human function into four domains: body functions; body structures; activities and participation; and environmental factors. These domains match well with the goals of exercise training and physical rehabilitation programs; specifically to identify, measure and treat physical impairments (body function and structure); to reverse or normalize activity limitations; and to enhance participation in all settings.

Peer-review

It is a well written review concerning several domains to assess the function outcome of patients with organ transplants subjected to exercise training. It is very helpful for the readers.

Abstract

AIM

To evaluate the incidence and characteristics of kidney stones in kidney transplant recipients.

METHODS

A literature search was performed using MEDLINE, EMBASE, and Cochrane Database of Systematic Reviews from the inception of the databases through March 2016. Studies assessing the incidence of kidney stones in kidney transplant recipients were included. We applied a random-effects model to estimate the incidence of kidney stones.

RESULTS

Twenty one studies with 64416 kidney transplant patients were included in the analyses to assess the incidence of kidney stones after kidney transplantation. The estimated incidence of kidney stones was 1.0% (95%CI: 0.6%-1.4%). The mean duration to diagnosis of kidney stones after kidney transplantation was 28 ± 22 mo. The mean age of patients with kidney stones was 42 ± 7 years. Within reported studies, approximately 50% of kidney transplant recipients with kidney stones were males. 67% of kidney stones were calcium-based stones (30% mixed CaOx/CaP, 27%CaOx and 10%CaP), followed by struvite stones (20%) and uric acid stones (13%).

CONCLUSION

The estimated incidence of kidney stones in patients after kidney transplantation is 1.0%. Although calcium based stones are the most common kidney stones after

transplantation, struvite stones (also known as “infection stones”) are not uncommon in kidney transplant recipients. These findings may impact the prevention and clinical management of kidney stones after kidney transplantation.

Core tip: The authors performed this meta-analysis to assess the incidence and characteristics of kidney stones in kidney transplant recipients. The estimated incidence of kidney stones in patients after kidney transplantation is 1.0%. Calcium based stones (CaOx and CaP) are the most common kidney stones after transplantation following by struvite stones and uric acid stones. The findings from this study may impact the management of kidney stone prevention after kidney transplantation.

Incidence of kidney stones in kidney transplant recipients: A systematic review and meta-analysis. *World J Transplant* 2016; 6(4): 790-797 Available from: URL: <http://www.wjgnet.com/2220-3230/full/v6/i4/790.htm> DOI: <http://dx.doi.org/10.5500/wjt.v6.i4.790>

INTRODUCTION

Kidney stones are one of the most common metabolic disorders and urological problems with a prevalence of 7.2%-7.7% in the adult population, and a ten-year recurrence rate of $\geq 30\%$ ^[1-4]. The incidence of kidney stones is increasing especially in industrialized countries with an estimated global prevalence between 10%-15%^[5-8]. Approximately 13% of men and 7% women will have a kidney stone during their lifetime^[5,8].

Previous studies have shown that stone recurrence rates may be lower, when glomerular filtration rate (GFR) reduced^[9,10]. Thus, patients with advanced chronic kidney disease (CKD) or end-stage kidney disease (ESRD) may encounter less stone disease^[10], reported being as low as 0.68%^[11]. After successful kidney transplantation, ESRD patients subsequently have significant improvement in renal function resulting in urinary excretion of metabolites that increases risk of stone disease. Studies have identified kidney stones in allograft kidney as one of the serious problems in kidney transplant recipients^[12-40]. However, unlike the general population, the incidence and characteristics of kidney stones in kidney transplant recipients are not well studied. The aim of this meta-analysis was to appraise the incidence and types of kidney stones after kidney transplantation.

MATERIALS AND METHODS

Cheungpasitporn W and Thongprayoon C individually

examined published studies and conference abstracts indexed in MEDLINE, EMBASE, and Cochrane Database from the inception of the databases through March 2016. The search strategy used is detailed in the supplementary material (Item 1). Further pertinent studies were retrieved by conducting a manual search using references from the articles that were reclaimed from the search strategy noted above. We followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines for systematic reviews and meta-analyses^[41] and previously published guidelines^[42,43].

The inclusion criteria were as follows: (1) randomized controlled trials or observational studies (case-control, cross-sectional, cohort studies, or case series); (2) patient population age > 18 years old; and (3) data on kidney stones in kidney transplant recipients were provided. The search was limited to English-language studies. Both published studies and conference abstracts were incorporated. Study eligibility was independently determined by the two investigators mentioned earlier. Differing decisions were settled by joint agreement.

A standardized information collection form was applied to derive the following data: The first author of each study, study design, year of publication, country where the study was conducted, number of kidney transplant recipients studied, number of patients with kidney stone, age and gender of patients with kidney stones, time of diagnosis after kidney transplantation, type of donor (Live or deceased donor), type and location of kidney stones, and period of follow-up.

Statistical analysis

MetaXL software (EpiGear International Pty Ltd)^[44] was utilized for data analysis. The incidence rates (IRs) and 95% CIs of adverse effects were reported using a DerSimonian-Laird random-effects model^[45]. A random-effects model was implemented due to the high likelihood of inter-study variances. The Cochran Q test was completed to assess statistical heterogeneity. The I^2 statistic was added to evaluate the degree of variation across studies related to heterogeneity instead of chance. An I^2 of 0%-25% represents insignificant heterogeneity, 26%-50% low heterogeneity, 51%-75% moderate heterogeneity and > 75% high heterogeneity^[46]. To assess for publication bias funnel plots were used^[47].

RESULTS

Our search strategy yielded 1554 articles. Of these, 1397 articles were excluded following the review of their title and abstract based on their relevance and the eligibility criteria. The remaining 157 articles underwent full-length review, and an additional 136 were excluded for failing to meet the criteria. Twenty one articles^[12-29,36,38,40] met all inclusion criteria and were identified for the meta-analysis of kidney stones in kidney transplant recipients (Table 1). Supplementary Item 2 outlines our search methodology

and selection process.

Incidence of kidney stones in kidney transplant recipients

The incidence of kidney stones after kidney transplantation within the 21 individual study ranged between 0.2% to 4.4% with an overall meta-analytical incidence of 1.0% (95%CI: 0.6%-1.4%) with evidence of a high level of heterogeneity ($I^2 = 93\%$, $P < 0.001$; Figure 1).

We performed a sensitivity analysis limited only to the studies that provided data on time of kidney stone diagnosis after kidney transplantation; the estimated incidence of kidney stones was 0.9% (95%CI: 0.7%-1.2%), and there was evidence of a high level

of heterogeneity ($I^2 = 60\%$, $P < 0.001$; Figure 2). The mean duration to diagnosis of kidney stones after kidney transplantation was 28 ± 22 mo.

Subgroup analyses by geographic information were also performed. The estimated incidences of kidney stones were 0.9% (95%CI: 0.3%-1.7%; $I^2 = 94\%$) and 0.7% (95%CI: 0.5%-0.9%; $I^2 = 40\%$) in the United States and Europe, respectively. Data on the incidence of kidney stones in kidney transplant recipients in other geographical area were limited as shown in Table 1.

Characteristics of kidney transplant recipients with kidney stones

The mean age of patients with kidney stones was 42 ± 7

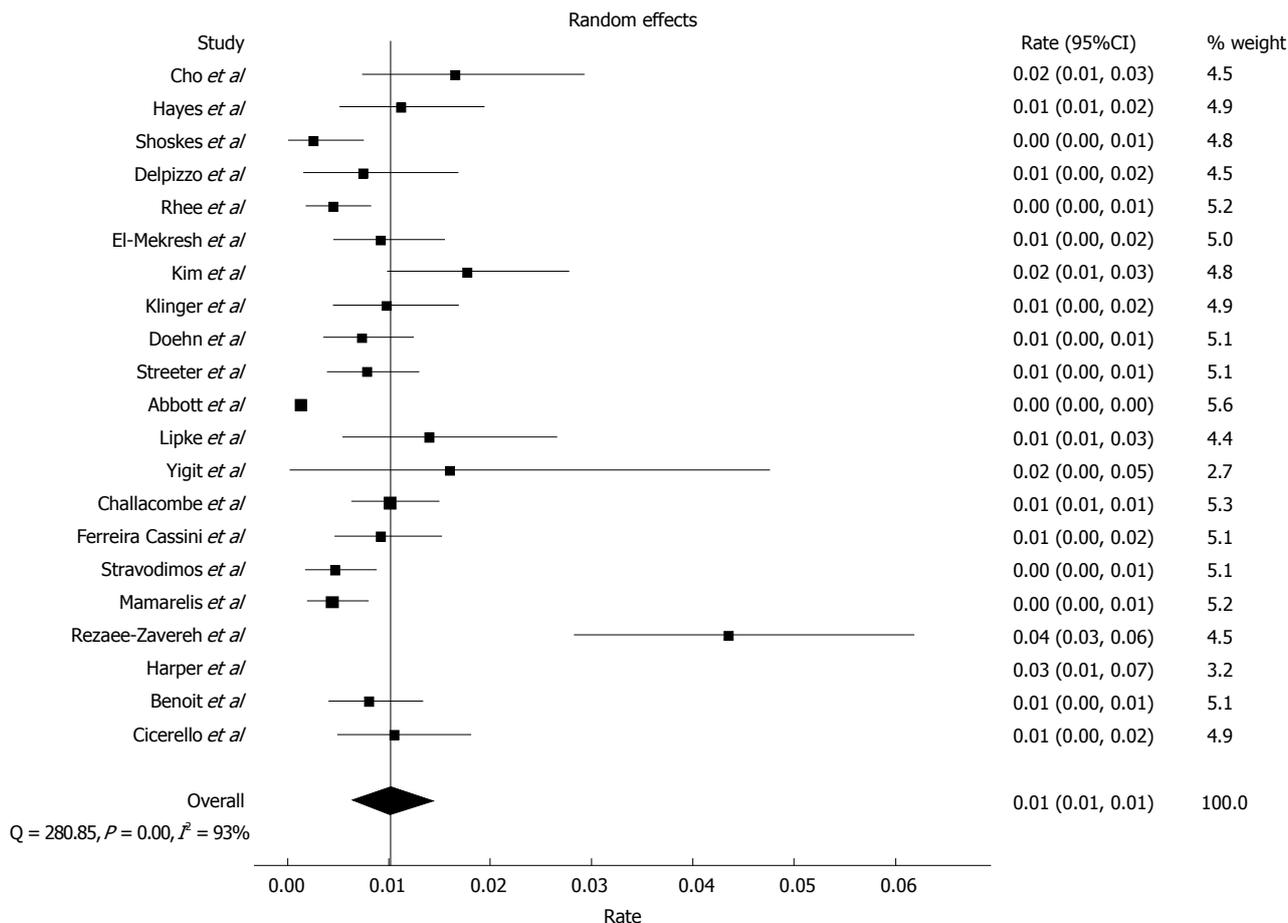

Figure 1 Forest plot of incidence of kidney stones in kidney transplant populations.

years. Within reported studies (Table 1), approximately 50% of kidney transplant recipients with kidney stones were males.

Types of kidney stones in kidney transplant recipients

Sixty-seven percent of kidney stones were calcium-based stones (30% mixed CaOx/CaP, 27%CaOx and 10%CaP), followed by struvite stones (20%) and uric acid stones (13%) as shown in Table 1.

Risk factors for kidney stones in kidney transplant recipients

Despite limited data on urinary supersaturation and risk factors for kidney stones, studies reported increased risk of kidney stones in kidney transplant recipients with hyperparathyroidism, hypercalciuria, hypocitraturia, hypophosphatemia, and urinary tract infection^[28,38]. Harper *et al*^[38] found that urinary excretion of magnesium and phosphate was at the lower range for all kidney transplant recipients with kidney stones. Uncommonly, urinary outflow obstruction and foreign bodies were also found as risk factors for kidney stones in kidney transplant patients^[28,48].

Allograft failure in kidney transplant recipients with kidney stones

As in general patient populations, kidney stones can

also cause acute kidney injury in kidney transplant recipients^[49-52]. Since kidney transplant recipients can have obstructed kidney stones without any symptom of pain^[26,28], prompt diagnosis and the removal of obstructed stones are the keys to preventing renal allograft failure^[18]. Rezaee-Zavereh *et al*^[29] reported no significant association between kidney stones after transplantation and graft survival (OR = 1.04; CI: 0.71-1.54). With the prompt removal of stones, Kim *et al*^[18] found no significant changes in renal allograft function at diagnosis and after removal of kidney stones.

Evaluation for publication bias

Funnel plot evaluating publication bias for the incidence of kidney stones in kidney transplant recipients demonstrated slight asymmetry of the graph and thus suggested the presence of publication for positive studies regarding the incidence of kidney stones.

DISCUSSION

In this study, we demonstrated that an overall incidence of kidney stones in kidney transplant recipients was 1.0%. The mean age of recipients with kidney stones was 42, and half of stone formers were males. Calcium based (CaOx and CaP) stones were the most common types of kidney stones after kidney transplantation,

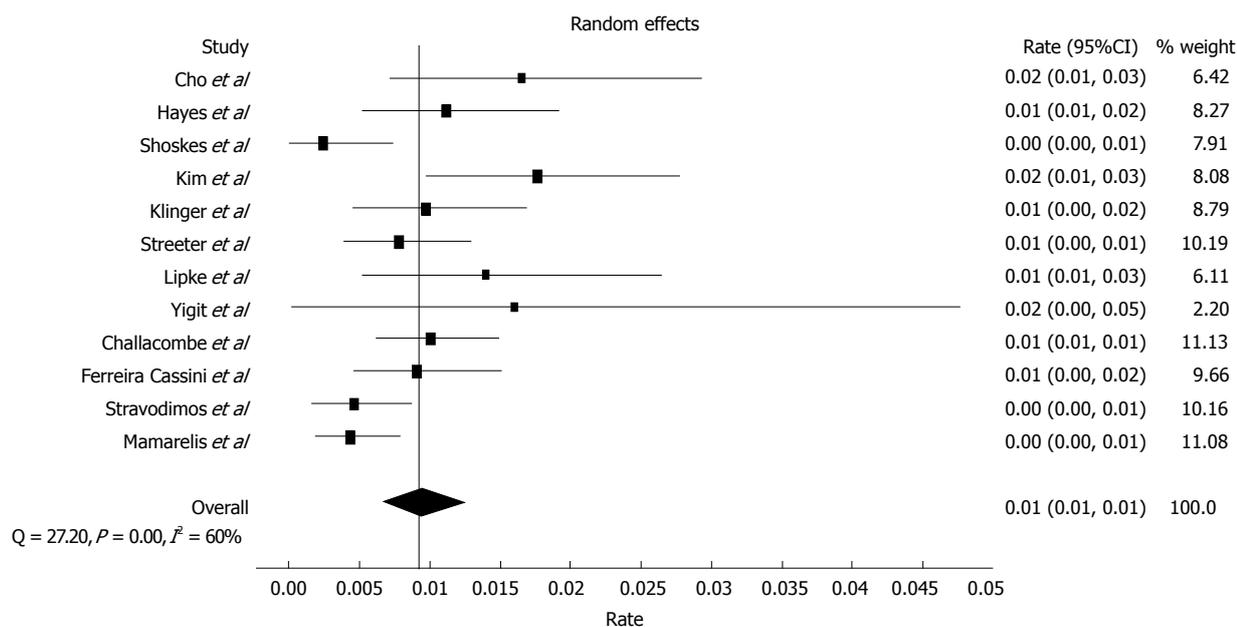

Figure 2 Forest plot of incidence of kidney stones in kidney transplant populations limited only to the studies that provided data on the time of kidney stone diagnosis after kidney transplantation.

followed by struvite stones and then uric acid stones.

The incidence of kidney stones after kidney transplantation from our meta-analysis is much lower than reported in the general adult populations^[5-8]. Although the mechanisms behind the lower incidence of kidney stones after kidney transplantation, when compared with the general population, are only speculative, there are several plausible explanations. First, with the observation that new kidney stones are usually formed in transplanted allograft kidney but not in native non-functioning kidneys, kidney transplant recipients have significantly improved but still lower GFRs than those in healthy general populations, which may be "protective" for stone disease^[9,10]. Second, transplanted kidneys are from healthy donors ideally without tubulointerstitial defects, one not uncommon cause of kidney stones. Third, it is possible that kidney stones after kidney transplantation are underdiagnosed since recipients may spontaneously pass them from the transplanted kidney/ureter without pain or awareness.

Calcium based (CaOx and CaP) stones are the most common types of kidney stones in the general population as well as after kidney transplantation as demonstrated in our meta-analysis. Interestingly, struvite stones (ammonium magnesium phosphate) or "infection stones" is more common in kidney transplant recipients (20%) than in the general population (10%-15%)^[53]. Since struvite stones are associated with infection with urea-splitting bacteria and the principles of treating struvite stones are different than other stones types, including removal of all stone fragments and use of antibiotics^[53], this information is important for future studies targeting prevention and management of kidney stones after kidney transplantation.

There are several limitations to our study. First, there were statistical heterogeneities in the analysis of the incidence of kidney stones. The potential sources of this heterogeneity included differences in diagnostic methodology of kidney stones and follow-up duration. However, a sensitivity analysis that limited studies to those that only provided data on time of kidney stone diagnosis still showed a similar incidence rate of kidney stones, consistent with the finding of our primary analysis. Second, most included studies were conducted in developed Western countries with the majority of the subjects being Caucasian. Thus, our findings may not represent renal transplant populations from other parts of the world. Lastly, the data on urinary supersaturation and risk factors for kidney stones were limited. Although struvite stones represent an association with urinary tract infection, it is still unclear the risk factors for other stone types after kidney transplantation, and future studies are needed.

Our meta-analysis demonstrates that the estimated incidence of kidney stones in patients after kidney transplantation is 1.0%. Although calcium based stones are the most common kidney stones after transplantation, struvite stones are the second common type. These findings may impact clinical prevention and management of kidney stones in kidney transplant recipients.

COMMENTS

Background

Renal stones are one of the most prevalent metabolic disorders and urological problems. However, with reduced kidney functions, patients with advanced chronic kidney disease (CKD) or end-stage kidney disease (ESRD) may encounter less stone disease. After successful kidney transplantation, ESRD patients have significant improvement in kidney functions and may develop

kidney stones in their allograft kidney.

Research frontiers

The incidence and characteristics of kidney stones in kidney transplant recipients are not well studied. It is thus necessary to assess the incidence and types of kidney stones after kidney transplantation.

Innovations and breakthroughs

In this study, the authors demonstrated that an overall incidence of kidney stones in kidney transplant recipients was 1.0%. The mean age of recipients with kidney stones was 42, and half of stone formers were males. Calcium based (CaOx and CaP) stones were the most common types of kidney stones after kidney transplantation, followed by struvite stones and then uric acid stones.

Applications

The data in this study demonstrates an estimated incidence of kidney stones in patients after kidney transplantation of 1.0%. Calcium based stones and struvite stones are common types of kidney stones after transplantation. These findings may impact the clinical management of kidney stones prevention in kidney transplant recipients.

Terminology

CaOx: Calcium oxalate; CaP: Calcium phosphate; CKD: Chronic kidney disease; GFR: Glomerular filtration rate; NR: Not reported.

Peer-review

This is a reasonable first meta-analysis of incidence of kidney stones in kidney transplant recipients. The results have potential clinical applications.
